Fig. 4 Cleavage of satellite I DNA with Hind restriction enzymes. *a*, (1) total bovine DNA (1 μg) digested with Hind II + III restriction enzymes. (2) High molecular weight satellite I DNA (0.5 μg) digested with Hind II + III. (3) Satellite I DNA (0.5 μg) cleaved with EcoRI then with Hind II + III. (4) SV40 DNA (2 μg) cleaved with Hind II + III. (5) Total bovine DNA cleaved with Hind II + III. The Hind enzymes were isolated as described in ref. 25. The DNAs were cleaved in buffer containing enzyme and 0.006 M $MgCl_2$ + 0.01 M Tris *p*H 7.4 + 0.1 mM DTT for 12 h at 37° C. After digestion and extraction with phenol, the DNA was precipitated with ethanol and resuspended in 20 μl of 1/4 × E buffer containing 20% sucrose. The samples were then placed on to the 4% polyacrylamide slab gel. The gel contained 4% acrylamide (Bio-Rad), and 0.2% N′N′-methylene-bis-acrylamide (Eastman Kodak) and was polymerised by the addition of NNN′N′-tetraethylenediamine and ammonium persulphate. Electrophoresis was for 6 h at 50 V. Molecular weights were measured relative to the SV40 fragments[37]. b in position 2 = 7.4×10^5 daltons, c in positions 1,2,3,5 = 1.2×10^5 daltons, e in position 3 = 5.7×10^5 daltons, d in position 3 = 1.8×10^5 daltons. Other bands in 2 and 3 are partial cleavage products. *b*, EcoRI cleaved satellite I DNA was digested with Hind III (a gift of Dr R. Roberts). The Hind III + EcoRI cleaved DNA in position 2 has the same mobility as RI cleaved satellite in position 4. An aliquot of the Hind III reaction mixture was taken and to it added the Hind II enzyme. The DNA from this experiment is shown in position 3. The SV40 DNA fragments obtained by cleavage with Hind II + III are shown in positions 1 and 5.

separately and together on the DNA. Satellite I DNA was cut with EcoRI. After extraction with phenol, the DNA was redigested with the Hind II enzyme. The products of this double enzyme digestion were DNA fragments of three molecular weight classes as measured by electrophoresis in 4% polyacrylamide gels (Fig. 4*a*, *b*). The molecular weights are: 5.7×10^5, 1.8×10^5 and 1.2×10^5 daltons. That there is a true repeating unit within the satellite is further indicated by the finding that the amount of DNA in each one of these three bands is proportional to its fraction of the repeat length. Thus, the relative amounts of radioactivity in the three bands are 65%, 20% and 15%.

An unambiguous map of these restriction sites (see Fig. 5) within the repeat unit can be deduced from the following: (1) The distance between the two Hind II restriction sites is 1.2×10^5 daltons. This accounts for the 1.2×10^5 dalton fragment (c) seen in both the double enzyme (EcoRI + Hind II), and the Hind II digestions. (2) The RI cleavage site must be 1.8×10^5 daltons from one of the Hind II sites. This accounts for the 1.8×10^5 daltons band (d) resulting from the double digestion (EcoRI + Hind II). (3) The 7.4×10^5 dalton band (b) arising from the Hind II digestion is cut once by EcoRI to yield 5.7×10^5 (e) and 1.8×10^5 (d) dalton bands. These two bands orient the RI site with respect to the Hind II sites.

A conclusion of the restriction map shown in Fig. 5 is that the repeat unit detected is tandemly repeated (. . . ecdecdecd . . . .). Inverse tandem repeats (. . . ecddce . . .) can be eliminated as this would be detected as a band at 3.6×10^5 daltons (d + d) in the Hind II cleavage experiments.

Evolution of satellite I DNA

The evolution of satellite DNA poses a paradox. On the one hand, apparent fluctuations of satellite content in related species are quite well documented[5,12,26]. In the genus *Dipodomys* the amount of density satellite DNA ranges from barely detectable in *Dipodomys spectabilis*, to more than half the nuclear DNA content in *Dipodomys ordii*[27]. In general, it is not clear as to whether these sequences are lost from the basic genome or through translocations and mutations become unrecognisable. By contrast to this interspecies variability, is the remarkable homogeneity of repeats that can exist within one satellite[14]. Furthermore, it is clear that different satellites within the same organism[14,28] and in different species[14,29] are related to each other. The problem then in satellite evolution is to account for apparently rapid changes in content and in sequence, while allowing for homogeneity within tandem arrays and sequence relationships between different satellites.

Two basic mechanisms for satellite evolution can be considered, one being unequal crossing over and the other DNA replication. From mathematical considerations, Smith[30] has shown that if tandem arrays of sequences become heterogeneous, unequal crossing over will tend to homogenise the array. By this process of unequal crossing over, the sequence of one repeat unit will eventually dominate the cluster. With regard to the origin of arrays, unequal crossing over can also clearly increase or decrease the size of an array by a single recombination.

Mechanisms of satellite DNA evolution based on DNA replication must address themselves to the frequency of replication origins in this DNA. In the case of the bovine satellite I DNA which comprises 7% of the genome, there must be 144,000 copies of the 1,400 base pair repeat. It seems reasonable to assume that the 2,000–3,000 tandem repeats of the 1,400 base pair unit that are present on each autosomal chromosome contain interspersed within them multiple sites for the initiation of DNA synthesis. Alternately, each 1,400 nucleotide repeat may contain such a signal. Reciprocal intrastrand recombination in direct tandem repeats will favour excision and the formation of independent rings. These recombinations, in fact, seem to occur because polymorphism in human centric-heterochromatin indicating deletions in satellite DNA content have been shown to be widespread[31,32]. If a satellite DNA circle formed by such an excision contains a sequence for the initiation of DNA synthesis it may undergo rolling circle replication and amplification. That the enzymes needed for such a process are available in higher cells at meiosis has been shown, as Hourcade *et al.*[33] and Bird *et al.*[34] have demonstrated that ribosomal DNA

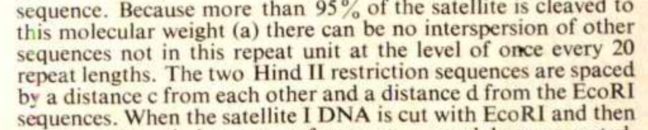

Fig. 5 Restriction map of satellite I DNA. Assuming that this satellite is approximately equally distributed on all 58 autosomes[16] there are 2,000–3,000 repeats of unit (*a*) in each chromosome. This represents the spacing of the EcoRI restriction sequence. Because more than 95% of the satellite is cleaved to this molecular weight (a) there can be no interspersion of other sequences not in this repeat unit at the level of once every 20 repeat lengths. The two Hind II restriction sequences are spaced by a distance c from each other and a distance d from the EcoRI sequences. When the satellite I DNA is cut with EcoRI and then the Hind II restriction enzyme fragments e, c and d are generated. When the satellite DNA is cut with the Hind II enzyme alone, fragments b and c are generated. Partial cleavage products of the double enzyme experiment are: e + c, and c + d. Partial cleavage of Hind II on high molecular weight satellite yields a fragment of size b + c. No polarity to the strand shown can be deduced from the data presented. Therefore, the repeat unit can either be ($^{5'}$–ecdecd–$^{3'}$) or ($^{3'}$–ecdecd–$^{5'}$)●

is amplified by a rolling circle mechanism in *Xenopus* oocytes. The product of this rolling circle replication is a tandem array of identical repeats. To become part of the permanent germ line of the organism, the amplified DNA must subsequently recombine back into a chromosome. This model could account for the origin of new satellite sequences since the repeat that is excised might be sufficiently diverged from the bulk of the satellite DNA. The existence of a previously undetected long range order in satellite DNA is a strong prediction of this model.

The data presented here indicate that two stages were involved in the origin of satellite I DNA in the bovine genome. The first stage involves the small duplications indicated by the renaturation rate to develop the 1,400 base pair repeat, which may have arisen either by a DNA replication process or by unequal crossing over. The second stage involves the production of tandem arrays of this repeat. Should unequal crossing over occur at any point of small homology within the tandem array, regularity of the higher order repeat will be destroyed, because the 1,400 nucleotide units would presumably pair in a staggered orientation. Perhaps the mechanism of recombination could place a restriction upon such staggering (for example, the joining between recombining strands might always include one repeat unit in phase). In view of the contrived nature of this restriction, DNA replication schemes, specifically the rolling circle, seem more feasible for this second process.

Whatever the mechanism involved, amplification may occur rarely. After the satellite DNA has been incorporated into the genome, base changes, insertions and deletions will tend to obscure the homogeneity of the array. In a previous study[35], we have shown that the distribution of EcoRI sites in the mouse satellite is very irregular. We interpreted this to be an indication of this divergence process and that the correction of the repeats in this satellite is either an imperfect or a rare event. But, other restriction enzymes or more complete sequence data on the mouse satellite may indicate a long order organisation to this DNA. It will be important to know whether all satellite DNAs possess a regularity at the level of organisation reported here, or if this is particular to the bovine satellite I.

I thank Dr Joe Sambrook for help in the preparation of this manuscript, Dr J. Maio for advice in isolating the satellite and for use of his Model E centrifuge at various times and Dr P. Sharp for help with the electron microscopy. I have been supported by a Damon Runyon Cancer Research Postdoctoral Fellowship. This work was supported by a grant from the National Cancer Institute.

Near absence of hard X-ray pulsations in Her X-1

We have previously presented[1] spectral results for Her X-1 in the energy range 20 to 100 keV and have set an upper limit of about 40% for the pulsating component. We have recently made further observations on this source with a telescope of much larger area and have obtained a longer exposure during its bright phase in the binary cycle (phase = 0.25) and almost in the middle of its 'on' period in the 35-d cycle (phase = 0.45 to 0.55). The new observations set an upper limit of 10% for the pulsating component in the energy range 20 to 45 keV which has important consequences on the models proposed for the X-ray emission features of Her X-1.

The balloon flight was carried out from Hyderabad, (17.3° N) on December 12, 1973. The balloon floated at an altitude of 4 mbar and Her X-1 was observed during 0536 to 0654 UT for 4,240 s.

The X-ray telescope, with a field of view 8° × 8°, comprised four NaI crystals each of area 97 cm^2 and thickness 3 mm,

The TAG hydrothermal field

THERE is abundant evidence that seawater penetrates, and circulates within, the oceanic crust at active spreading centres Low heat flow values from ridge crests imply that heat must be removed locally by water circulation[1–6] Furthermore, hydrous metamorphosed oceanic crust and oceanic serpentines, which required voluminous quantities of water during their formation[7–9], also have isotopic compositions which indicate that the isotopic sources had low $\delta^{18}O$ values, such as are found in seawater[10] The tectonic setting of strike–slip and normal faulting along the rift valley scarps of oceanic ridges is conducive to the penetration of dense, cold water down the fractures, the heating of the water at depth, and the exhalation of the less dense hydrothermal water as submarine springs along fracture systems

During the 1972 and 1973 cruises of the Trans-Atlantic Geotraverse (TAG) project of the National Oceanic and Atmospheric Administration (NOAA), extensive bathymetric and geophysical surveys, and dredging, were carried out on an area two degrees square between the Kane and the Atlantis Fracture Zones on the Mid-Atlantic Ridge at 26° N The usual assemblage of pillow basalts, metamorphosed pillow basalts, diabases and gabbros were dredged from scarps within 20 km of the distinct rift valley[11]

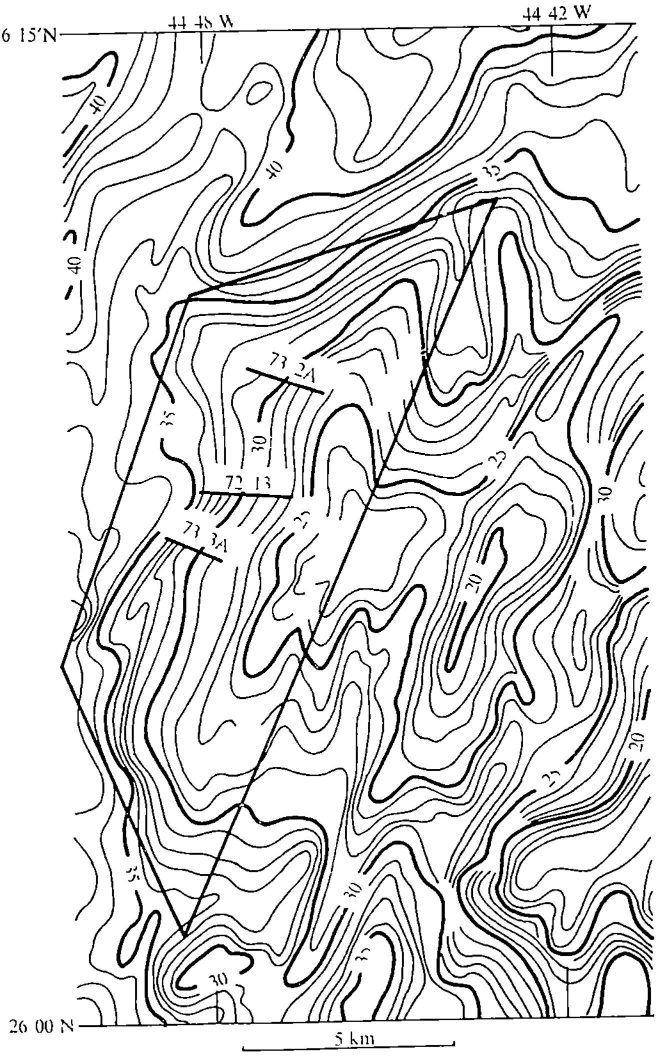

Fig 1 Location of the 1972 and 1973 dredge sites from which hydrothermal manganese was recovered This region covers part of the rift valley in the upper left corner, the eastern wall of the rift valley and a part of the eastern ridge crest highlands[15,35] Contours are in hundreds of metres The TAG hydrothermal field is shown within the solid straight lines which enclose an area of approximately 100 km^2

Along one section of the eastern wall of the rift valley, however, every dredge recovered thick hydrothermal manganese encrustations that overlie and cement underlying talus (Fig 1) Several lines of evidence suggest that this region is an active hydrothermal field

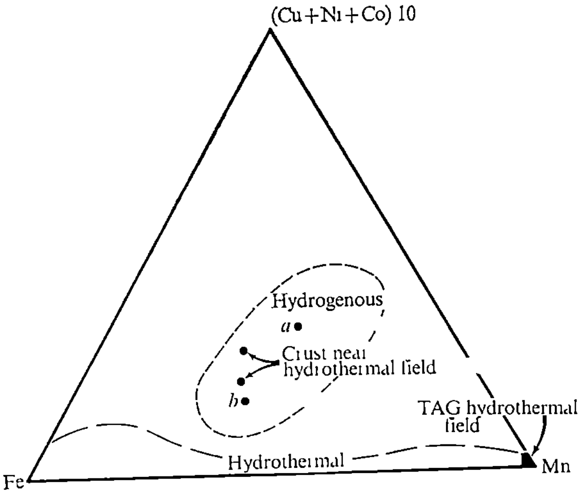

Fig 2 Range of composition of manganese deposits from the TAG hydrothermal field on an Fe–Mn–(Cu+Ni+Co) 10 ternary diagram[16] Average compositions of Pacific (*a*) and Atlantic (*b*) hydrogenous ferromanaganese nodule are from Price and Calvert[34] The two hydrogenous ferromanganese crusts were collected from within 50 km of the hydrothermal field Submarine, hydrothermal ferromanganese deposits have been reported from seamounts, submarine volcanoes, and the Afar and Red Sea spreading centres[16]

The manganese deposit is more than 50 mm thick but is found only 3–8 km from the median axis of the valley and thus must have grown about two orders of magnitude faster than typical open ocean, hydrogenous ferromanganese deposits Rapid growth has been confirmed by $^{230}Th/^{234}U$ and $^{231}Pa/^{235}U$ data which indicate growth rates of 130–250 mm per 10^6 yr respectively[12] The possibility that this rapid growth could be the result of a remobilisation of manganese in reduced, organic-rich, ponded sediment[13,14] is unlikely, because photographs of the ocean bottom[15] snow the hydrothermal deposit growing on essentially bare, current swept talus 500–1,500 m above the rift valley floor Chemically, the deposit is within the hydrothermal region (Fig 2), and mineralogically it consists primarily of birnessite and secondarily of todorokite[12,17]

A positive thermal anomaly (0 14° C) was found in the water column over the hydrothermal region[18] Also, the suspended weak-acid-soluble particles rich in iron and manganese, which were collected over the hydrothermal site, are far more concentrated than similar particles found to either side of the ridge crest[19] Photographs show encrustations covering only the talus slopes[15] Magnetic surveys indicate that the Brunhes normal axial anomaly contains a magnetic low region, the boundaries of which coincide closely with other estimations of the hydrothermal field boundaries[15,35] (Fig 3) Presumably, the hydrothermal alteration of the magnetic mineral component of the pillow lavas has greatly reduced intensity of magnetisation[20] Perhaps most significant, this observation of a distinctive magnetic irregularity associated with hydrothermal activity may become the geophysical exploration tool for the rapid location of new oceanic hydrothermal sites

Ferromanganese deposits and ferromanganese-rich sediments at the interface of basalts and overlying sediments are common features of ophiolites[21–23] Petrological evidence suggests that some ophiolites may have been formed off

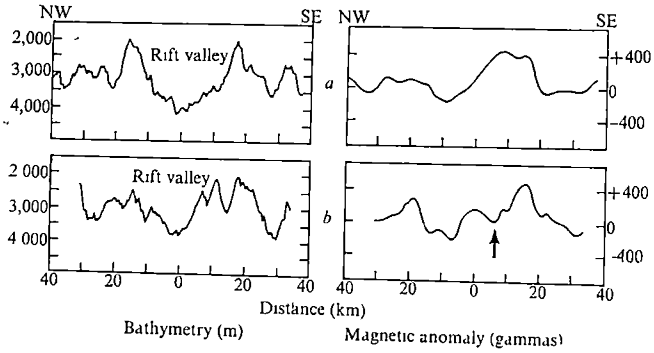

Fig 3 Bathymetric and residual magnetic profiles across the rift valley of the Mid-Atlantic Ridge near 26°N (refs 15 and 35) *a*, 12 km north of the TAG hydrothermal field, showing the strong Brunhes normal over the axial valley, which is typical of all of our profiles from outside the hydrothermal field, *b*, profiles across the TAG hydrothermal field, the arrow indicates the magnetic low in the axial anomaly

ridge axes[24-26], suggesting that hydrothermal mineralisation could occur away from a ridge axis In any case, this does not detract from the probability that the hydrothermal mechanisms that operated in many ophiolitic complexes to form cupreous pyrite bodies[23 27-29], altered pillow lavas, and overlying manganiferous oxides, were similar to that now operating on the Mid-Atlantic Ridge at 26°N Although massive sulphide bodies have not yet been recovered from this site, disseminated pyrite occurs in greenstone pillow lavas dredged from adjacent fault scarps Sulphide deposits are not rare in altered oceanic rocks[30,31] Thus, we infer that the TAG hydrothermal field may at present be forming Troodos-type, massive, stratiform, sulphide bodies within pillow lavas below the manganese deposits

The sharp transition from the precipitation of metal sulphides to the precipitation of metal oxides at the seawater–basalt interface is probably controlled largely by a sharp gradient of oxygen concentration from hydrothermal fluids which have little oxygen, to bottom waters which have relatively high concentrations of oxygen A reasonable estimate of the fugacities of oxygen, and sulphur, and of the *p*H values that may operate in such a system, has been given by Meyer and Hemley[32] The source of sulphur in these hydrothermal systems may in part be reduced sulphate from the influxed seawater, but some sulphur is probably leached from rocks that react with hydrothermal fluids (unpublished work fresh pillow lavas, 1,000 p p m sulphur, adjacent greenstones, 400 p p m sulphur) The iron and manganese are probably leached from crustal rocks under low fO_2 conditions, much of the dissolved iron may be removed from fluids as sulphides at lower temperatures close to the surface, but a significant quantity becomes suspended in the ocean water column[19] Because the iron readily precipitates as hydroxides at lower oxygen concentrations than manganese compounds[33], the particulate iron phase must bypass the manganese crust at the TAG hydrothermal field

Ancient tropical weathering in Calabria

From the lower Crati valley in Calabria, to the Peloritani Mountains in Sicily, metamorphic and intrusive igneous lithotypes represent the bulk of the Apennine mountain range A wide cover of Tertiary sediment overlies these rocks, mainly along the coastal areas The metamorphic and igneous rocks are in a weathered state The weathering may be tens or even hundreds of metres deep Deep weathering characterises crystalline rocks in a rapidly uplifting region such as Calabria

Current opinion is that the weathering of the intensely fractured crystalline rock masses has resulted from the action of Mediterranean climatic conditions short rainy winters, alternating with long dry summers, and periods of frost[1]

In fact today the area has a meso-Mediterranean type of climate[2] warm dry summers, relatively mild and humid winters and mostly clear, sunny weather throughout the year Rainfall varies from 600 mm yr^{-1} to 1,500 mm yr^{-1}, with about 45% falling during the winter and only 5–8% falling in the summer period, and there is considerable variation from year to year The mean annual temperature is about 17° to 18° C along the coast, about 14° C in the transition zone to the mountains and lower in the highland area[3]

I have collected evidence which suggests that deep weathering is peculiar to tropical rain-forest areas, which have mean annual temperatures between 20° C and 30° C, little annual temperature range and no frost In these areas rainfall may be over 3,000 mm yr^{-1} (ref 4)

In present day and ancient rain-forest tropical areas typical profiles of weathering of crystalline rocks, such as granite or diorite, can be seen Organic sandy soil overlies decomposed rocks of a sandy texture within which the original discontinuities are still preserved (saprolite) The layer is underlain by spheroidally weathered boulders, generally surrounded by sandy material and at the bottom of the profile there are jointed, deeply weathered rocks with sand or clay along the major joints[5]

This is the weathering profile commonly observed in Calabrian granites

Furthermore, there are several conditions, in addition to the presence of a favourable climate, which must be fulfilled before such weathering can occur These include a peneplained landscape, prolonged tectonic quiescence, only a slight amount of erosion, and fracturing to a great depth[6] Only the last of these conditions has been fulfilled in Calabria during the recent geological past, and it is the only condition which is satisfied there today

It thus seems probable that what occurs in Calabria is the intense erosion of an exposed, fossil, deeply weathered mantle This implies that evidence of the necessary conditions will only be found in older geological formations

The deep weathering of Calabrian crystalline rocks is normally considered as an inconsistency which disturbs petrological and structural observations What I have suggested provides the opportunity to understand the tectonic events which occurred since the production of the weathering

Moreover, the need of a better definition of the real relationships between fossil weathered zones and present day morphological features and erosional processes, cannot be disregarded when considering problems of soil erosion and natural slope stability

Mechanism for producing NO from nitrogen in flames

THE principal chemical reactions which generate the pollutant nitric oxide, NO, from atmospheric nitrogen in combustion systems, are generally recognised[1] to be those first proposed by Zeldovich[2]

$$O + N_2 \rightarrow NO + N \qquad (1)$$

$$N + O_2 \rightarrow NO + O \qquad (2)$$

It is the first reaction in this chain sequence which determines the rate of reaction, and therefore under some combustion conditions reaction (2) may be supplemented by others, such as $N + OH \rightarrow NO + H$ The Zeldovich mechanism is thought[1] to operate generally in flames where oxygen atoms are first produced in the reaction zone, often in concentrations well above those of equilibrium at the temperature which the burnt gases finally attain[3] Measurements[1,4,5] of the rate of production of NO in flames, have revealed a consequent acceleration arising from these superequilibrium concentrations of oxygen atoms

In contrast, Fenimore[6] concluded that NO is produced by an additional mechanism This is thought to operate in or very close to the reaction zone of a flame, and involves a hydrocarbon fragment which attacks molecular nitrogen, for example, $CH + N_2 \rightarrow HCN + N$ Nitric oxide could then be produced by reaction (2), as well as by the oxidation of HCN It should be noted that hydrocarbon radicals such as CH are found generally only in or close to the reaction zone of a flame, because they disappear in the burnt gases downstream by rapid bimolecular processes for example, by $CH + O \rightarrow CO + H$ Because flame gases at atmospheric pressure have a residence time in their reaction zone of no more than 50 µs, the outcome has accordingly been termed 'prompt' NO Although Fenimore's suggestion has been rejected several times[1], particularly in systems which are fuel lean, it has received some support[7,8]

The work reported here represents a preliminary attempt to test whether 'prompt' NO is produced in addition to that from the Zeldovich scheme A fuel-rich flame, of unburnt composition $H_2/O_2/N_2 = 3/1/4\ 75$, was burnt at atmospheric pressure on a water-cooled burner made from stainless steel hypodermic tubes The design of the burner was similar to that described by Padley and Sugden[9], except that it produced only one flame of 16 mm diameter, approximately 0 3 m long, with a flat reaction zone, about 0 1 mm thick, located about 1 mm from the burner face The burnt gases of the flame had a temperature of 2,000 K, which corresponds to an equilibrium concentration for NO of around 7 parts per million (p p m) The gases at various points along the axis of this flame were sampled through a water-cooled probe (made entirely from quartz) into a chemiluminescent NO analyser That instrument gave the concentration of nitric oxide as a function of axial distance along the flame As the radial profiles of velocity, temperature and concentration in the early part of the burnt gases are 'top hat' ones, the system is a good approximation to a one-dimensional flow system Determinations of concentrations, such as [NO], as a function of axial distance, can easily be transformed into functions of time for the first 50 mm of the burnt gases, where the axial velocity is constant, at 11 3 m s^{-1}, and the gases are not disturbed by air entrainment or after-burning Such measurements were made in the flame itself and also with a little of the hydrogen replaced with acetylene to give an overall concentration of 1% by volume of hydrocarbon Such an amount of acetylene in the unburnt gases has been shown[10] not to affect the temperature or composition of the burnt gases, apart from the introduction into them of a small amount of CO Acetylene is, however, likely to release many short-lived radicals into the reaction zone, such as CH and C_2

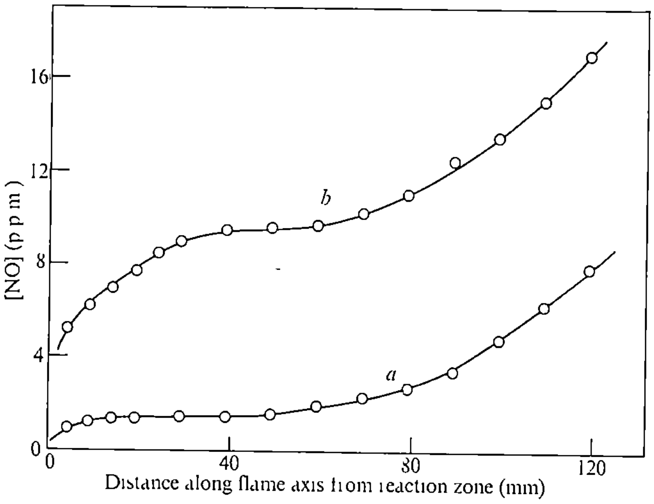

Fig 1 Variation of the concentration of nitric oxide with position along the axis of a flame of unburnt composition $H_2/O_2/N_2$ = 3/1/4 75, and temperature 2,000 K *a*, [NO] without additives to the flame, *b*, burner supplies contain 1% by volume of acetylene

The results are shown in Fig 1 In the absence of added acetylene, [NO] rises sharply in the first 5 mm of the burnt gases and is then almost constant up to about 50 mm (Fig 1*a*) After that, there is another definite increase probably because of the entrainment of O_2 and N_2 from the surrounding atmosphere, and after-burning of the excess hydrogen, with a consequent temperature rise The steady level attained by [NO] around 50 mm downstream, is roughly 0 2 of that expected for equilibrium It is thus clear that the formation of NO, which in this instance must be by the Zeldovich scheme, is slow under these particular conditions, in spite of the fact that oxygen atom concentrations are expected[9,10] to exceed their equilibrium values by up to a factor of 3 × 10^3

In the presence of 1% by volume of acetylene, [NO] rises to a first steady level (at around 40-60 mm) almost seven times higher (Fig 1*b*), which is approximately that for equilibrium Subsequently, [NO] increases downstream because of air entrainment and the gradual temperature increase with after-burning, after the first 40 mm the trends of the two mixtures are parallel (Figs 1*a*, *b*) These observations can be interpreted only in terms of two additive mechanisms for producing NO The Zeldovich scheme is 'singled out' by the first mixture (Fig 1*a*), relating entirely to the simple $H_2 - O_2 - N_2$ system Added to curve *a* is that amount of NO produced in the early part of the flame (although here it does not seem to be confined entirely to the reaction zone but extends to the first 40 mm of the burnt gases) giving curve *b* on the addition of 1% of acetylene This behaviour, which arises from the presence of hydrocarbon, corresponds to the production of 'prompt' NO These data relate to the particular flame conditions used here, and although they demonstrate that, if after-burning is neglected, the 'prompt' NO is almost six times that from the Zeldovich scheme, that is not always so In fact, the ratio of 'prompt' to Zeldovich NO depends on such variables as $[H_2]/[O_2]$ in the unburnt gas supplies, flame temperature, the quantity of acetylene added, and so on These matters will be discussed elsewhere

Table 1 Possible reactions for attacking N_2 in flames

No	Reaction	Standard enthalpy changes at 0 K ΔH J mol^{-1}
(3)	$CH_3+N_2\rightarrow HCN+NH_2$	157±22
(4)	$CH_3+N_2\rightarrow CN+NH_3$	244±12
(5)	$CH_2+N_2\rightarrow HCN+NH$	88±30
(6)	$CH_2+N_2\rightarrow CN+NH_2$	222±30
(7)	$CH+N_2\rightarrow HCN+N$	9±15
(8)	$CH+N_2\rightarrow CN+NH$	200±25
(9)	$C+N_2\rightarrow CN+N$	193±17
(10)	$CO+N_2\rightarrow CN+NO$	636±11
(11)	$HCO+N_2\rightarrow HCN+NO$	240±21
(12)	$HCO+N_2\rightarrow CN+HNO$	560±40
(13)	$H_2CO+N_2\rightarrow HCN+HNO$	350±31
(14)	$H_2CO+N_2\rightarrow HNCO+NH$	337±40
(15)	$CH_3O+N_2\rightarrow HNCO+NH_2$	58±63
(16)	$C_2+N_2\rightarrow CN+CN$	48±25
(17)	$C_2H+N_2\rightarrow HCN+CN$	80±48

Although these observations establish the importance of 'prompt' NO under these conditions, the chemical reaction initially responsible has not been identified We give some of the possibilities in Table 1, together with their associated heats of reaction, for all species in their ground electronic states These enthalpy changes were derived from dissociation energies of diatomic molecules quoted by Gaydon[11] and of polyatomic molecules listed by Herzberg[12], Cottrell[13] or the JANAF Tables[14] Five reactions (5, 7, 15, 16 and 17 in Table 1) seem to be the only candidates for the attack of N_2 by a hydrocarbon fragment, because they have the lowest heats of reaction Admittedly, activation energies can exceed endothermicities, and also the various hydrocarbon radicals do have differing concentrations in a flame But as an increase of 100 KJ mol^{-1} at 2,000 K in the activation energy of a reaction reduces its rate by a factor of 400, we conclude that all the reactions (Table 1), apart from the five mentioned, can be excluded on thermochemical grounds Of the five possibilities, reactions (16) and (17) are unlikely, because they involve a four-centre reaction In the same way, reaction (15) is a very weak candidate, because its transition state lacks plausibility, furthermore, CH_3O is not one of the most common radicals associated with the combustion of a hydrocarbon That leaves reactions (5) and (7) The latter is more likely both sterically and energetically, the primary products of the attack of N_2 are HCN and N If reaction (5) also operates, only one other product, NH, is involved, which is known[15] to have its concentration in these flames linked to that of free nitrogen atoms

$$NH + OH \rightleftharpoons N + H_2O \qquad (18)$$

There is thus very little to distinguish between the products of reactions (5) and (7) In any event, whether NH or N is produced initially, NO is most probably formed[15] by

$$N + OH \rightleftharpoons NO + H \qquad (19)$$

in these hydrogen-rich flames

The other product, HCN, is common to both reactions (5) and (7), as well as to other reactions in Table 1, on account of its stability Its concentration is coupled[16] to that of CN by an equilibration of

$$HCN + H \rightleftharpoons CN + H_2 \qquad (20)$$

with NO resulting[16] from one of two exothermic reactions

$$CN + O_2 \rightarrow CO + NO \qquad (21)$$
$$CN + OH \rightarrow CO + NH \qquad (22)$$

Reaction (22) is followed by reaction (18) and then by reaction (19) In a fuel-rich flame, such as that studied here, $[O_2] \ll [OH]$ and reaction (21) is, therefore, probably unimportant

These considerations indicate that in fuel-rich systems NO can be formed from HCN by a succession of four reactions reactions (20), (22), (18) and (19), whereby $HCN \rightarrow CN \rightarrow NH \rightarrow N \rightarrow NO$ Taking reaction (7), the most probably primary reaction, HCN and N will be produced Both of these will produce NO, but HCN—at the beginning of the sequence of reactions—will do so at a much slower rate than N atoms, which give NO in a rapid, single-step process It could thus well be that roughly half of the NO is generated very quickly, and the rest relatively slowly from HCN, with the result that the appearance of 'prompt' NO could extend into the burnt gases, as observed in Fig 1 In this context, HCN has been observed[7] in the burnt gases of hydrocarbon flames as an intermediate in the production of 'prompt' NO

We thank Mr F J M A Pereira for assistance with the concentration measurements and discussion

Evidence for a complete mixed valence solid solution series in $\mathrm{Fe}_3^{2+}(\mathrm{H_2O})_3[\mathrm{PO_4}]_2$ (phosphoferrite) $\mathrm{Fe}_3^{3+}(\mathrm{OH})_3[\mathrm{PO_4}]_2$ (kryzhanovskite)

HOMONUCLEAR intervalence-transfer absorption of the first transition series cations has aroused considerable interest for two reasons[1] First, it may give rise to intense colour which is not predicted by the addition of the colours of either of the individual ions Second, it may lead in some chain structures to strong anisotropy in electronic conduction A classic example is vivianite, $\mathrm{Fe}_3^{2+}(\mathrm{H_2O})_8[\mathrm{PO_4}]_2$ although colourless when fresh, upon partial oxidation of the transition metal the compound assumes a deep blue which is at its maximum intensity when the electric vector of polarised light is parallel to the axis of the two iron atoms in the octahedral edge-sharing dimer of the crystal structure Extensive study on this and on other systems has led to a considerable body of literature[1]

In the homologous series $\mathrm{Fe}_3^{2+}(\mathrm{H_2O})_n[\mathrm{PO_4}]_2$, where all n water molecules and all oxygens associated with the phosphate tetrahedra are also bound to the inner sphere of the transition metal, extensive oxidation of $n = 8$ (vivianite) and $n = 4$ (ludlamite), leads to destruction of the crystal structure[2] For $n = 3$ (phosphoferrite), it is possible to synthesise the crystalline ferric analogue of a natural mineral with initial composition $(\mathrm{Fe}^{2+}_{2\,1}\mathrm{Mn}^{2+}_{0\,8}\mathrm{Ca}^{2+}_{0\,1})(\mathrm{H_2O})_3[\mathrm{PO_4}]_2$ by heating crystals in air[2] These observations suggest that the balance of electrostatic valence is the basis for the stability of the $n = 3$ homologue over an extensive range of Fe^{2+} oxidation to Fe^{3+}

I have examined single crystals of pure synthetic Fe_3^{2+}-$(\mathrm{H_2O})_3[\mathrm{PO_4}]_2$ with the phosphoferrite structure The use of the pure compound makes it possible to study the complete Fe^{2+}–Fe^{3+} mixed valence series without ambiguities which might arise from other substituents such as Mn^{2+} and Ca^{2+} usually found in natural crystals Crystals of the synthetic compound are pale green with prismatic development parallel to the [100] axis (Fig 1)

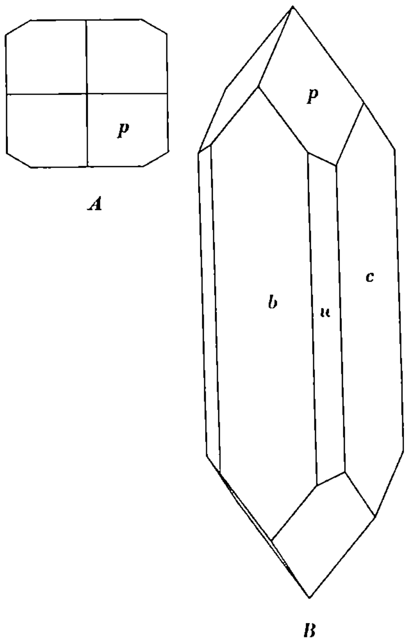

Fig 1 Crystal development of $\mathrm{Fe_3(H_2O)_3[PO_4]_2}$ (phosphoferrite) showing the forms *c*{001}, *b*{010}, *w*{021}, and *p*{111} *A*, Plan, *B*, clinographic projection

Several single crystals were placed on a glass slide and heated in a muffle furnace at 180° C for 24 h The products were deep red and optically transparent with no evidence of decomposition In the early stages of heating, the crystals became progressively darker green Crystals of the ferrous compound were crushed, powdered with Si (a = 5 4301 Å) standard and the mixture uniformly smeared on a glass slide A chart diffractogram with scan speed of 1° min^{-1} in 2θ utilised graphite monochromatised CuKα radiation The same slide was then heated at 180° C for 24 h and another diffractogram was prepared Rotation and Weissenberg photographs were obtained for the ferrous compound and for the same crystal heated at 180° C for 24 h The space group for both crystals was established as *Pbna*

Results of the powder studies, the calculated data obtained by least-squares refinement, are given in Table 1 and the single crystal studies in Table 2 Evidence for the existence of the ferric end member is provided by the deep red colour of the crystal, the volume reduction of about 6 1 Å^3 per Fe atom computed from the cell volume, and from the optical properties of the two compounds The indices of refraction are α 1 678(3), β 1 695(3), γ 1 710(8) with Z || *a*, sign (—), 2V large for the ferrous compound and α 1 873(3), β 1 878(3), γ 1 995(4) with Y || *a*, sign (+), 2V ~ 20° for the ferric equivalent Gladstone–Dale calculations provide densities which are similar to those computed from the unit cell I did not determine specific gravity directly because of the possibility of cracks in the heated compound

The evidence clearly points to a complete solid solution series between $\mathrm{Fe}_3^{2+}(\mathrm{H_2O})_3[\mathrm{PO_4}]_2$ (phosphoferrite) and

$Fe_3^{3+}(OH)_3[PO_4]_2$ (kryzhanovskite) In addition, the mosaic spreads of the same reflections for the two compounds were identical within error of the powder diffractometer experiment This suggests that the oxidised equivalent is a single homogeneous crystal One interesting aspect of this solid solution series which involves a ferrous and a ferric end member is that no vacancies need occur over the octahedral sites to maintain charge balance Moore[2] has proposed that the intracrystalline reaction is an auto-oxidation–reduction, that is, $2[Fe^{2+}(H_2O)^0] \rightarrow 2[Fe^{3+}(OH)^-] + H_2\uparrow$

The interesting feature of the phosphoferrite structure includes a kinked octahedral edge-sharing chain which is oriented parallel to the [001] axis of the crystal[2] Equivalent chains are linked to each other only through the corners with Fe-Fe distances considerably longer than the distances within the chains Writing the cell formula $Fe(1)_4Fe(2)_8(H_2O)_{12}[PO_4]_8$ to distinguish the nonequivalent Fe atoms, the sequence of iron atoms in the chain is Fe(1)–Fe(2)–Fe(2)–Fe(1)–Fe(2)–Fe(2)

In the natural type kryzhanovskite with octahedral composition $(Fe^{3+}_{1\ 8}Mn^{2+}_{1\ 0}Ca_{0\ 1}Mg_{0\ 1})$, the ordering scheme is nearly $Fe(1) = Fe^{3+}$ and $Fe(2) = Mn^{2+}_{1\ 0}Fe^{3+}_{0\ 8}Ca_{0\ 1}Mg_{0\ 1}$, according to the structure analysis of Moore[2] It is not known, however, if the Fe(1) site or the Fe(2) site oxidises first or if the oxidation sequence is disordered for intermediate mixed valences of the pure iron compound

* From the cell volume, formula weight and Avogadro's number

† From the Gladstone–Dale relationship The specific refractive energy for Fe_2O_3 was adopted as $k = 0\ 272$ from Moore[3] for epidotes ($k = 0\ 270$) and from strengite and metastrengite, $Fe^{3+}(H_2O)_2[PO_4]$, ($k = 0\ 274$) The specific refractive energies for the other more accurately known oxides are from Larsen and Berman[4]

Several crucial experiments are in progress including routine refinement of the crystal structures of the ferrous and ferric end members and refinement of the intermediate composition $Fe^{3+}/(Fe^{2+} + Fe^{3+}) = 0\ 33$ This last experiment is particularly important since it should answer the question whether the ordering scheme is $Fe(1) = Fe^{3+}$, $Fe(2) = Fe^{2+}$, $Fe(1) = Fe^{2+}$, $Fe(2) = 1/2Fe^{2+} + 1/2Fe^{3+}$, or $Fe(1) = Fe(2) = 2/3Fe^{2+} + 1/3Fe^{3+}$ In addition, single crystals of a range of compositions can be conveniently oriented for optical study

I thank Dr Enrico Mattievitch for the crystals and the US National Science Foundation for financial support

Viscoelastic effects in boundary lubrication

THE traditional 'time dependence of static friction' approach, which is used to explain observed variations in static friction, has limited validity[1] The appropriate governing variable is the rate of increase of the tangential force coefficient, $\dot{\theta}$, and not the static contact time as has been suggested previously[1] ($\dot{\theta} = \dot{F}/N$ where N is the normal load forcing opposing surfaces together and $\dot{F}$ is the rate of application of the shearing force)

Experimental work using steel surfaces lubricated by various surface films has shown that surface conditions play a very large role in determining the exact μ_s–$\dot{\theta}$ relationship for a given friction couple where μ_s is the coefficient of static friction The results are briefly summarised in Fig 1 The static friction of steel surfaces, tested when coated with thin oxide films or under 'clean' (high vacuum) surface conditions, was not dependent upon $\dot\theta$ over the given range of $\dot\theta$ values When the surfaces were covered with a monolayer of a metallorganic soap, however, the μ_s–$\dot\theta$ behaviour exhibited the expected dependence on rate The shape of the μ_s–$\dot\theta$ curve (Fig 1) depends on the boundary lubricant involved, but all three curves show an upper and a lower asymptote Exposing the steel surfaces to the laboratory atmosphere results in a similar μ_s–$\dot\theta$ behaviour, presumably because of the adsorption of hydrocarbons on the surfaces This experimental work demonstrates clearly that the static friction of steel can be significantly modified by appropriate boundary lubricants

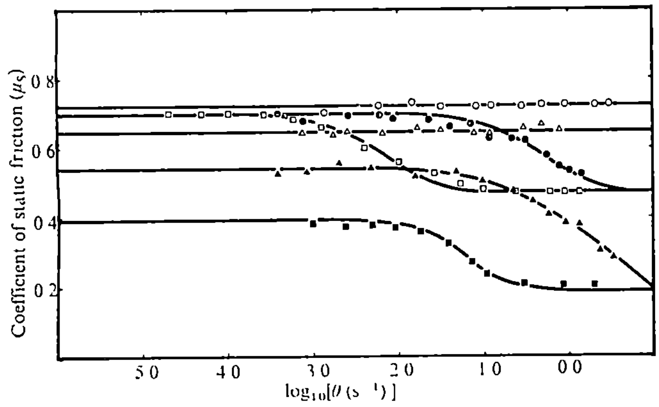

Fig. 1 Static friction, μ_s against $\log_{10}\dot\theta$ for C1020 steel with various surface treatments △, Water-formed oxide, 0 2 × 10^{-8} torr, exposed to $Ca(OH)_2$ in air for 20–48 h—Langmuir Blodgett deposition, □, $Ca(St)_2$—Langmuir Blodgett deposition, ■, $Fe(St)_3$—abrasion technique of Smith and McGill[2]

A model representing the coefficient of static friction, μ_s, as a function of $\dot\theta$ has been developed This model is based on the assumption that the real contact area between the surfaces grows in a viscoelastic manner until a critical shear stress is reached The model has been formulated (see Fig 2) by considering that the interfacial contact region deforms as a three-parameter viscoelastic solid having k_1 and k_2 as its elastic parameters, and c as the viscosity parameter The initial area of contact, A_i, is established by N $A_i = N/p_m$, where p_m is the mean yield pressure of the material Junction growth ends when a critical shear stress, T_0, is reached The μ_s–$\dot\theta$ curve then has the form

$$-\frac{k_1}{p_m}+\left[\frac{k_2}{(k_1+k_2)}\right]\tau\dot\theta\left[1-\exp\left(-\frac{\mu_s}{\dot\theta\tau}\right)\right]+\left[\left(\frac{k_1}{T_0}\right)-1\right]\mu_s=0 \qquad (1)$$

where $\tau = c\left[\frac{(k_1+k_2)}{k_1 k_2}\right]$ is the relaxation time

This equation predicts upper and lower asymptotes for μ_s as follows

$$\mu_{s\,\max}=\frac{T_0}{p_m}\left[\frac{k_1}{(k_1-T_0)}\right] \text{ for } \dot\theta \ll 1 \qquad (2)$$

$$\mu_{s\,\min}=\frac{T_0}{p_m}\left[\frac{(k_1+k_2)}{(k_1+k_2-T_0)}\right] \text{ for } \dot\theta \gg 1 \qquad (3)$$

Using the experimental data and these equations, a relaxation time may be assigned to each of the boundary lubricants For given asymptotes, a larger relaxation time shifts the μ_s–$\dot\theta$ curve to the left This shift may be interpreted as an improvement in the lubrication of the surfaces

In addition, from the experimentally determined relaxation times, a dimensionless μ_s–τ^* curve was prepared for all the boundary lubricants which had the same upper and lower asymptotes All the experimental data fall on to this general curve

Fig. 2 General form of the μ_s–$\dot\theta$ curve

In a further study, the effect of temperature on the μ_s–$\dot\theta$ behaviour of steel lubricated with a calcium stearate monolayer showed that the relaxation time decreased with increasing temperature These results demonstrated that an increase in temperature produced a progressive deterioration in the quality of lubrication in the context of the shift effect discussed earlier

From equation (1) it is obvious that a 'loading time', where F is constantly increasing, and a 'delay time', where F is held constant, are not equivalent in their effect on area growth For the calcium stearate monolayer case, for example, it was calculated that for a delay time of 1 s, the contact area is increased by 0 5% Even if the delay time is infinite, the area increase is only about 10% These calculations reveal why delay times will not increase significantly μ_s values, and why measurements of the interfacial electrical resistance[1] do not indicate appreciable area growth during the delay period

Thus, the transverse load rate dependence of static friction may be associated with the viscoelastic properties of lubricant monolayers It is believed that the viscoelastic explanation of the observed friction behaviour reflects more accurately the physical processes involved in the sliding of one body over another

An auditory illusion

I HERE report a novel and striking auditory illusion, which provides a paradox for theories of pitch perception and auditory localisation[1,2], and which varies in correlation with the handedness of the listener The stimulus configuration which produced the illusion consisted of a sequence of tones, alternating in pitch between 400 Hz and 800 Hz (Fig 1*a*) Each tone lasted 250 ms, with no gap between tones The sequence was presented at equal amplitude to both ears simultaneously; however, when one ear received 400 Hz the other received 800 Hz, and *vice versa* Thus the same two-tone combination was presented constantly, but the ear of input for each component switched every 250 ms

It is easy to imagine how this pattern should sound if perceived correctly However, 86 subjects listened to a 20-s presentation of this sequence, and none obtained the correct percept Instead, various illusory percepts were reported (Table 1), the most common being a single tone oscillating

Table 1 Categories of illusory percept

	Octave (%)	Single pitch (%)	Complex (%)
Right handers ($n = 53$)	58	25	17
Left handers ($n = 33$)	52	9	39

Figures show the percentages of right or left-handed subjects obtaining a given percept The two groups of subjects differed significantly in the relative distribution of their percepts (χ^2 = 6 8, d f = 2, P<0 05) Octave indicates the illusion of a single tone oscillating from ear to ear, whose pitch oscillates synchronously from one octave to another Single pitch indicates the illusion of a single tone oscillating from ear to ear, whose pitch either remains constant or shifts very slightly Complex comprises various complex percepts, such as two alternating pitches in one ear, with a third pitch intermittently in the other, or two alternating pitches oscillating from ear to ear and two further pitches alternating at twice the speed localised at the back of the head This group of percepts tends to be quite idiosyncratic and unstable, however, no subject reported the stimulus correctly

from ear to ear, whose pitch also oscillated from one octave to the other in synchrony with the localisation shift (Fig 1*b*) Two subjects with absolute pitch identified these oscillating pitches as G_4 (392 Hz) and G_5 (784 Hz), these are closest on the musical scale to the 400 Hz and 800 Hz presented The percept depicted by one of these subjects is shown on Fig 2

This synchronous alternation of apparent pitch and localisation is paradoxical The perception of alternating pitches can be explained by assuming that the listener processes the input to one ear and ignores the other But then both the alternating pitches should seem to be localised in the same ear Alternatively, the oscillation of a single tone from ear to ear can be explained by supposing that the listener suppresses the input to each ear in turn But then the pitch of this tone should not change with a change in its apparent localisation

A further surprise involves the patterns of apparent localisation for the two pitches at the two ears in right and left-handed subjects Right handers had a highly significant tendency to hear the high tone in the right ear and the low tone in the left (P < 0 001, two-tailed on a binomial test), and also to maintain a given localisation pattern when the placement of the earphones was reversed (P < 0 001, two-tailed on a binomial test) Left handers did not localise the tones preferentially either way, however, though they showed a marginally significant tendency to retain a given localisation pattern when the earphones were reversed (P - 0 05, two-tailed on a binomial test) This difference between right and left handers is consistent with findings relating patterns of hemispheric dominance to handedness[3,4] and so suggests that we tend to localise the high tone to the side producing the most effective input to the dominant hemisphere[5-7] and the low tone to the other side

The localisation patterns on Table 2 are based on the two initial presentations of the sequence, however, with continued listening these patterns sometimes reverse, as in reversals of ambiguous figures in vision[8] Thus these localisation patterns represent strong tendencies, rather than absolute rules

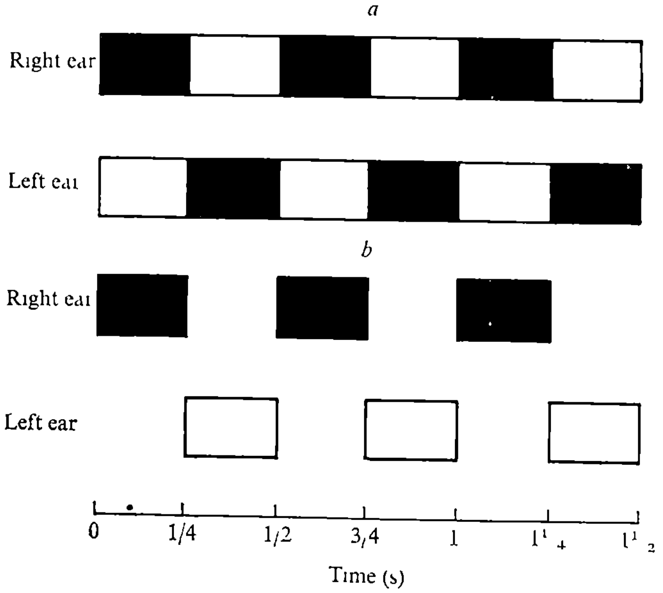

Fig 1 *a*, Representation of the stimulus configuration which produces the illusion Filled boxes represent tones of 800 Hz and unfilled boxes tones to 400 Hz The tones were sinusoids, and their phase relationship varied randomly They were played to subjects at a level of 75 dB SPL *b*, Representation of the illusory percept most commonly obtained

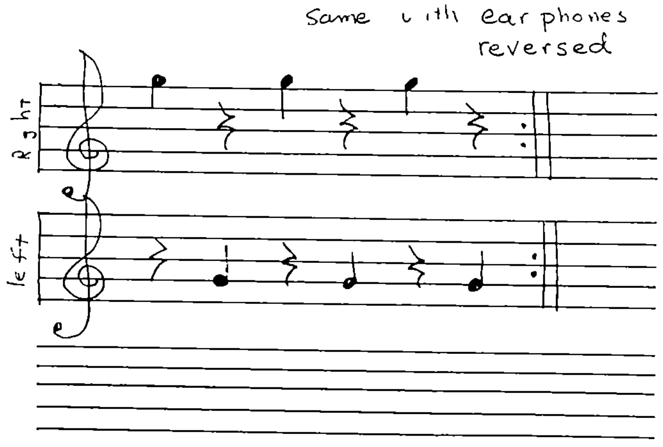

Fig 2 Percept of the stimulus depicted by a subject with absolute pitch The writing is that of the subject herself Her statement 'Same with earphones reversed' shows that the high tones were localised in the right ear and the low tones in the left, irrespective of the positioning of the earphones

Table 2 Patterns of apparent localisation for the two pitches at the two ears in subjects who obtained the octave illusion

	RR	LL	Both
Right handers	25	5	1
Left handers	6	7	4

Each subject was twice given a 20-s presentation of the stimulus sequence, with earphones placed one way initially and then reversed The order of earphone placement was strictly counterbalanced for both right and left-handed subjects Figures show the number of right or left-handed subjects obtaining a given localisation pattern RR, high tone localised in the right ear and low tone in the left on both stimulus presentations LL, high tone localised in the left ear and low tone in the right on both stimulus presentations Both, high tone localised in the right ear and low tone in the left on one stimulus presentation, and high tone localised in the left ear and low tone in the right on the other

The question arises whether a given localisation pattern depends on absolute or relative pitch levels in the stimulus configuration To determine this, I selected twelve right handers who had consistently localised the 800 Hz tone in the right ear, and the 400 Hz tone in the left, showing no tendency to reverse this pattern over several listening sessions These subjects were presented with tape segments consisting of tones alternating between 400 Hz and 800 Hz, between 200 Hz and 400 Hz, and between 800 Hz and 1,600 Hz, the other parameters being identical These sequences were presented for 20 s each in counterbalanced order, with earphone positions also counterbalanced Except for one subject s report on the 200 Hz–400 Hz sequence, the higher of the two tones in each pattern was always localised in the right ear and the lower in the left I conclude that these localisation patterns depend on the pitch relationships between the competing tones, and not on a pattern of ear preference at different pitch levels Further, when I presented the two sequences channelled through spatially separated loudspeakers instead of earphones, the illusion was still obtained, even though both sequences were now presented to both ears, with only localisation cues to distinguish them.

Maternal behaviour and the effects of stress in tree shrews

THE tree-shrews (family Tupaiidae), small squirrel-like mammals occurring throughout South-east Asia, are currently classified[1] into two subfamilies: Ptilocercinae (nocturnal pen-tailed tree-shrews; genus *Ptilocercus*) and Tupaiinae (diurnal tree-shrews; genera *Tupaia, Anathana, Dendrogale, Lyongale, Urogale*). The overall systematic status of the family is still controversial. The tree-shrews are variously allocated to the Primates[2–3], Insectivora or to an entirely separate order of mammals[4–6]. Recently the unusual maternal behaviour of one tree-shrew species, *Tupaia belangeri*, together with other reproductive characteristics, has been interpreted as further evidence excluding tree-shrews from the Primates[1]. Key features of maternal behaviour in captivity are that the mother deposits her young in a separate nest subsequently visited for suckling only once every 48 h. If such behaviour and its functional correlates are typical of all tree-shrew species, arguments based on reproductive peculiarities could be more confidently integrated with considerations of methodology, general morphological evidence[7], detailed information on the central nervous system[8] and the results of biochemical investigations[9] to reach a balanced assessment of the phylogenetic relationships of tree-shrews.

A comparative study has now been carried out by one of us (F.D'S.) on the reproduction of three tree-shrew species representative of the adaptive range within the subfamily Tupaiinae (possibly excluding *Dendrogale*). The study included one of the largest, predominantly terrestrial species *Lyonogale tana* (average body weight 200 g), the intermediate, semiarboreal *Tupaia belangeri* (*cf. T. glis* average body weight 145 g), and the smallest, extensively arboreal species *Tupaia minor* (average body weight 44 g)[10]. Details of laboratory maintenance and observation are provided by Martin[1]. In the period May 1971 to February 1973, twenty litters were born (a total of forty-three infants: sixteen *T. minor*; sixteen *T. belangeri*; eleven *L. tana*). Thirty (70%) of the infants survived to sexual maturity (thirteen *T. minor*; ten *T. belangeri*; seven *L. tana*). Data have also been collected on three additional litters (six infants) of *T. belangeri* reared by their mothers in Martin's laboratory.

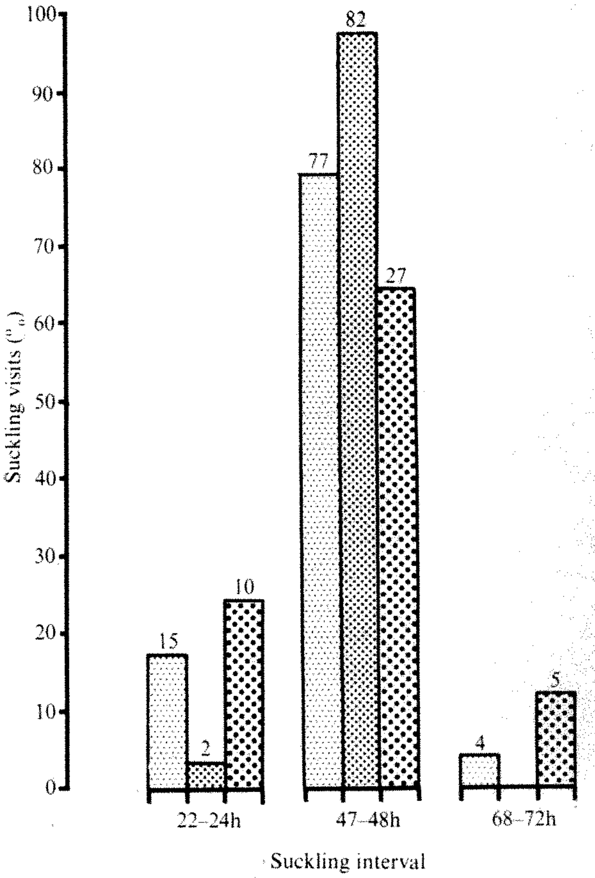

Fig. 1 Histogram of suckling intervals for the three tree-shrew species. Fine stippling: *T. minor*; Medium stippling: *T. belangeri*; Coarse stippling: *L. tana*. The three limited ranges shown on the abscissa cover all the observed suckling intervals. Numbers above the bars indicate numbers of observations.

One of us (F.D'S.) has now demonstrated, under established conditions[1], that both *T. minor* and *L. tana* also typically exhibit 48-h suckling intervals whilst rearing their young in separate nest-boxes (Fig. 1). Accordingly, weight curves (Fig. 2) show a characteristic zig-zag pattern, since the milk continues to be digested without replenishment over each 48-h period. *L. tana* and *T. minor* infants, like *T. belangeri*, maintain a constant body temperature of about 36° C from birth onwards. With all three tree-shrew species, the amount of milk given to the litter by the mother at each suckling visit is considerable (*L. tana* average, 9.4 g; median, 9.4 g; *T. belangeri* average, 4.8 g; median, 5.0 g; *T. minor* average, 1.8 g; median, 2.0 g). Analysis of the milk of the three species shows that both the calorific density and the fat calorie content are extremely high (total solids: *L. tana*, 33.5%, *T. belangeri*, 40.4%, *T. minor*, 44.6%. In all three species: fat, >17%; protein, 6–11%; lactose, <2.5%.) It has been suggested[1] that this milk composition is necessary for constant maintenance of an elevated body temperature by the young. In addition, the solid content of the milk is inversely proportional to the adult and infant body size of the species concerned. The high protein content of the milk is consistent with the normal rapid growth rate of the young (Fig. 2). In all three species, as reported for *T. belangeri*[1], each suckling visit made by the mother is very short. The quantity of milk (q) given increases with the species' body size, but the duration (d) of the suckling visit decreases with increasing body size, means for 3 litters each: *L. tana* q=9.4 g (2.0–19 g) (1.0–11 m); d=3.9 min; for *T. belangeri*, q=5.0 g (1.0–10 g); d=5.8 min (2.5–9.5 m); for *T. minor*, q=2.0 g (1.0–6.5 g); d=6.6 min (2.5–10 m). The small litter sizes of the three species (usually one to three) are probably constrained by the minimum infant body weight consistent with maintenance of a constant elevated body temperature (compare Fig. 2) and by the upper limit of milk production by mother tree-shrews. In fact, one unusual litter of four infants was successfully reared by a *T. belangeri* mother; but the amount of milk given to the litter as a whole was little different from that given to typical litters of two or three young (average total amount of milk given during nest phase to three litters of two is 153.6 g (range 134–172 g); total given to litter of four was 181.0 g).

Thus this peculiar pattern of maternal behaviour is, under appropriate conditions, typical of *T. minor*, *T. belangeri* and *L. tana*, with only minor variations according to body size. Circumstantial evidence indicates that *Urogale everetti*[11] behaves similarly and, although no evidence is yet available for *Dendrogale* it seems that this 'absentee system' of maternal care might be typical for the Tupaiinae. It remains to be seen whether *Ptilocercus* possesses the same characteristics. Certainly, it is difficult to reconcile the pattern found in the Tupaiinae with the suggestion that tree-shrews are derived from the ancestral primate stock, since all living primates are characterised by the advanced condition of the young at birth and by the great elaboration of mother–infant contacts[12].

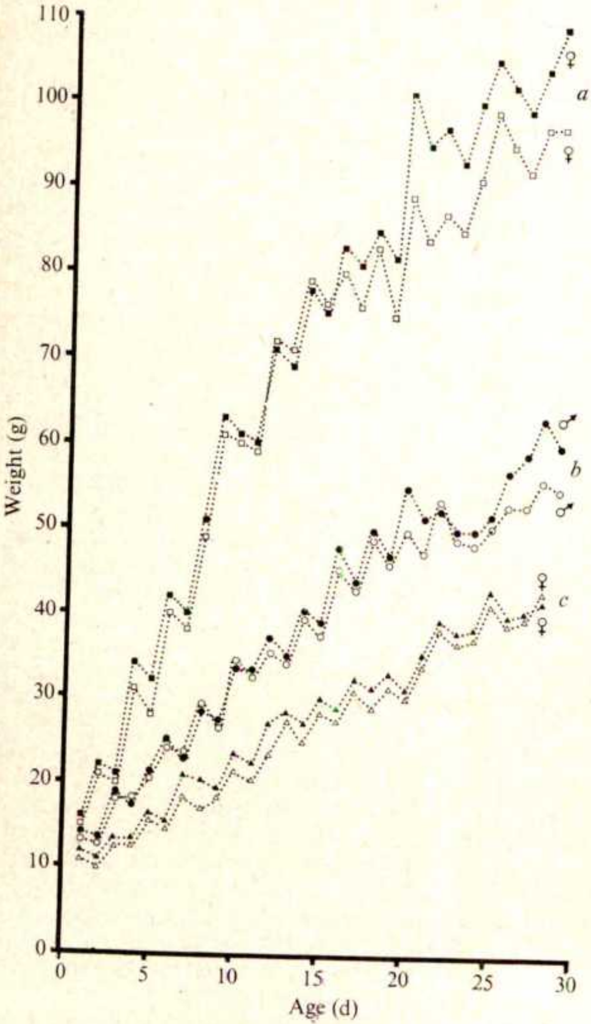

Fig. 2 Weight curves for single litters of two young per litter, for *L. tana* (*a*); *T. belangeri* (*b*); *T. minor* (*c*). The birth weights of the three species are relatively similar but weights diverge considerably by the end of the nest phase. The dip in *T. belangeri* (*b*) weights at 3 weeks coincided with the arrival of a new laboratory technician (an event known to disrupt tree-shrew maternal behaviour[1]).

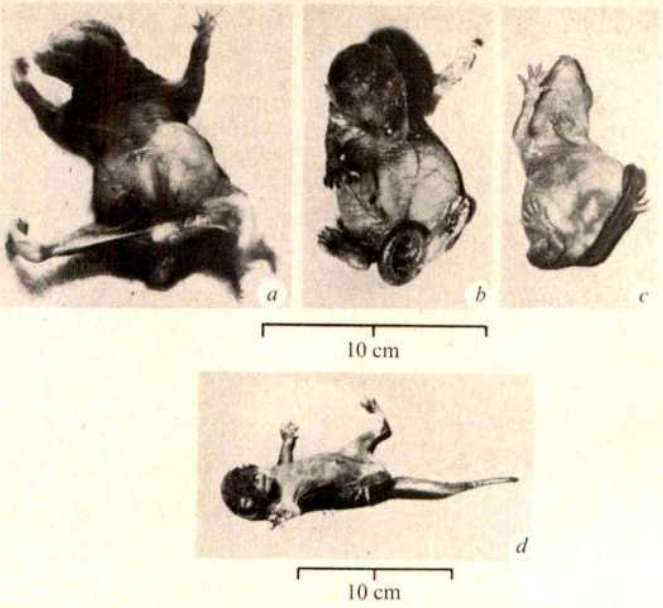

Fig. 3 Neonate *L. tana* (*a*); *T. belangeri* (*b*); *T. minor* (*c*), showing stomachs distended with milk ingested immediately after birth. At the end of each 48-h interval between suckling visits the stomach is deflated. (*d:* 10-d-old *T. belangeri* just before suckling). Note the altricial condition of the neonates.

Sorenson[13] has recently questioned the occurrence of this pattern of maternal behaviour in tree-shrews and has suggested that the 48-h rhythm may be peculiar to *T. belangeri*. Earlier careful studies, however, did not disclose such behaviour in this species and it is surprising that Sorenson did not observe similar behaviour with *Tupaia longipes*, a very close relative of *T. belangeri*. D'Souza's subsequent observations of the "absentee system" in both *T. minor* and *L. tana* (Fig. 3) conflict with Sorenson's account and a laboratory artefact may have been involved at some point. A clue is provided by von Holst's[14] observations that mild social or general environmental stress will distort maternal behaviour in *T. belangeri*, so that the suckling intervals become shorter but less milk is given over a 48-h period. (More severe stress leads to cannibalism of infants and eventually to sterility.) An example of such mild disruption was produced in Martin's laboratory by two fire-bell tests at a time when a female *T. belangeri* was rearing infants. After each fire alarm, the suckling rhythm accelerated, but the quantity of milk given over the 48 h was reduced by about 30% below expectation. The outcome of the two bell tests (Fig. 4) was that the development of the young was retarded (for example the eyes opened 3 d late and emergence from the nest was delayed by 4 d). Thus where the 48-h suckling rhythm has not been observed with tree-shrews breeding in captivity, the composition of cage groups and/or the general environmental conditions provided may inadvertently have led to modification of maternal behaviour. This interpretation is entirely supported by an examination of infant mortality rates. Martin achieved infant survival rates of about 80% with pairs of *T. belangeri*, kept under improved conditions[1], whereas D'Souza has attained survival rates of 70% with all three species. This compares with survival rates of 25% on average (mortality rates of 75%) with various colonies in which the 48-h rhythm was not apparent. An exception occurred with a colony maintained by Kuhn and Starck[15], where females were kept isolated after mating and where infant survival rates of 60% were achieved; but no data on maternal suckling behaviour were provided. In fact, Conaway and Sorenson[16] hand-reared many of their tree-shrew offspring because infant mortality was extremely high. In a study conducted by Sorenson and Conaway with *Tupaia montana*[17], the mortality rate of the offspring born in captivity was apparently 100%. If the survival rate can be taken as a criterion of the degree of immunity of maternal behaviour from disruption in captivity, it seems likely that the 48-h suckling rhythm is the more 'natural' pattern, although no relevant field observations have yet been conducted.

As one further test of the 48-h suckling rhythm in *T. belangeri*, Martin removed infant tree-shrews five times from the nest for periods of about 36 h between suckling visits to see if this had any effect on maternal behaviour. The weight curves of the infants ranked in the upper range recorded for the species[1]. It is striking that total removal of the infants from the nest for long periods has virtually no effect on tree-shrew maternal behaviour, whereas two 30-s fire-bell tests can produce marked disruption. The results reported here should establish that the 48-h suckling rhythm is indeed typical of several members of the Tupaiinae when maintained under relatively stress-free conditions, whilst at the same time providing a cautionary tale for research workers concerned with the interpretation of behaviour in captive colonies of animals.

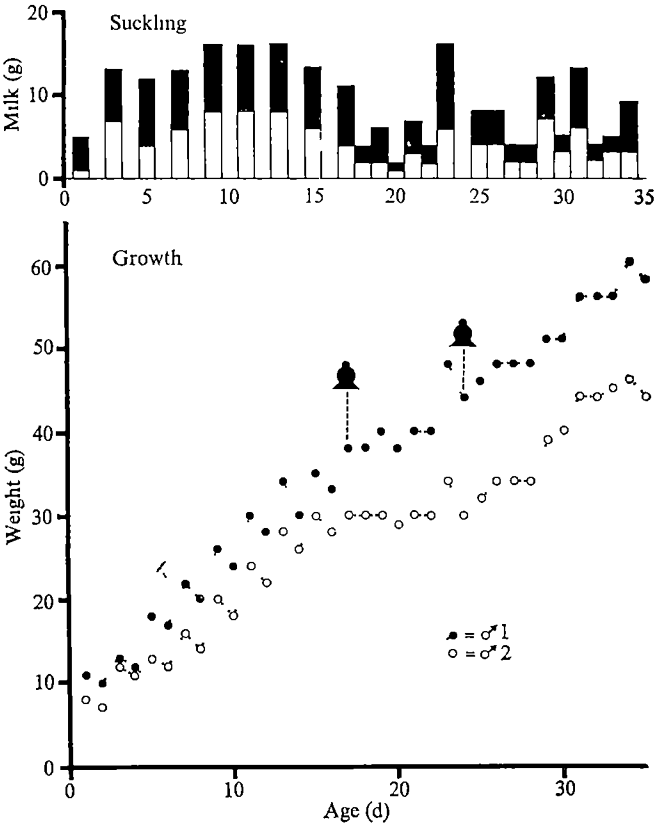

Fig. 4 Weight curves (lower) and histogram showing milk intake (upper) for a litter of *T. belangeri*. Two fire-bell tests were carried out on days 16 and 23, in both cases resulting in disruption of the 48-h suckling rhythm, reduction in milk intake per 24 h and depression of the weight curve. ■, ♂ 1, □, ♂2.

The analysis of tree-shrew milk was carried out by R. L. J. Lyster, National Institute for Research in Dairying, Herr K. Noack, Allgauer Alpenmilch Gesellschaft (after Martin[1]), and Dr D. L. Frape, Spillers Ltd. We thank Dr Gilbert Manley for a critical reading of the manuscript.

Trace element content and body size in molluscs

WHEN trace element concentrations in shellfish are expressed on a weight-specific basis (as $\mu g\ g^{-1}$) highest values are often recorded in the smallest individuals[1]. In these cases, it is difficult to assess whether observed differences in element tissue concentrations between populations reflect real differences in environmental trace element constitution, or are merely due to variations in body size. This problem can be avoided by determining element concentrations over a range of body sizes and reference made to a specific size for comparative purposes.

Element concentrations have been measured in individual molluscs over a wide size range. Six estuarine species have been examined: limpets, *Patella vulgata* L. and *P. intermedia* Jeffreys; the cockle, *Cerastoderma edule* (L.), the mussel, *Mytilus edulis* L.; and clams, *Mercenaria mercenaria* L. and *Venerupis decussata* (L.). Limpets were collected from Portishead, on the Severn Estuary and the River Helford, Cornwall, cockles from Southend, Essex, *M. mercenaria* from Southampton Water, and *V. decussata* and *M. edulis* from Poole Harbour, Dorset.

Nitric acid digestion techniques were employed, trace element concentrations being determined by atomic absorption spectrophotometry in a final volume of 5–20 cm^3 1 M HCl (with additional dilution if necessary). Theoretical instrument sensitivities for the various elements in the minimum volume used of 5 ml are Cd 0.05, Cu 0.1, Fe 0.5, Ni 0.5, Pb 0.5 and Zn 0.05 μg. Because such limits apply only to pure solutions, not subject to matrix effects found in digestates of animal tissues, minimum amounts considered were generally at least five to ten times greater than the above values. Concentrations obtained have been expressed as the content (μg per individual) and as the weight-specific concentration ($\mu g\ g^{-1}$). Both have been plotted against dry body weight (g). Regression lines were fitted by the method of least squares and all were significantly correlated at the 0.1% level.

The method of statistical analysis employed is analogous to that relating functions of metabolism to body weight[2,3]. Total trace element content per individual Y relates to body weight W as a power function expressed by:

$$Y = aW^b \qquad (1)$$

Pars. Chr. [illegible] Library
SCIENCE COLLEGE

which on logarithmic transformation yields a regression of the form

$$\log_{10} Y = \log_{10} a + b \log_{10} W \qquad (2)$$

The weight-specific relationship Y′ to body weight is essentially similar. Dividing (1) throughout by W yields

$$Y' = Y/W = aW^{b}/W = aW^{b-1} \qquad (3)$$

Logarithmic transformation produces a linear function

$$\log_{10} Y' = \log_{10} a + (b-1) \log_{10} W \qquad (4)$$

Clearly equations (2) and (4) have related regression coefficients and share a common intercept (Y and $Y' = \log_{10} a$ when $W = 1.0$, $\log_{10} W = 0$).

The precise relationship between trace element content (μg) and dry body weight (g) differs depending upon element and species. Three general relationships have been identified (Figs 1–4 and Table 1). First, element content is related to $\simeq$ 0.75 power of body weight. This relationship was true for copper in all species examined. A variety of other elements exhibited the same relationship (Table 1), the actual values obtained for the regression coefficients of 32 lines (relating to the various elements in the six species examined) ranged from 0.67 to 0.85. Covariance analysis yielded no significant difference between pairs of coefficients. Pooling the sums of the squares and sums of the products of deviations from the regression[4] gave a common regression coefficient of $b = 0.77 \pm 0.04$ (weight-specific slope -0.23) (Figs 1 and 2).

Second, element content is directly related to body weight ($b \simeq 1.00$). Nickel in all bivalve species examined and also lead and zinc in *M. mercenaria*, iron and zinc in *V. decussata* and cadmium in *M. edulis* exhibited this relationship to body weight. The actual regression coefficients of 15 lines varied from 0.97 to 1.17, no pair of slopes being significantly different from one another. These lines yielded a common regression coefficient of 1.03 ± 0.02. In these cases tissue element concentrations are independent of size (Fig. 3).

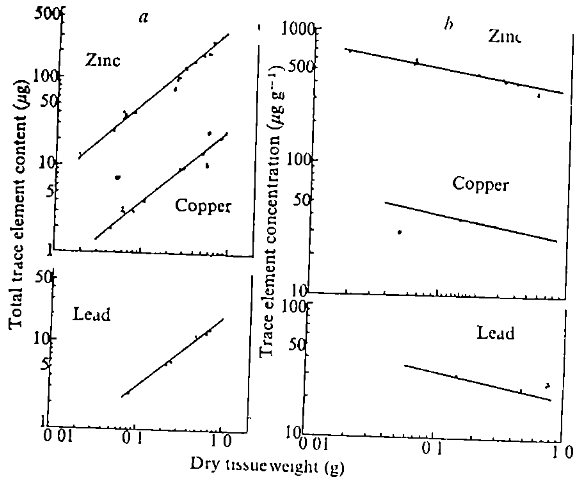

Fig. 1 Relationship of *a*, element content (μg) and, *b*, element concentration (μg g⁻¹) to body weight (g) for copper, lead and zinc in the limpet *Patella vulgata* collected on August 3, 1973 from Portishead, Severn Estuary.

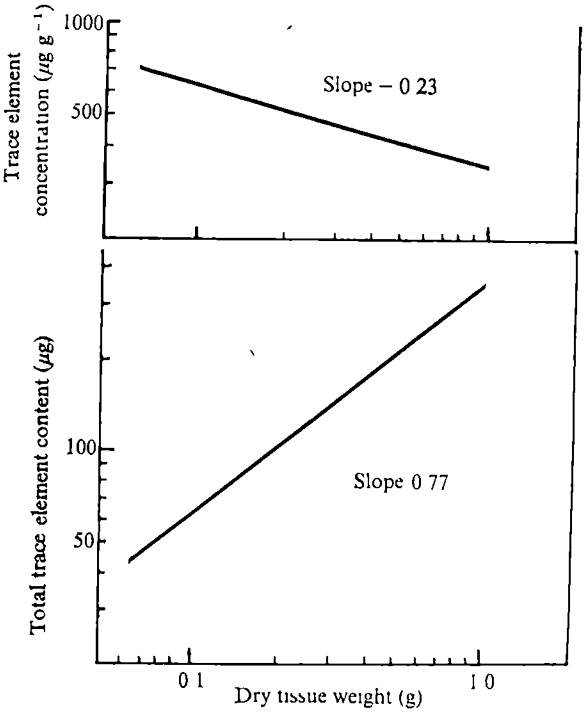

Fig. 2 Relationship of element content (and concentration) to body weight where element content related to 0.77 power of body weight. The data shown pertains to zinc in *P. vulgata* collected from Portishead, Severn Estuary.

Third, element content is related to square of body weight ($b \simeq 2.00$). This pattern was only observed for a single element, cadmium, in the limpet *P. vulgata* (Fig. 4). Therefore in this specific case, element tissue concentration is directly proportional to body weight.

Some earlier observations in the literature are consistent with the above relationships. A regression slope of 0.77 (weight-specific slope of -0.23) dictates that smaller individuals contain a higher concentration of metal than larger individuals. Such differences have been recognised for lead in *M. edulis*[1], zinc in *P. vulgata*[5] and copper and iron in *M. mercenaria*[6]. The converse situation, with higher concentrations of cadmium in large limpets compared with small individuals, has previously been reported for *P. vulgata* collected from the Severn Estuary[5,7]. In the molluscs studied, however, it was usual for element concentrations to decrease or remain constant with increasing body weight. Species from other phyla would be expected to exhibit similar relationships, certainly concentrations of

cadmium, copper, iron, manganese and zinc either decrease, or remain constant, in whole fish when expressed as a function of size, weight or length[8]

In molluscs, as in biota in general, absolute tissue element concentrations are related or determined by environmental concentrations Within each species, however, different elements display different relationships to body weight (Table 1) Regression coefficients related to body weight by a power of 0 77 implies a connection with metabolism, as many metabolic processes display a similar relation to body weight The common regression coefficient of 0 77 ± 0 04 is not significantly different from the coefficient of 0 75 ± 0 015 describing the relationship of respiration of poikilotherms to body weight[9], a value generally accepted to relate many metabolic functions to body weight Thus in cases where an element is related to 0 77 body weight some aspect of metabolism could well be influencing final trace element content

Where the element content is directly related to body weight, as has been found for a variety of elements in several species, then a function of body weight such as the binding of specific compounds within the tissues may play some role in determining the total body element burden The absolute amount of metal, however, is not dictated by the amount of such binding compounds within the tissues At least certain metals such as cadmium and nickel in *Mytilus*, retain a specific slope relation of ≃ 1 00 between total body element content and body weight, even though the absolute amount of the metals within the tissues differed by twelvefold for cadmium and twofold for nickel between two separate populations studied

A relationship to the square of body weight as shown by cadmium in limpets can best be explained as being due to removal of this element from body circulation and accumulation within specific tissues, possibly as a result of some exceptional affinity The slope value of 2 00 in the limpet population examined, may well be due to the unusually elevated environmental cadmium concentration in the Severn Estuary Populations of limpets from other areas, where environmental cadmium concentrations are lower and more normal, exhibit slopes between 1 3 and 1 5 which may well indicate that in this specific case, the slope is variable and related to the environmental cadmium concentration

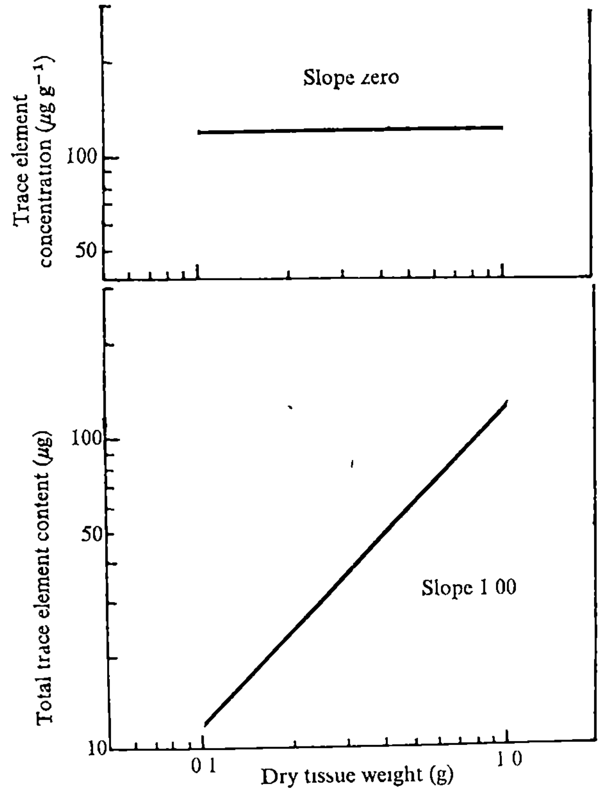

Fig 3 Element content directly related to body size, weight-specific concentration independent of size This example relates to nickel in the cockle *C edule*

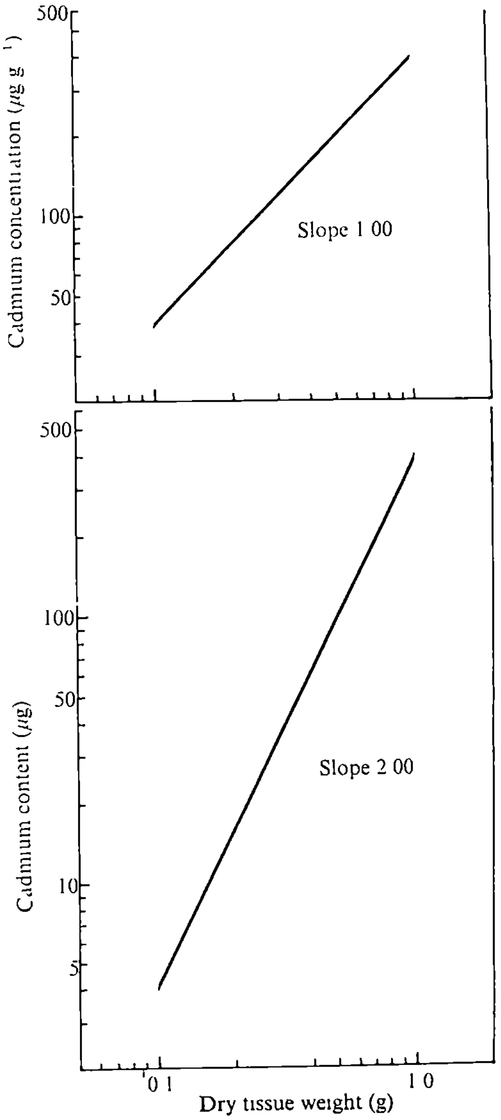

Fig 4 Relationship of cadmium content (and concentration) to body weight in the limpet *P vulgata* where cadmium tissue concentration (μg g^{-1}) is directly related to body weight Limpets collected from Portishead

Knowledge of the regression coefficients of lines relating trace element content (or the weight-specific concentration) to body weight is potentially a considerable aid in the monitoring of metals within shellfish Evidence is being gathered which suggests that in most cases the regression coefficient relating element content to body weight remains constant irrespective of season or environmental element concentration The only case so far identified where the slope differs between populations is that for cadmium in *P vulgata* discussed above, though other exceptions may also be expected If values of *b* are indeed constant for a particular element within a species, data pertaining to element content or concentration and mean tissue weight for a sample of similar sized individuals may be substituted, together with the appropriate slope for the element and species in question, into equations (2) or (4) The calculated intercept ($\log_{10}a$) converted to real values may then be used for comparison between populations irrespective of the size of the individuals sampled and analysed The influence of seasonal variations and environmental element concentrations on the above relationships is receiving further investigation

LSD treatment of *Pieris brassicae* and consequences on the progeny

At 20° C, under white light illumination and circadian rhythm, nymphal diapause of *Pieris brassicae* is dependent on a short 9-h photophase Some psychodysleptics (mescaline sulphate and LSD), when injected during the photosentitive larval period, suppress diapause induction as if the larvae were subjected to a long 16-h photophase[1] Abnormalities in the behaviour of the progeny of treated animals were observed We studied them for three generations after the treatment

Three couples of *P brassicae*, progeny of a single original pair, were isolated The progeny of each of these pairs were divided into two groups, one served as control (normal stock) and the other was treated with LSD Control and treated animals of each progeny, respectively, were pooled at the end of each experiment after assessment of the fluctuation Both stocks were subjected to a 9-h white light photophase treatment at 20° C (14,600 erg cm^{-2} s^{-1} with a Mazda TFR/40/BBL lamp)

LSD was diluted in Ringer solution to different concentrations Animals were injected with 5 μl of the solution 24 h after the fourth moult

As previously described[1] injection of 20 μg of LSD per animal results in about 80% of continuous development and 20% diapause induction In the parental generation the LD_{10} was 35 μg per animal

Among non-diapausing animals, different crosses were performed (Table 1) The normal partners were taken from the normal stock defined earlier

The first striking observation was that all these F_1 larvae were highly resistant to LSD with a LD_{10} higher than 60 μg per animal Second, 100% of the diapausing progeny of cross B, whether or not injected with 20 μg of LSD, died either at the end of the chrysalid stage or as malformed imagos (Table 1, B_1 and B_2, respectively)

Among diapausing animals, new crosses were performed (Table 1) Normal animals were taken from the progeny of the normal stock defined earlier The sensitivity of the F_2 larvae to LSD in the three types of crosses seemed very high the LD_{10} fluctuated between 5 and 10 μg per animal

Different effects resulting from a treatment by LSD are apparent in the progeny of treated animals an altered response to a 9-h photophase and the sensitivity to toxic effects of the drug Two types of toxic effects have been detected One is a short term effect measured through LD_{10}, the second is a long term effect apparent at the imaginal moult in diapausing animals

The progeny of treated males and females (Table 1, B_1 and B_2) die at the imaginal moult although the egg laying ability of parents and hatching percentage, which were measured during all these experiments were found to be normal

The early toxic effect of LSD follows a curious pattern with a LD_{10} of 35 μg for the parents, of more than 60 μg for the F_1 and 5–10 μg for the F_2 and the F_3

The high resistance to LSD of the second generation may be explained by a detoxification mechanism, consequence of the parental treatment, enhanced by a further LSD treatment which could explain the slight improvement of viability in column B_2 Analysis of the effect of LSD on diapause induction must take the existence of such a resistance mechanism in account

Table 1 Effect of LSD on diapause induction by a 9-h photophase

Parents		Treated		Not treated			Control (Ringer)
Total number		378		312			59
% diapausing		18		78			86
F_1	A treated ♂ × normal ♀		B treated ♂ × treated ♀		C normal ♂ × treated ♀		Control
	A_1	A_2	B_1	B_2	C_1	C_2	
Total number	77	111*	60	101*	91	128*	312
% diapausing	99	100*	25	97*	79	48*	78
F_2		A_1 ♂ × normal ♀			C_1 ♀ × normal ♂		C_2 ♀ × normal ♂
Total number		107			133		110
% diapausing		45			57		65

* When some animals were treated again, their total number and percentage of diapause are given (F_1 column 2)
Amount of LSD injected per animal was 20 µg The control value in F_1 is taken from the parents

The untreated progeny of treated males and females (B_1) show 25% of diapause induction only This 'parental effect' is only observed if both parents were treated and completely disappears after a 20 μg LSD treatment (B_2) Such an induced resistance to LSD is asymmetric If only one of the parents is treated and if this parent is the male, then treatment of the progeny has no effect (A_1/A_2) If this parent is the female, then a slight shift toward photophase resistance after LSD treatment can be observed (C_1/C_2)

We must then conclude that the resistance mechanism observed in the F_1 is very efficient when transmitted by males (A_1) and less efficient when transmitted by females (C_1) The LSD triggered enhancement of the resistance to the drug seems to be transmitted only by the males (A_2 and B_2) and is only apparent when a parental effect is present (B_1/B_2)

This parental effect can be observed in the F_2 generation even if only the grandfather or the grandmother was treated with LSD (results are statistically different from the normal 80% of diapause induction with less than 1% chance of error) We are apparently able to observe this transmission because the resistance mechanism, which in the F_1 masked the parental effect, is absent in the F_2

The most probable target for LSD is the genetic material present in the germinal cells of the parental generation Successive crosses with normal animals lead to a dilution of treated genetic material and a progressive shift toward a normal situation

Damage to chromosome structure after LSD treatment has been described in different animals such as mice, humans and amphibians[2-6]. Unfortunately such damage is difficult to detect in Lepidoptera.

If what we have found in an insect is also true in mammals then we should observe a high resistance to LSD in the progeny of treated parents and physiological effects detectable even several generations after treatment could be predicted as these are common features of the different crosses we have performed. This could be confirmed in mice.

Regions of the freezing curve causing changes in structure and viability of ram sperm

WHEN ram spermatozoa are chilled and frozen, their acrosomes are damaged even in the presence of protective substances in the diluent. It has been suggested[1] that these structural changes contribute to the reduced fertility of frozen ram semen. Although the motility and structure of spermatozoa are affected to different extents by freezing it is not known if these changes occur simultaneously or are caused at different stages of the freezing process.

The present work was designed to identify the critical regions of the freezing curve by assessing the motility of and acrosomal damage to spermatozoa after cooling to various temperatures below zero. The experimental design was a 4^2 factorial array of temperature to which the sample was cooled (−5° C, −15° C, −45° C and −196° C) and level of egg yolk in the diluent (0%, 0.15%, 0.75% and 3.75% v/v). Samples of ram semen were diluted in a buffered glucose solution similar to that described previously[1] except that the glucose content was increased from 185 mM to 247 mM. The semen was diluted at 30° C and then cooled at a constant rate of 0.21° C min^{-1} to 5° C. An equal volume of diluent containing glycerol was added at 5° C and the diluted semen was held at this temperature, for not less than 5 h. The final dilution rate was 20-fold. Semen was frozen in plastic straws (0.25 ml, Cassou, l'Aigle) at a constant rate of 12° C fall min^{-1} to −55° C in a controlled freezing device. For lower temperatures the straws were transferred at −55° C to liquid nitrogen (−196° C). The order of the freezing treatments in successive replications of the experiment was determined according to a Latin square design. By this means, the main effect of freezing treatments was separated from the possible influence of differences in the equilibration time at 5° C.

The samples were thawed 10 min after reaching the final temperature. All samples were examined under the microscope within 5 min of thawing, and motility was estimated on a subjective scale of 0–4 (ref. 2) and the percentage of motile spermatozoa was estimated to the nearest 10%. Smears of frozen–thawed semen were fixed, stained and scored as described by Watson and Martin[1], who scored acrosomal damage on a 0–3 scale (0 for an undamaged acrosome and 3 indicating loss of the acrosome).

The results and statistical analyses are shown in Table 1. A significant decline in the motility and percentage of motile cells after cooling and warming was seen in those samples cooled to −15° C or below, compared with those cooled only to −5° C ($P < 0.001$). Crystallisation of the external medium occurred at −12° C. Samples cooled to −5° C were therefore supercooled but not frozen; all other samples were frozen. This probably accounts for the reduction in survival of frozen samples since no difference in survival rate was detected between samples cooled to −15° C, −45° C and −196° C. Spermatozoa frozen to −15° C or below showed a greater mean acrosomal deterioration than those supercooled to −5° C ($P < 0.01$), but freezing to −45° C or −196° C was less detrimental than freezing to −15° C ($P < 0.001$). The greatest changes in the acrosomes were seen in those spermatozoa frozen to −15° C. Damage to acrosomes did not result from crystallisation of the suspending medium, however, since the degree of damage was similar in the samples cooled to −5° C and −196° C. Dehydration of the cells with consequent salt concentration, and intracellular ice formation and recrystallisation could all be factors contributing to the damage since these events could occur during the 10 min pause before rewarming. They are less likely to occur at lower temperatures because of the lower energy state of the sample.

Table 1 Mean survival and acrosome scores for ram spermatozoa cooled to different temperatures in diluents containing various levels of egg yolk

	Treatment	Motility (Scale, 0–4)	% Motile	Acrosome score (Scale, 0–3)
A	Temperature to which cooled (° C)			
	1 −5	2.44	45.94	1.11
	2 −15	1.86	30.94	1.51
	3 −45	1.63	27.34	1.23

‖ 63-3 (for equilibration effect) degrees of freedom for 'error'.

The presence of egg yolk in the diluent improved the survival of spermatozoa after cooling and warming ($P < 0.001$). Survival with 0.75% egg yolk was significantly greater than with either the higher or the lower level of egg yolk ($P < 0.05$—motility score; $P < 0.001$—percent motile score). Acrosomal damage was decreased by increasing levels of egg yolk ($P < 0.05$). More egg yolk was thus required to protect the acrosomes, than to preserve motility. It may be that the stresses induced by chilling and freezing in the large surface area of the membranes surrounding the head of the spermatozoa are greater than those in the region of the midpiece. If a membrane-coating hypothesis is advanced for the protective action of egg yolk, the more labile membrane structures of the acrosome may require a greater concentration of egg yolk in order to stabilise them than do those involved with the movement of the spermatozoon. A similar pattern of response to the egg yolk levels was shown by the samples cooled to −5° C, to that seen in those cooled below the freezing point, since the 'cooling temperature × egg yolk level' interaction was non-significant for all scores. This supports the view that egg yolk plays a protective role during and after freezing similar to that before freezing.

Bank and Mazur[3] discussed the fact that there is no simple correlation between the survival and the degree and type of structural alteration of cells during freezing. For ram spermatozoa under the conditions in this experiment, motility was mainly affected by the phase change occurring near to −12° C, but the critical region, in which structural changes occurred, extended from this temperature to about −45 °C. It may well be that the freezing curve which allows maximum survival with minimum structural alteration has different cooling rates for different regions of the curve.

This work was supported by a grant from the Australian Wool Board.

Proteoid roots are microbially induced

ALTHOUGH some workers[1] have examined environmental factors affecting the formation of dense clusters of rootlets ('proteoid roots') in many taxa of the Proteaceae, the causal agents have not been elucidated. The basic phenomenon is an intense, localised production of short lateral roots occurring particularly in nutritionally poor conditions. Purnell[2] and Lamont[3] were unable to detect bacteria, actinomycetes or fungi in newly formed proteoid roots although microorganisms were sometimes found in older roots. Here we demonstrate that proteoid roots are caused by non-infecting rhizosphere microorganisms.

Nine hundred gram lots of two soils poor in nutrients (a podzolised soil, Mount Burr sand, South Australia[4] with 3 p.p.m. sodium bicarbonate extractable P; and a lateritic podzolic soil from Dwellingup, Western Australia[5] with less than 1 p.p.m. extractable P) were wetted to 70% field capacity with distilled water and placed in lidded polythene pots. Watering tubes of polythene tubing (1 cm diameter) with the lower end buried 2 cm into the soil were sealed into the lid, and the open end was covered with a metal cap. The assemblies were sterilised by γ irradiation (5 Mrad, Minster Carpets, Dandenong, Victoria). Seeds of *Banksia grandis* Willd. were surface sterilised and germinated on a nutrient agar[6]. Two sterile seedlings were planted in each pot by inserting the radicles through slits cut aseptically in the lid of the pot, and then sealing with petroleum jelly. Microbial inoculum was prepared by shaking 10 g of fresh proteoid roots (with attached rhizosphere soil) of *B. grandis* from a nutrient-poor soil in 200 ml sterile distilled water and 1 ml of this suspension was introduced through the watering tube to each 'inoculated' pot and 1 ml of sterile distilled water to uninoculated controls. Watering throughout the study was with sterile distilled water introduced by the capped water tubes. The plants were randomly distributed in a controlled environment growth cabinet and harvested after 4 months' growth at 20° C, with a 12 h day with light from Osram mercury vapour lamps (MBFR/u, 400 W, General Electric Company, London), providing 20,400 lumen m^{-2}.

In Mount Burr sand, none of the plants in the 12 sterile control pots produced proteoid roots while the plants in all 12 of the inoculated pots did; proteoid roots were particularly marked around the point of inoculation. In the lateritic podzolic soil none of the plants in the nine replicate control pots which remained sterile formed proteoid roots while all plants in the 12 inoculated pots did. The plants in the three microbially contaminated pots produced proteoid roots. None of the proteoid roots sectioned from inoculated pots was infected and we conclude that growth of microorganisms in the rhizosphere triggered formation of proteoid roots by the plant. Some microorganisms are known to produce growth substances affecting root morphology after infection by them[7,8] but this seems to be the first report of a major change in root morphology by non-infecting rhizosphere microorganisms.

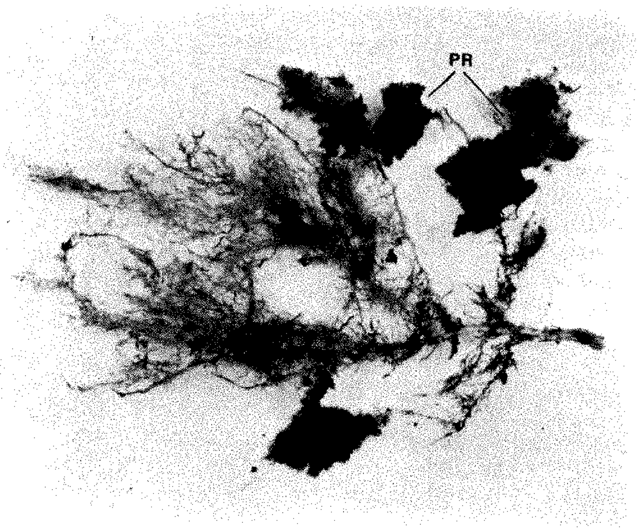

Fig. 1 Clusters of proteoid roots (PR) *Banksia grandis* (× 0.355).

Direct microscopic observation of proteoid roots from inoculated pots following staining[9] showed the rhizosphere to be dominated by bacteria. Counts of total bacteria, total aerobic viable bacteria, pseudomonads[10], Gram-negative bacteria[11], and *Bacillus spp.* (after heating dilutions for 10 min at 80° C) showed the rhizoplane numbers and frequency of these groups to be similar per mg of root with proteoid roots and corresponding non-proteoid roots on the same plant. Thus, the above counts did not give any suggestion of the identity of the causal organisms. Pure culture studies are proceeding. The production of proteoid roots in three pots with contamination infers that either a very common airborne organism or a wide range of organisms could induce proteoid root formation. If specific organisms are involved, however, it is not impossible that a few of them survived the γ-irradiation treatment.

Dry weight of shoots of plants with proteoid root and without proteoid roots respectively were 1.22 g and 0.67 g in Mount Burr sand (difference significant at $P<0.01$) and 1.40 g and 0.79 g in the lateritic podzol (difference significant at $P<0.01$). In each soil the weights of the roots of plants with proteoid roots and plants without proteoid roots were almost identical. Proteoid roots accounted for approximately half the root weight in Mount Burr sand and approximately 40% of the root weight in the lateritic podzolic soil. Jeffrey[12] demonstrated the importance of dense surface mats of proteoid roots trapping sudden phosphate accessions and also attributed an increased uptake of phosphate from solution culture to their greater absorbing surface. Figure 1 indicates the intense exploration of soil afforded by proteoid roots, and this would be expected to enhance uptake of poorly mobile ions already in the soil[13] as well as trapping added nutrients. Baylis[14] and Bowen[15] have commented on the importance of mycorrhizal associations in compensating low root density in uptake of poorly mobile ions from soil.

Uptake of ^{32}P from 5×10^{-6} M KH_2PO_4 in 5×10^{-4} M $CaSO_4$ over 15 min at 20° C showed uptake of phosphate by proteoid roots to be 1.82 ± 0.18 (s.e.) $\times 10^{-13}$ mol cm^{-2} s^{-1} compared with $0.48 \pm 0.07\times10^{-13}$ mol cm^{-2} s^{-1} for similar young unsuberised non-proteoid roots (differences significant at $P<0.01$). Assuming the microbial component of uptake to be similar (as indicated by the similar microbial counts and composition above) the enhanced phosphate absorbtion by proteoid roots is due not only to their greater surface area but also to increased absorbing ability. Stimulation of phosphate uptake and translocation by noninfecting rhizosphere microorganisms has been suggested for other plant groups[16,17].

We see the results as being significant in demonstrating yet another system which plants have evolved for enhancing their nutrition in low nutrient soils, not by themselves but in association with soil microorganisms. Other, better known, examples are legume and nonlegume nitrogen fixation[18] and various types of mycorrhizas[19] increasing ion uptake. Lamont[1] demonstrated experimentally that low or unbalanced N and P status of the growth substrate enhances proteoid root formation in nonsterile conditions. Our demonstration that rhizosphere microorganisms induce proteoid root formation suggests a need to examine the extent to which observed differences between soils in proteoid root formation are due to soil microbiological differences rather than soil chemical and physical differences.

Oxygen microenvironment and respiratory oscillations in cultured mammalian cells

OXYGEN transport in cultures of attached mammalian cells depends on the kinetics of gas diffusion through the overlaying medium. Working with liver parenchymal cells, Stevens[1] calculated that the oxygen requirements and energy demands of a monolayer culture could not be met by atmospheric pO_2 if the fluid overlay was deeper than 0.34 mm. McLimans[2] theorised that under the standard medium overlay of 1.5–5.0 mm, oxygen depletion by a respiring monolayer of liver parenchymal cells would exhaust the atmospheric oxygen supply at the plane of the attached cell sheet within 35 min. His model suggests that adaptive growth of cultured cells occurs only when respiration does not exceed the delivery of oxygen to the monolayer.

To test these theories and the validity of arguments linking oxygen availability with respiration, energy metabolism and the regulation of cell growth, we constructed microoxygen cathodes[3,4] and investigated microenvironmental pO_2 in the medium overlaying attached cultures of WRL-10A cells. This subline of the L-cell mouse fibroblast, isolated in our laboratory[5], was used because we already had information about changes in medium pO_2 and respiratory rates during regulated states of growth and differentiation of these cells in suspension cultures[6,7]. Cells were grown attached to optically flat 50 mm Petri dishes with 6 ml of Eagle's minimum essential medium (MEM) supplemented with 20% horse serum, antibiotics and glutamine. Dishes were placed on the stage of an inverted microscope inside an environmentally controlled chamber, and maintained at 35° C in a humidified atmosphere of 5% CO_2 and air. A Pt/Ir oxygen microcathode with a tip 1–3 μm in diameter and a corresponding resolution 6–20 μm in diameter, was secured in a micromanipulator clamp, and positioned in the centre of the objective field so that descent of the cathode could be observed. An Ag/AgCl reference anode placed in a saline well adjacent to the dish was joined to the medium by an agar bridge. Starting at the fluid–air interface, the cathode was

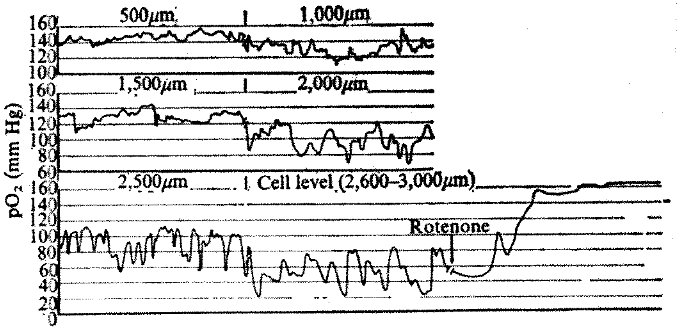

Fig. 1 Oscillations of microenvironmental pO_2 in the medium overlaying attached cultures of 10^7 cells per 50 mm Petri plate were measured amperometrically with calibrated Pt/Ir microoxygen cathodes polarised between 0.6 and 0.8 V. The oscillations were traced on a strip chart recorder connected to an electrometer which was attached in series to a cathode and a Ag/AgCl reference anode. The current output of these sensitive cathodes ranged between 0.5×10^{-11} and 0.5×10^{-12} A per mm Hg. Distances measured in micra represent depths from the surface of the medium towards the attached cell sheet. Oscillations at each depth are presented in comparable 30-min segments.

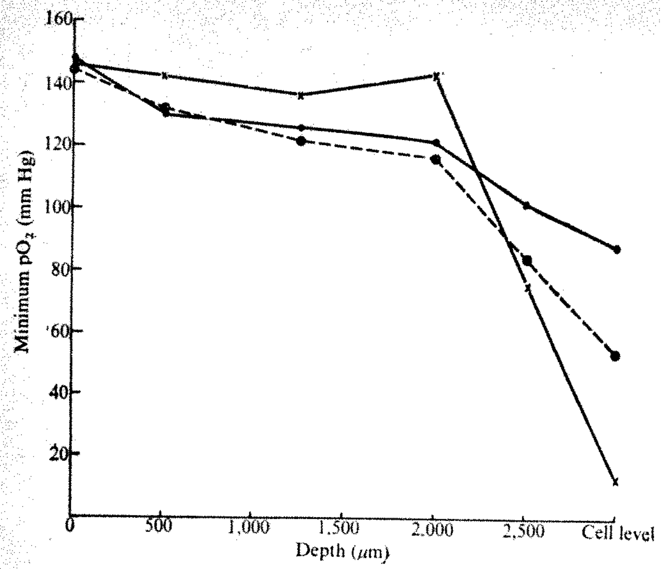

Fig. 2 Density-related oxygen gradients in the medium overlaying populations of attached WRL-10A cells. Experimental cultures contained 5×10^6 (●——●), 10×10^6 (○ - - - - ○), and 16×10^6 (×——×) cells per plate. Minimum pO_2 values represent means of the lowest pO_2 readings obtained from all oscillations recorded at each indicated depth.

lowered through the medium towards the attached cell layer and pO_2 changes were measured polarographically at selected depths. Pilot experiments detected the existence of oscillating concentration gradients of oxygen above the attached cell sheet. Because this oscillatory phenomenon had neither been predicted nor described in any literature on mammalian cell cultures we have tried to describe these dynamic oxygen fluctuations in detail, to determine their origins, to establish their relationship to cell density and to derive from them clues about oxygen availability as it relates to mechanisms controlling respiratory activity in attached populations of exponentially proliferating cells.

Using populations of 10^7 cells per plate, continuous recordings were made of the pO_2 oscillations at specific depths in the overlaying medium. A composite of the collected data (Fig. 1) shows that oscillation amplitude increased with depth. At 500 μm the oscillations were very shallow, at 1,000 μm and 1,500 μm they were slightly larger, but still relatively small while at 2,000 μm and 2,500 μm oscillations were mixed large and small. Continuous undampened oscillations with major and minor peaks occurred at cell level and their mean peak frequency ranged from 0.34 – 0.56 per min in different experiments. At each increasing depth, oscillations occurred within a characteristic range of progressively decreasing minimum and maximum pO_2. For example, at 500 μm they occurred between 140 and 160 mm Hg, while at the cell level they occurred between 20 and 80 mm Hg. Correspondingly, conditions of minimum O_2 availability at the various depths are described by a mean minimum pO_2 gradient, that is an oxygen gradient based on the average of the lowest pO_2 readings obtained from all the oscillations recorded at each particular depth. After recording the pO_2 oscillations at the cell level for 30 min (Fig. 1), 50 μl of a rotenone solution, 10^{-8} M in ethyl alcohol, were added to determine whether the oscillations were related to cellular respiratory activity. The effect of this respiratory inhibitor[8] was an immediate cessation of oscillations, followed by 9 min of maintained low pO_2, a last oscillatory rise and fall of local oxygen tension and a subsequent steady increase in pO_2. This brought the microenvironmental oxygen tension back into sustained equilibrium with atmospheric oxygen. Having thus demonstrated that the oscillations are an expression of cellular respiratory activity with oxygen depletion due to cell respiration and oxygen replacement due to diffusion, we investigated the effect of cell density on mean minimum pO_2 gradients.

Replicate cultures seeded with 7.0×10^5 cells per Petri plate were maintained by daily medium renewal and analysed polarographically at cell densities of approximately 5, 10 and 16×10^6 cells per plate. Comparisons of pO_2 gradients (Fig. 2) showed that from the air–fluid interface down to 2,000 μm, all three cell densities had media oxygen tensions that were relatively high and nearly in equilibrium with atmospheric pO_2. From 2,000 μm down towards the cell level, however, the oxygen tension decreased sharply in a directly inverse relationship to increasing density. Thus, the negative slope of the 5×10^6 cell population is the least steep and the slope of the 16×10^6 cell population is steepest. Likewise the mean minimum pO_2 at the cell level also decreased in direct proportion to increasing cell density, with the value of the 5×10^6 cell population reaching approximately 100 mm Hg, the 10×10^6 cell population reaching about 60 mm Hg, and the 16×10^6 cell population reaching about 19 mm Hg. Thus in attached cultures oxygen availability and microenvironmental O_2 gradients are directly related to the density and combined respiratory activity of the entire cell population.

When the amplitudes of the pO_2 oscillations were measured and their mean values at increasing depths compared (Fig. 3), the following correlations appeared. In cultures of 5 and 10 million cells the mean oscillation amplitude increased with depth down to 2,500 μm. At each depth the mean oscillation amplitude for the 10^7 cell population was significantly greater than the corresponding amplitude of the 5×10^6 cell population. Amplitude therefore increased as a function of both depth and increasing density. At densities of 16×10^6 cells and greater, the combined respiratory activity of the larger population intermittently reduced the microenvironmental oxygen supply at the cell level to extremely low levels, at which the respiratory activity seemed to be affected by oxygen limitation. Oscillatory behaviour in these high density populations is under investigation.

Our results indicate that the respiratory activity of WRL-10A cells under the condition of these experiments is periodic rather than constant. Furthermore, the density-dependent nature of

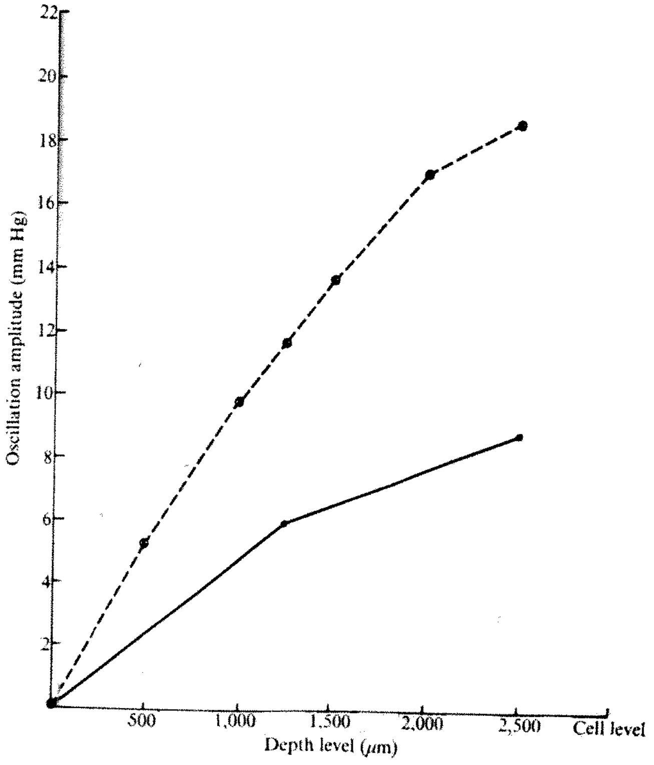

Fig. 3 Amplitudes of oscillations in exponentially growing cultures with 5×10^6 (●——●), and 10^7 (○ - - - ○) cells per plate. The values shown represent the means of all oscillations, large and small, recorded at each indicated depth.

the oscillations and of the media pO_2 gradients suggests that the entire cell population, or at least very large portions of it, respires in synchrony. This is evident because individual cells respiring periodically but out of phase, would tend to dampen or cancel out the oscillations. In the cellular microenvironment, the succession of predominantly undamped oscillations with minimum pO_2 values above 15 mm Hg reflects both the continuous cycles of partial depletion and renewal of microenvironmental oxygen and a control of respiratory activity that cannot be ascribed to mere periodic fluctuations of oxygen availability. We suggest therefore that cellular respiration in these cultures responds to environmental feedback[9] that is subject to modification by local exhaustion and diffusion of essential nutrients and metabolites and can alternately and synchronously turn the respiratory system on and off in a large number of cells. Such an oscillating system might consist of an energy balance between AMP, ADP and ATP or a fluctuation in some oxidisable substrate pool such as NADH, or a matrix of these and other interdependent variables such as pO_2, *p*H, pCO_2, glucose, Na^+ and K^+ all working in concert to control respiration and growth metabolism[10,11].

Stoker[12] demonstrated that populations of attached 3T3 cells, having reached confluency and stopped growing, can be induced into highly localised growth by gentle local agitation of the supporting medium. His inference is that the microenvironmental diffusion barrier proposed by Rubin and Rein[13] was reduced by the local disturbance thus changing the concentrations of essential growth factors or inhibitors and stimulating localised mitotic activity. Our data have provided direct demonstration of localised dynamic changes in the constitution of the growth media of attached cultures. The proposition that such changes may play an important role in growth regulation will be tested by extending these investigations to 'contact inhibited' cells.

Developmentally regulated cell surface alterations in *Dictyostelium discoideum*

THE life cycle of the cellular slime mould, *Dictyostelium discoideum*, can be divided into two mutually exclusive phases[1]. The vegetative state, in which the cells divide by fission every few hours, is characterised by the absence of intracellular communication; whereas the developmental social state, which is initiated by the exhaustion of nutrients, exhibits many forms of such interactions. These include the ability to respond to and relay chemotactic signals[2], and to form stable species-specific cell to cell contacts[3-5]. The ability to form stable cell contacts can develop in the absence of a chemotactic gradient, as demonstrated by the immediate formation of normal aggregates upon plating of cells which have been maintained in suspension in a nutrient-free salt solution for 8–9 h (ref. 1). New antigens appear and function on the cell surface during development[3,4]. Gerisch and his coworkers have shown that univalent antibodies directed against the surface of 12 h cell aggregates interfere specifically with the formation of the stable cell to cell contacts[4-6]. Furthermore, it has been demonstrated that a developmentally controlled, heat-stable component, which is present in membrane preparations from 12 h aggregates, interferes specifically with the morphological and biochemical development of the organism (J.E.S., and J. Tuchman, unpublished, and J. Tuchman *et al.*, unpublished).

Most studies on cellular components which reside on the outer cell surface of the plasma membrane are complicated by the fact that the cell surface membrane must be disrupted in order to be purified and characterised. For some molecules on the outer cell surface this complication can be avoided by selectively labelling them before disruption of the cell[7,8].

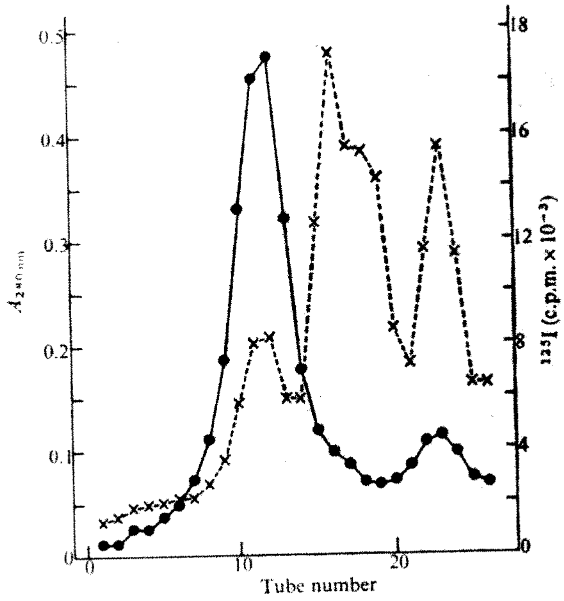

Fig. 1 Sucrose gradient profile of subcellular fractions of ^{125}I-labelled *D. discoideum* cells have formed firm aggregates 12 h after nutrient deprivation and plating. Cells were suspended at 10^8 cells ml^{-1} and carrier-free $Na^{125}I$ usually to a concentration of 400 μCi ml^{-1}. The reaction was initiated by the addition of lactoperoxidase (E.C. 1. 11. 1. 7) (Calbiochem) and glucose oxidase (E.C. 1.1.3.4) (Worthington Biochemicals) to final concentrations of 20 μg ml^{-1} and 0.1 units ml^{-1}, respectively. The reaction was allowed to continue for 10 min at room temperature with occasional swirling. The reaction was stopped by addition of phosphate buffered iodide, PBI (phosphate buffer saline with the NaCl replaced by NaI), and the cells were pelleted through a cushion of PBI + 10% glycerol. The resulting pellet was resuspended in 1 ml of PBS and frozen at 70° C. After thawing of the cells (which resulted in cell lysis), membranes were prepared by layering the suspension over a linear gradient of 0.5–2.0 M sucrose, 0.02 M Tris, *p*H 8.0, 0.005 M $MgCl_2$. The gradients were centrifuged at 23,000 r.p.m. for 18 h at 4° C in a MSE SW 6 × 14 rotor. ●, ^{125}I (c.p.m.); ×, A_{280nm}. The membrane containing turbid band was diluted with at least five volumes of 0.02 M Tris, *p*H 8.0, 0.005 M $MgCl_2$, and centrifuged at 30,000 r.p.m. for 30 min at 4° C in an MSE SW 6 × 14 rotor.

We used the Na^{125}I-lactoperoxidase–glucose oxidase coupled system[9] to monitor some of the developmentally controlled changes on the cell surface of *D. discoideum*. This method selectively labels proteins which have a tyrosine exposed to the extracellular aqueous environment. We observed that the plasma membrane of *D. discoideum* in its vegetative growth phase contains two major proteins (molecular weights about 135,000 and 55,000) which are on the external surface and accessible to labelling by the ^{125}I-lactoperoxidase system. After the cells have progressed through their developmental phase to the point of forming firm aggregates a new major protein (molecular weight about 130,000) becomes accessible to labelling. Other less prominent labelled proteins show quantitative changes in their availability to this reagent. *D. discoideum*, strain Ax-2, an axenic haploid strain[10], was grown to mid-log phase 3–5×10^6 cells ml^{-1}) in HL-5 medium[11]. The cells were collected and washed free of nutrients in cold pad diluting fluid (PDF)[12], and 5×10^7 cells were deposited on black Millipore filters (4.25 cm). After proceeding through their normal developmental phase for varying periods of time, the cells were harvested in cold PDF, washed once with phosphate buffered saline (PBS), and then with PBS+5 mM glucose. The cell surface was then labelled with ^{125}I (carrier-free Na^{125}I, Radiochemical Centre, Amersham, Bucks) using the Na^{125}I-lactoperoxidase–glucose oxidase coupled system as described in Fig. 1.

The labelled cells were lysed and fractionated on a linear sucrose gradient, as shown in Fig. 1. The lowest band in the gradient contains practically all of the TCA precipitable ^{125}I counts. This turbid band, when viewed under a phase contrast microscope, or by electron microscopy, is seen to consist of large membranous fragments, as well as smaller vesicular components[13]. Whereas longer centrifugation results in further sedimentation of the other bands, the position of the turbid ^{125}I-containing band is not affected, and it is, therefore, assumed to be at its isopynic density (about 1.16–1.17 g ml^{-1}) (J.E.S. and J. Tuchman, unpublished).

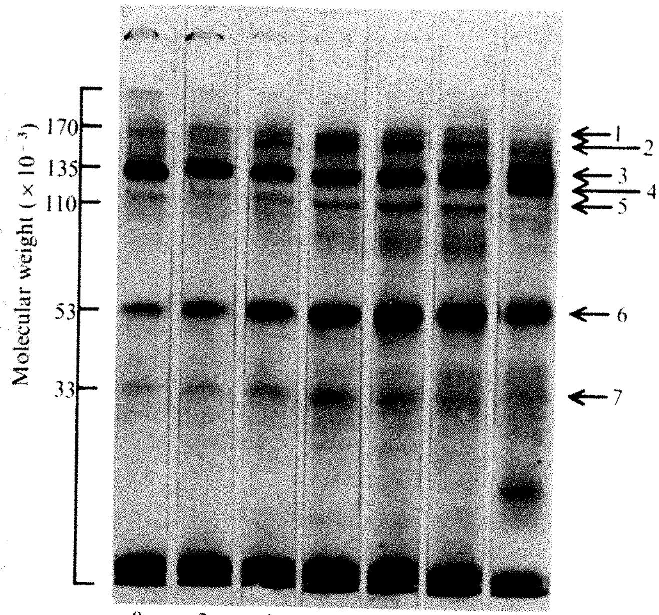

Fig. 2 Autoradiogram of 7.5% sodium dodecyl sulphate-polyacrylamide slab gel electrophoretogram of ^{125}I-labelled membranes of *D. discoideum* at various stages of normal differentiation. Membranes were dissolved in sample buffer containing 1% SDS 0.01 M dithiothreitol, 10% glycerol, and 0.05 M Tris, *p*H 6.8, by boiling for at least 2 min. Electrophoresis was done in slabs where 12 samples could be run in parallel on the same slab[16]. The buffer system used was that of Laemmli[17]. Electrophoresis was done at 50 V for about 1 h, until the bromophenol blue marker entered the separation gel, and then at 100 V (about 10 V cm^{-1}) until the marker reached the bottom. The slabs, after they were stained with Coomassie blue if required, were dried down on to paper, and autoradiographs made on Kodirex X-ray film.

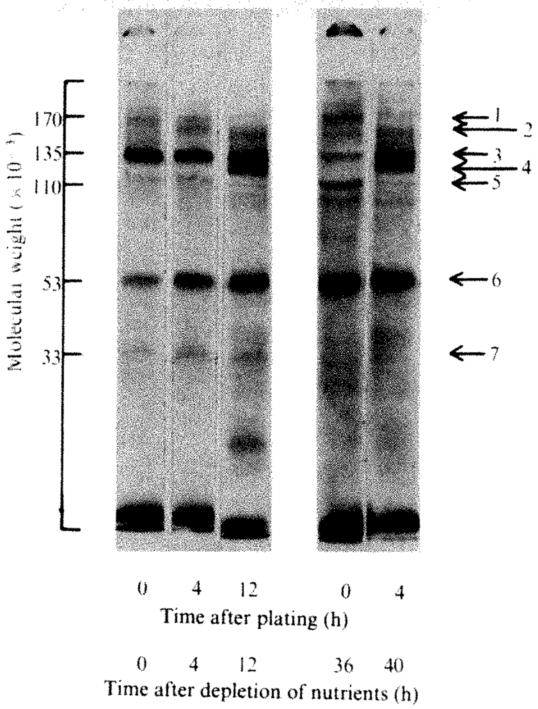

Fig. 3 Autoradiogram of 7.5% SDS-polyacrylamide slab gel electrophoretogram of ^{125}I-labelled membranes of *D. discoideum* at various stages of normal differentiation or at various stages of development of 'aggregation competence' in suspension culture. Samples for suspension culture were collected as described and resuspended at 10^7 cell ml^{-1} in PDF. The cells were maintained for various periods of time in shaking culture. In the above experiment the cells were maintained in liquid suspension culture for 36 h at which time one aliquot of 10^8 cells was labelled with ^{125}I. An identical aliquot was plated on black Millipore fitters and allowed to form firm aggregates (3–4 h after plating), before labelling.

In the absence of lactoperoxidase and glucose oxidase, the labelling is only 0.6% of the control level, suggesting that the reaction is totally dependent on the exogeneously added enzymes, which presumably do not enter the cell. Removal of 94% of the TCA precipitable counts by mild trypsinisation of whole cells (leaving the cells intact) also supports the conclusion that the label is only attached to proteins on the cell surface. If cells which have been mildly trypsinised after labelling are fractionated by sucrose gradient centrifugations essentially all of the remaining TCA precipitable counts are found with the soluble proteins. Furthermore, if the cells are lysed (freeze–thaw) before the labelling procedure, the ^{125}I counts are found to parallel closely the $A_{280\,nm}$ profile in the sucrose gradient, and SDS polyacrylamide slab gel electrophoretic analysis of such preparations shows that the protein banding patterns obtained by staining with Coomassie blue or by ^{125}I autoradiography are essentially identical. These observations indicate that the reaction labels only a discrete portion of the cellular proteins of intact cells, that this selectivity is dependent on the integrity of the cells and that all of the labelled proteins reside on the outer surface of the plasma membrane where they are accessible to trypsin.

During the first 12–14 h of normal differentiation (after depletion of nutrients) *D. discoideum* proceeds from unicellular amoebae to a multicellular organism composed of approximately 5×10^5 cells (ref. 14). At any point during these early stages of development the organism can be readily collected and mildly disrupted into a single cell suspension[15]. If intact cells of such samples are labelled with ^{125}I and their isolated membranes analysed by SDS-polyacrylamide gel electrophoresis, the results shown in Fig. 2 are obtained. For convenience, seven of the more noticeable ^{125}I-containing bands are numbered. It is interesting that none of these seven labelled bands (with the possible exception of band No. 6) comigrates with any of the major Coomassie blue staining bands of the same preparations. Although quantitative changes can be seen in several of the labelled proteins, the most noticeable change is the appearance of band No. 4 between 10 and 12 h after plating. At this point in the morphogenetic pathway, *D. discoideum* has just formed firm pointing aggregates. Up to 10 h after plating there is an apparent increase in the labelling of bands Nos 2, 5, and 6; whereas, the labelling of band No. 3 seems to decrease over this period.

The initial triggering event for the shift from the unicellular state to the multicellular state is the exhaustion of nutrient supply[14]. Thus, the zero point for the timing of developmental steps in *D. discoideum* is quite easily established experimentally. Gerisch has shown that the functional state of cells maintained in suspension in a nutrient free medium changes; after 8–9 h they become capable of forming aggregates immediately after plating[1]. These aggregation competent cells, like normal aggregating cells, show an elongated morphology and a preference for end-to-end contacts. Furthermore, they express an antigen(s) which is present on the surface of aggregating cells, but not on growth phase, single cells[4]. As shown in Fig. 3, *D. discoideum* can be maintained in suspension culture for at least 36 h without the appearance of the ^{125}I-labelled band No. 4. The same result is obtained for suspension cultures maintained for shorter periods of time, for example 16 h. It is interesting that in these conditions, as in normal development, the amount of labelling of bands Nos 2, 5 and 6, seems to increase while that of band No. 3 decreases considerably. Moreover, if these same cells are plated to allow them to form normal aggregates, the labelling of band No. 4 appears very rapidly and coincident with the morphological development of firm pointing aggregates.

Thus, in our conditions the acquisition of 'aggregation competence' in suspension cultures is not accompanied by any major qualitative change in the iodinatibility of cell surface proteins, although interesting quantitative changes do occur. Band No. 4 (which appears coincident with the formation of firm aggregates after about 12 h of normal development) is iodinatible only after the suspension culture cells are plated and allowed to form firm aggregates. Consequently, the iodinatibility of band No. 4 does not appear to be associated with the changes in cell surface molecules which are necessary for chemotaxis or aggregation competence in *D. discoideum*. These experiments show clearly that the availability of band No. 4 to this reagent is not due solely to the timing of independent metabolic events initiated by nutrient deprivation. Rather its iodinatibility seems to require participation of the cells in certain intercellular and morphogenetic interaction.

We thank Mary C. Humphries and Jacqueline Bye for their technical assistance.

Meiosis in *Dictyostelium mucoroides*

THE cellular slime moulds are favourable organisms for the study of morphogenetic processes. But so far, genetic analysis of their development has been hampered by the apparent absence of a true sexual cycle, although progress has been made in parasexual genetic analysis[1–3]. Recent ultrastructural observations of the macrocysts of two species have suggested, but not proved, that karyogamy and meiosis are an integral part of dormancy and germination of this developmental stage[4–6]. We present here genetic confirmation that in *D. mucoroides* (strain DM-7) the assortment of mutant traits among progeny of single macrocysts is consistent only with meiosis.

Macrocysts of DM-7 are postulated to contain at least one zygote. The fusion and karyogamy of two haploid cells of possible genotypes (*aB*) and (*Ab*) gives rise to a dihybrid of genotype (*AaBb*). Since DM-7 is homothallic, either parental genotype may fuse with itself as well, giving roughly equal numbers of uniparental and biparental macrocysts, on the assumption that there is one zygote per cyst[7]. In biparental cysts, the assortment of genetic factors among the four primary daughter nuclei of a meiosis results in a particular type of tetrad. Only three kinds of tetrad are possible from a single meiosis, regardless of the linkage relationships of the markers in the dihybrid nucleus[8]. They are the parental ditype (*aB*+*aB*+*Ab*+*Ab*), the non-parental ditype (*AB*+*AB*+*ab*+*ab*), or the tetratype class (*aB*+*Ab*+*AB*+*ab*). DM-7 is advantageous in that single macrocysts can be germinated wtih high efficiency and progeny samplings analysed for possible tetrad assortments..

Individual macrocysts possessing two or more zygotes could possibly arise through independent karyogamies, or by mitoses of a diploid zygote nucleus. These alternative mechanisms are distinguishable from the outcome of a single meiotic event (see below).

The progeny yield of DM-7 macrocysts often approaches 200 amoebae. Ultrastructural studies of germinating cysts have indicated that cytoplasmic cleavage is preceded by many nuclear divisions[6]. The timing of these apparent mitoses relative to a postulated meiotic event may influence the efficiency of this system for genetic analysis.

From these considerations and others, we predict that progeny of a single macrocyst will assort into one of only three tetrad classes, on the assumption that: (*a*) a single karyogamy followed by one (or more) meiosis generates all of the progeny; (*b*) there is no seriously detrimental mitotic or sampling selection against any single progeny

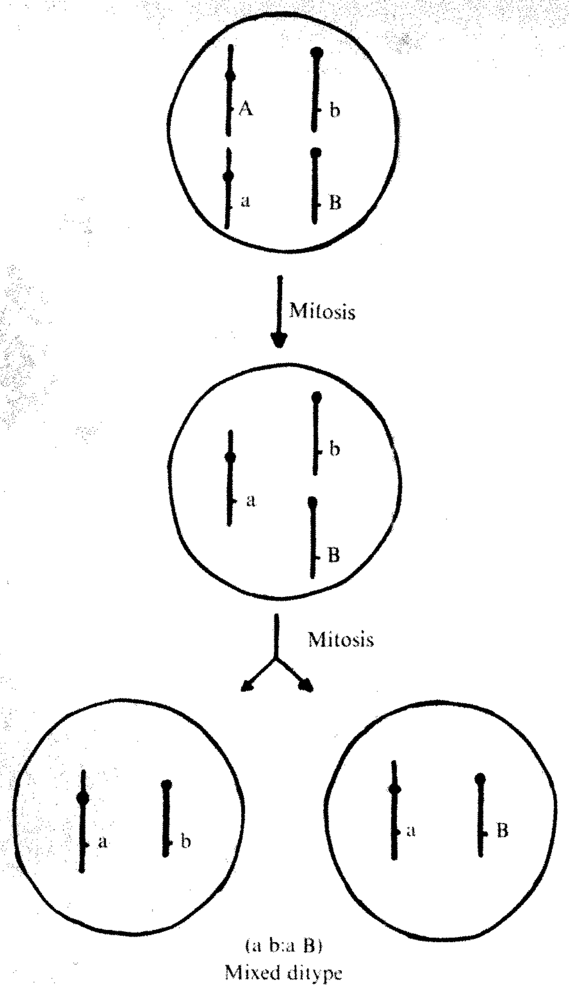

Fig. 1 Diagram of chromosomal losses associated with a hypothetical mitotic gene assortment mechanism in macrocysts. At the top is a dihybrid 'zygote' nucleus shown with only two chromosome pairs for clarity. An intermediate aneuploid stage during haploidisation, and two stable haploid nuclei are also represented. The mechanism of chromosomal loss is not depicted, whether by mitotic non-disjunction or by random cytoplasmic destruction. In the event that all daughter nuclei retain only two assortments of the markers of ditype will result. This outcome is most likely if one of the chromosomes bearing a mutant allele is lost at the first mitosis as indicated here. Otherwise, all copies of it must be lost from all daughter nuclei in successive mitoses. On a random basis six ditypes are equally probable, four mixed (for example, one shown above), one parental ditype and one non-parental ditype. The mixed ditype patterns of assortment do not occur in meiotic reduction division (see text).

genotype, and (*c*) there is no assortment through mitotic haploidisation.

Assumption (*c*) implies the possibility that within macrocysts some sort of accelerated parasexual mechanism could account for assortment patterns. Parasexual diploidy has been induced in *D. discoideum* under conditions similar to those used for macrocyst production^{3}. The dihybrid zygote could undergo haploidisation by chromosomal losses in successive mitoses^{9}. If such losses are random, single macrocysts would yield predominantly tetratype assortments but also several combinations inconsistent with meiosis (for example, Fig. 1). In the event that two genotypes arise from a single macrocyst, the parental and non-parental ditypes are just two of six equally probable ditype combinations (unlinked markers). So called 'tritypes' involving any three of the four segregant genotypes should also be recovered frequently. Thus recovery of mixed ditypes (Fig. 1) and tritypes together provides a simple test for the occurrence of mitotic haploidisation.

Table 1 Progeny samplings of single macrocysts for the cross *plq* × *cac*

Parental genotypes	Sample progeny clone phenotypes*				Macrocyst tetrad classification†	No. of macrocysts scored
(*plq*,+)×(+,*cac*)	(*plq*,+)	(+,*cac*)	(+,+)	(*plq*,*cac*)		
	145	0	0	0	PT (*plq*)	2

	0	0	16	19	NPD	1
	49	72	36	36	TT	6
Totals	228	507	52	55		16

Macrocyst production techniques were slightly modified from those worked out by Nickerson *et al.*^{10}. Cells of each genotype were collected and mixed before they became aggregation competent. Aliquots (0.25 ml) containing about 1.0×10^{7} cells of each genotype were deposited on 0.1% lactose, 0.1% peptone agar, the same medium as used for growth, but without additional bacteria. They were then placed in metal cans at 21° C to produce macrocysts. After storage for 22–35 d, the cross plates were removed from the container to initiate germination^{11}. Single macrocysts were picked and deposited in drops on to fresh, distilled water agar (2%). Drop transfers on the water agar effectively washed the macrocysts free of contaminating spores or amoebae. The germination plates were placed at 13°–15° C in a humid incubator, the interior illuminated by two 40 W incandescent tube bulbs. Significant germination began within 4 d and ultimately reached 60–80% of the transfers. Progeny of germinating macrocysts usually culminated in a small fruiting body on top of the cyst case. Blocks of agar with the cyst case, fruiting body and occasionally amoebal progeny were transferred to small aliquots of Bonner's salt solution^{13} containing suspended *E. coli*. The vortexed suspension was spread on to two PDB-5% agar plates per macrocyst and scored for clonal phenotypes after 3 d incubation at 28° C. Double mutant and wild type progeny clones were stable when sub-cloned on PDB-5% agar.

* Genotypes: (*plq*,+) = *plaque*, (+,*cac*) = *cactus*, (+,+) = wild type, (*plq*,*cac*) = the double mutant. The linkage relationships are undefined. The numbers are total progeny for the sum of the macrocysts scored.

† Tetrad classifications: PT, single parental type, PD, parental ditype; NPD, non-parental ditype; TT, tetratype class.

In this study, amoebae or spores were usually cloned on agar plates spread with *Escherichia coli* (B/r) for the screening of mutant strains and for analysis of the products of the genetic crosses. Clonal phenotypes of the three mutants selected for this study are shown in Fig. 2. The mutants *cactus*, *tag* and *plaque* each have an unusual morphological behaviour in one aspect of either clonal growth, aggregation streaming or fruiting body construction. In pairwise crosses each mutant phenotype is sufficiently distinctive to permit identification of all expected progeny phenotypes.

The crosses were initiated by mixing equal numbers of cells of each genotype under conditions leading primarily to macrocyst formation^{10}. Individual macrocysts were germinated according to the method of Nickerson *et al.*^{11} Contamination of the germinating macrocyst progeny by non-encysted parental amoebae or spores was eliminated by carefully controlling the conditions of macrocyst production, and after dormancy, by washing the cysts with drop transfers on the germination agar (H_2O). The lactose–peptone agar used for macrocyst production was dried overnight so that when aliquots of mixed cells (0.3 ml) were spread, a liquid film covering the aggregations persisted for only a few hours. Under prolonged wet conditions, the amoebae secrete large amounts of a slime material which traps cells or spores around the maturing macrocysts and prevents effective isolation and washing of the cysts. The complete set of progeny recoveries for the cross of *plaque* and *cactus* (*plq* × *cac*) is presented in Table 1. The numerical distribution of macrocysts classified as tetrads for all the crosses performed is given in Table 2.

The macrocyst progeny of *plq* × *cac* consistently fell into five classes (Table 1), three tetrad types and the two parental classes (selfed macrocysts). The reassortment of

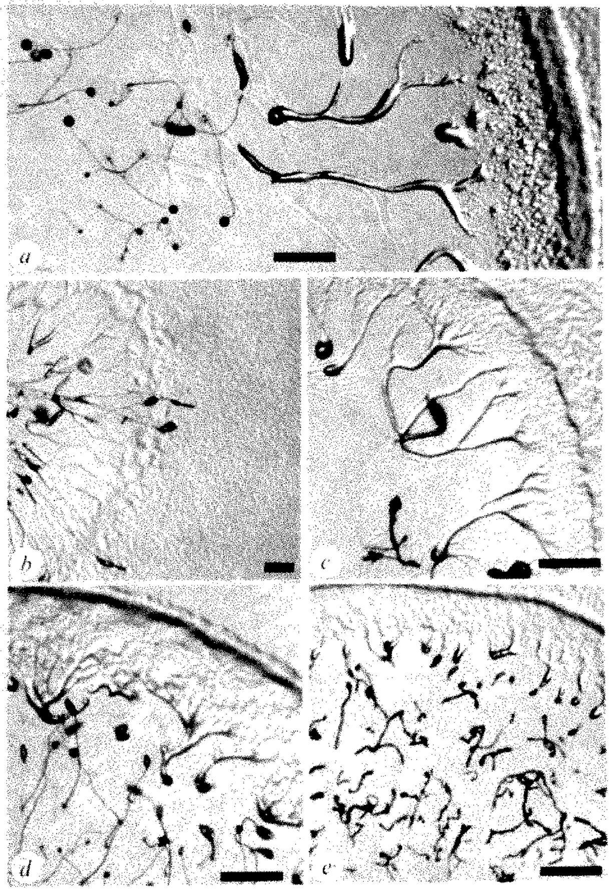

Fig. 2 Clonal morphology of DM-7 wild type and derivative strains (all bars represent 0.5 mm). The wild type stock and mutants were cultured with *E. coli* B/r on a buffered peptone–dextrose agar (designated PDB-2%)[8] at 21° C or 28° C. Mutagenesis procedures followed the method of Yanagisawa *et al.*[12], using nitrosoguanidine (Aldridge Chemical Co.). Surviving cells were initially regrown and screened on PDB with 5% replacing the 2% agar. The increased agar concentration restricts clonal spreading in the wild type (*A*) without affecting morphogenetic behaviour (screening efficiency 100+ clones per plate). *a*, DM-7 wild type. The clone boundary at right is the feeding front of amoebae on the bacterial lawn. Aggregation streams orient radially and are prominent, with complete fruiting bodies at the centre of the clone. *b*, The mutant clone *plaque* (*plq;* isolate 773–2). This mutant has a spreading feeding front on 5% PDB forming a 'halo' appearance around the clone, and prominent streaming, with complete though somewhat fragile fruiting bodies. *c*, Mutant *cactus* (*cac*; isolate 773–18). This mutant has a clone boundary and streaming like wild type, and complete fruiting bodies with excessively thickened stalks. *d*, Mutant *tiny aggregations* (*tag*; isolate 773–23). The clone boundary in this mutant is like wild type but aggregation size is much reduced in proportion to the clone size. Streams are radially polar and fruiting bodies are small, but complete. *e*, *cactus*, *tag*, a double mutant, which has reduced aggregation size characteristic of *tag* while stalk thickening indicates the cactus phenotype.

the two markers to produce wild type and double mutants in seven tetratype and non-parental ditype macrocysts conclusively establishes the existence of a dihybrid zygote stage (possible genotype: *plq*/+, *cac*/+). Second, significant numbers of progeny of each genotype were recovered from these macrocysts. Although the relative numbers are not always statistically equal, the suggestion is strong that there is no detrimental mitotic selection against any one of these genotypes during germination.

The mechanism of gene assortment, either meiotic or parasexual, is established from the data of Table 2. Of the 74 macrocysts germinated in the four crosses, 22 were classified as parental ditypes, non-parental ditypes or tetratypes. Each biparental macrocyst yielded a progeny genotype assortment in one of only the three normal kinds of tetrads, as expected for meiotic behaviour. Of particular interest are the ditypes; among 22 biparentals none germinated into the 'mixed ditype' outcomes which in parasexuality would be expected to be recovered with a higher frequency (ratio 2: 1, Fig. 1) than the total number of parental and non-parental ditypes (five germinated). The absence of mixed ditypes argues strongly that parasexual haploidisation is uncommon or not a part of the macrocyst cycle.

Table 2 Tetrad classification of individual macrocyst germinations in four crosses

Parental genotypes	Macrocyst tetrad classifications				Total no.
	PT	PD	NPD	TT	
(*plq*,+)×(+,*cac*)	7	2	1	6	16
(*plq*,+)×(+,*tag*)	12	0	0	5	17
(*cac*,+)×(+,*tag*)	11	1	0	4	16
(*cac*,*tag*)×wild type	22	0	1	2	25
Totals	52	3	2	17	74

Genotype and tetrad abbreviations are as in Table 1. The assignment of recombinant phenotypes was not difficult for any of the crosses. To prove the identification of the putative double mutant (*cac,tag*) it was back crossed to the wild type stock (line 4 above). Cactus and tag phentotypes were recovered in the single NPD and two tetratype macrocysts germinated. No unexpected progeny phenotypes were observed in any crosses, indicating that each mutant has a single lesion affecting its visible morphology.

An important question about the possible occurrence of multiple meioses is not totally resolved. The data in Table 2 are not consistent with the occurrence of independent karyogamies. In this case, few uniparental macrocysts should arise, and two kinds of expected tritypes ($aB+AB+ab$) and ($Ab+AB+ab$) were not found. Otherwise, mitoses of one original zygote before meiosis is still a possibility. This situation should never produce more than 50% ditypes from biparental macrocysts, whereas, a single meiotic event with no intrachromosomal crossing-over should yield 100% ditypes from the biparentals[8]. We are looking into this question, since any mutants which when crossed produce high frequencies of ditypes will also greatly facilitate the identification of linkage groups and mapping analyses.

We thank Professor D. Sheppard and A. Clark for valuable advice and critical reading of the manuscript, and Dr K. B. Raper for the DM-7 wild type strain. M. A. M. was the recipient of a UNIDEL foundation fellowship during this study. This investigation was supported by a grant from the National Institutes of Health.

'Isotope effect' in metabolism of radioactive cortisol in man

TRITIUM-labelled steroids have been widely used as tracers in the investigation of steroid metabolism, due to their high specific activity, low cost and low radiation dosage *in vivo*. The validity of any experiment using labelled steroids depends on the fact that the labelled and the endogenous materials are metabolised in a similar manner. In the case of the *in vivo* metabolism of the 1,2-^{3}H-labelled and endogenous cortisol in man, proof of this is lacking. The experiments of Cope and Pearson[1], and of Gold and Crigler[2] using mixtures of 1,2-^{3}H-cortisol and 4-^{14}C-cortisol suggested that these two different species of labelled cortisol were metabolised in a similar manner, and from this it was inferred that they could both be used as valid tracers for studying cortisol metabolism.

In the course of a study of the uptake and metabolism of cortisol by the human forearm[3], we made the preliminary observation that following the intra-arterial injection of a mixture of 1,2-^{3}H-cortisol and 4-^{14}C-cortisol into two healthy men, cortisol isolated from both arterial and venous plasma from one subject had a lower isotope ratio (^{3}H : ^{14}C) than the injected mixture. We have now injected intravenously a mixture of 1,2-^{3}H-cortisol and 4-^{14}C-cortisol into six healthy men and have produced substantial evidence of an istope effect.

The two radioactive steroids were stated by the supplier to be at least 96% pure. Dilution analysis immediately before use showed that they were both at least 95% pure. Blood samples were obtained 2 min after the injection and at 30 min intervals thereafter for 4 h. Urine collections were made at 2, 4, 8, 12 and 24 h after the injection. Unlabelled cortisol (100 μg) and unlabelled cortisone (100 μg) were added to each plasma sample ($n=48$); corticosteroids were extracted using dichlormethane and separated by paper chromatography using the system benzene–methanol–water (2:1:1). The cortisol and cortisone fractions were further purified by paper chromatography using iso-octane–*t*-butanol–water (10:5:9) and on a thin layer of silica gel using chloroform–methanol–acetic acid (90:5:5). The isotope ratios were measured on the TLC eluates.

The principal findings are summarised in Table 1. Regression analysis shows a significant relationship (at the 0.1% level) between plasma cortisol isotope ratio and time. There were no significant differences between the isotope ratios of cortisol and cortisone.

After hydrolysis of aliquots of urine with β-glucoronidase, the tetrahydro metabolites of cortisol were extracted with ethyl acetate and separated by paper chromatography (benzene–methanol–water; 2:1:1). The eluted metabolites were treated with sodium borohydride and sodium metaperiodate and the resulting 11-hydroxy-17-oxosteroids were chromatographed on paper using toluene–iso-octane–methanol–water (80:120:160:40), and their isotope ratios determined. No significant differences were found in the ^{3}H : ^{14}C ratio of 3α,11β-dihydroxy-5β-androstan-17-one (11-HE) derived from 3α,17α,21-trihydroxy-5β-pregnan-11, 20-dione (THE) or from 3α,11β,17α,21-tetrahydroxy-5β-pregnan-20-one (THF), and that of the purified starting material (10.25 ± 0.35). However, in all 30 urine samples, 3α,11β-dihydroxy-5α-androstan-17-one (11-HA) derived from 3α,11β,17α,21-tetrahydroxy-5α-pregnan-20-one (5α THF) had a lower isotope ratio ($8.93 \pm 0.23, P < 0.001$) than 11-HE derived from either THE or THF, or from the starting material.

Table 1 Isotope ratio of labelled cortisol before and after purification, and after recovery from plasma (mean ± s.d.)

	^{3}H : ^{14}C
Material injected (n = 20)	10.00 ± 0.25
Material injected after purification as for plasma (n = 13)	10.25 ± 0.35*
Plasma 2 min after injection (n = 6)	9.95 ± 0.33
Plasma 4 h after injection (n = 6)	8.95 ± 0.19*

* Significantly different at the 0.1% level.

As the maximum degree of radiochemical impurity in each of the injected steroids was 5%, even the most unfavourable combination of circumstances could only account for less than half of the observed difference in isotope ratio between THE and THF, and 5αTHF. In the case of the plasma cortisol data, the fact that neither chromatographic purification nor a short period (2 min) *in vivo* results in a change in isotope ratio suggests that radiochemical impurities cannot account for the changes in plasma cortisol isotope ratio observed over a period of 4 h.

Gold and Crigler[2], and others, have shown that, in contrast to 4-^{14}C-cortisol, 1,2-^{3}H-cortisol tends to separate from unlabelled cortisol in simple chromatographic systems, a phenomenon that we also have encountered in the present study. These physiochemical findings support the view that the behaviour of 4-^{14}C-cortisol more closely resembles unlabelled cortisol than does the tritium-labelled form. The differences we have observed in the *in vivo* metabolism of the two labelled species may therefore indicate that there are similar differences between the metabolism of unlabelled cortisol and its 1,2-^{3}H-derivative.

While these findings do not necessarily invalidate the use of 1,2-^{3}H-cortisol for tracer studies there may be circumstances where knowledge of this effect could significantly influence the interpretation of results.

The role of calcium ions in initiating transformation of lymphocytes

TRANSFORMATION of lymphocytes by antigens and by nonspecific mitogens (lectins and anti-immunoglobulin sera) is a consequence of the binding of the mitogen to specific receptors on the cell surface[1–3]. The receptors rapidly form clusters ('patches') which may aggregate into polar 'caps'[4] at higher mitogen concentration. These events initiate a series of biochemical changes—enhanced uptake of ions and metabolites[1], increased cyclic GMP[5], and increased metabolism of phosphatidyl inositol and other phospholipids (ref. 6 and V. C. M., M. J. Hayman and M. J. C., unpublished)—which culminate in DNA synthesis and mitosis 48–72 h later. Although the sequence, relative importance and control of these events is not yet defined, there is evidence for a primary role for Ca^{2+}. *Phaseolus vulgaris* phytohaemagglutinin (PHA) initiates a slow accumulation of Ca^{2+} by lymphocytes[7,8] and its stimulation of DNA synthesis is inhibited by citrate[9], EDTA (ref. 9) or EGTA (ref. 10). The inhibition is reversed by Ca^{2+}. It has also been shown that inhibition by the low concentrations (1.4 mM) of EGTA used did not prevent binding of PHA (ref. 11). Although these results showed Ca^{2+} to be an important factor in initiation of transformation it was not clear whether influx of Ca^{2+} was the only or even the main consequence of the binding of PHA.

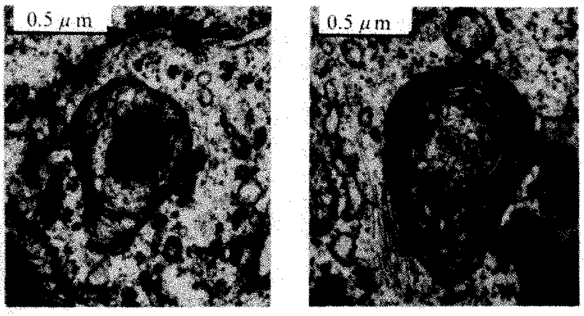

Fig. 1 Mitochondria from pig lymphocytes after 45 h in the presence of the ionophore A 23187 (0.8 μg ml^{-1}). Experimental details of the treatment are given under Fig. 2. In many cells up to one-third of the mitochondria showed dense granules, hypertrophied cristae or both. In dead cells the proportion of these forms was much higher.

Here we show that the Streptomyces antibiotic, A 23187, an ionophore specific for divalent cations[12], initiates a similar series of events to those caused by PHA. The ionophore is a monobasic carboxylic acid (molecular weight 531) two molecules of which form a lipid soluble complex with the cation and enable it to diffuse readily across biological membranes. Its structure has recently been determined[13]. We have studied its effect at micromolar concentration on the morphology of pig lymphocytes and on the incorporation of [6-^{3}H]-thymidine into DNA.

Pig lymphocytes were obtained from mesenteric lymph node as previously described[14]; about 15% of the cells were stained by a fluorescein-conjugated rabbit antiserum to pig immunoglobulin and on the basis of this criterion were judged to be B lymphocytes. Preliminary experiments showed a marked response to low concentrations of A 23187 (0.8 μg ml^{-1} per 10^6 cells). After 45 h culture the cells were indistinguishable under the light microscope from cells incubated with PHA and were agglutinated to a similar extent. Examination of electron micrographs revealed that 80–90% of the cells were enlarged (> 8 μm in diameter) and showed many of the features characteristic of PHA-transformed lymphocytes[15]. Thus, the cytoplasm was enlarged and showed marked endocytotic activity, the plasma membrane showed large pseudopodium-like extensions, there were many polysomes and an increased number of mitochondria. The main differences from PHA-treated cells were a lesser development of the rough endoplasmic reticulum and marked abnormalities of the mitochondria (Fig. 1) including large dense granules and hypertrophied cristae. In contrast with these enlarged cells, about 10% of the ionophore-treated cells appeared in all respects to resemble normal unstimulated lymphocytes and the possibility that A 23187 fails to activate a subpopulation of lymphocytes cannot be ruled out at present.

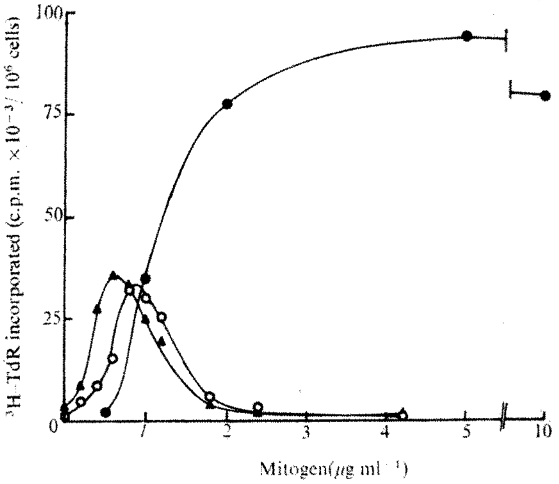

Fig. 2 Incorporation of ^{3}H-thymidine by pig lymphocytes as a function of concentration of A 23187 (○) or of PHA (●). The effect of sub-threshold amounts of PHA (0.3 μg, Wellcome Reagents Ltd) on the response to A 23187 is also shown (▲). The assays were performed as described previously[14], using cells (10^6) from pig mesenteric lymph node in 1 ml of Eagle's medium (containing 1.8 mM $CaCl_2$, 1 mM $MgCl_2$) supplemented with 20% (v/v) foetal calf serum. A 23187 was dissolved in ethanol (1.5 mg ml^{-1}) and diluted with 0.5 volumes of 10 mM Tris HCl buffer, *p*H 7.4; solutions were stored at 2° C in the absence of light and were used up to 4 weeks after preparation. Cultures were incubated at 37° C in an atmosphere of air containing 5% (v/v) CO_2 for 45 h before the addition of ^{3}H-thymidine (1 μCi) and for a further 5 h before recovery of the DNA. The reported values represent the means of duplicate estimations. The PHA curve was obtained with a different batch of cells from that used for the other two curves. The cells used for the A 23187 gave an incorporation of 140,000 c.p.m. with 2 μg PHA (see Fig. 5).

To obtain a quantitative measure of the stimulus, we followed the uptake of ^{3}H-thymidine into DNA after exposure to A 23187 for 45 h. The response to increasing amounts of ionophore is compared with that to PHA in Fig 2. Both PHA and A 23187 gave a sharp increase in thymidine uptake when their concentrations exceeded a certain critical threshold value and maximal incorporations of thymidine were induced by 0.8–1.0 μg of A 23187 and 2–4 μg of PHA. The response to PHA fell relatively slowly at higher concentrations whereas that to A 23187 declined sharply when the optimal concentration was exceeded. The absolute amounts of radioactivity varied considerably from one batch of cells to another but the maximal stimulation by the ionophore was usually about one-third to one-quarter of that caused by PHA. In view of this morphological evidence in support of transformation, it seems likely that the lower thymidine incorporation induced by A 23187

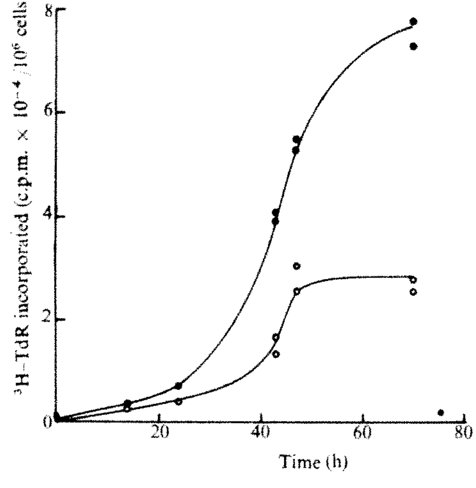

Fig. 3 Time course of ^{3}H-thymidine incorporation by pig lymphocytes in the presence of A 23187 (○) and PHA (●). Assays were performed as previously described using amounts of A 23187 (0.8 μg ml^{-1}) and PHA (2 μg ml^{-1}) giving maximal stimulation. ^{3}H-thymidine was incubated with cultures for a period of 4 h before the cultures were removed and the DNA was recovered.

relative to PHA does not represent a lower proportion of activated cells but is due to the perturbation of the metabolism of the cell by the penetration of the ionophore to the mitochondria.

We have not yet checked whether all the biochemical effects of PHA are duplicated by A 23187, but the parallelism of the morphological responses suggests a similar biochemical basis. Furthermore, the experiment shown in Fig. 3 demonstrates that thymidine uptake follows a similar time course with the two different stimuli.

If both mitogens act by facilitating entry of Ca^{2+} then it should be possible to obtain a response by combining subthreshold amounts of each. The curve (▲) in Fig. 2 shows this effect when the response to A 23187 was measured in the presence of 0.3 μg ml^{-1} PHA, which by itself had little effect (^3H-TdR incorporated: 3,600 c.p.m. 10^6 cells). This result also suggests that largely overlapping populations of cells were involved in the response to both agents. The converse experiment showing PHA response in the presence of A 23187 was complicated by inhibitory effects of the ionophore which will be considered later.

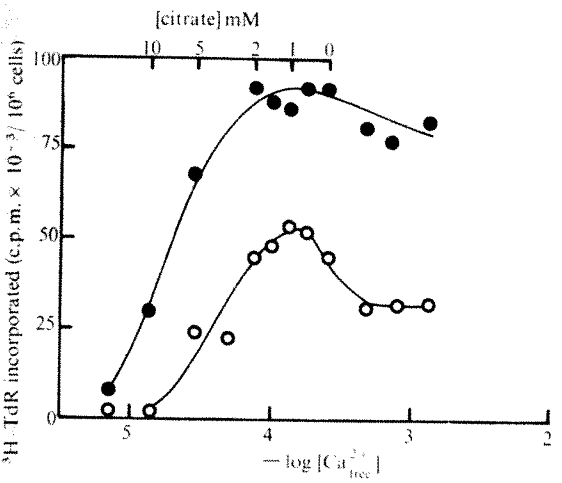

Fig. 4 Effect of concentration of Ca^{2+} on response of lymphocytes to PHA (●) or A 23187 (○). The experiments were carried out in foetal calf serum ($[Ca^{2+}]=3.2$ mM, measured spectrophotometrically using murexide[16]) diluted to 1:10 with Ca^{2+} free Eagle's medium. Ca^{2+} concentration was controlled by addition of Ca^{2+} or sodium citrate. In those samples in which extra Ca^{2+} was added it was assumed that 60% was free, the remainder being bound to PO_4 (1 mM, $K=1.8$ mM) or serum albumin (0.2 mM in Ca^{2+} binding sites, $K=1$ mM[17]). In those samples in which Ca^{2+} was complexed by citrate the concentration of bound divalent cation (x) was calculated from the total $[Ca^{2+}+Mg^{2+}]$ (M) and the concentration of citrate (C) and the dissociation constant $K=$ 0.5 mM, which is almost the same for both ions[18]. $2x=(M+K+C)-[(M+K+C)^2-4MC]^{1/2}$. The fraction of free $Ca^{2+}=(1-(x/M))$.

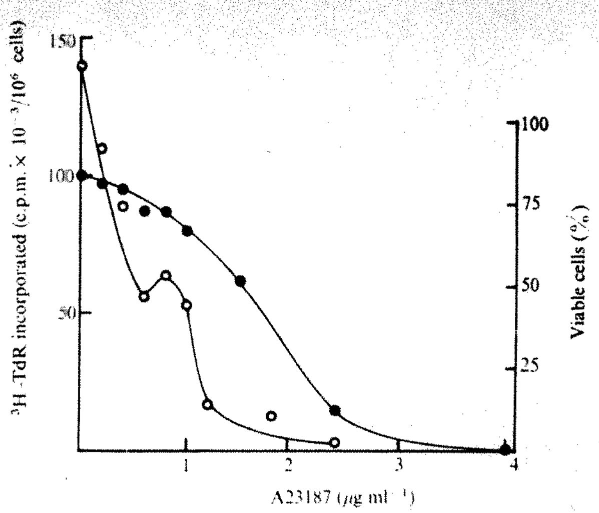

Fig. 5 Effect of A 23187 on incorporation of ^3H-thymidine into pig lymphocytes stimulated by 2 μg PHA per 10^6 cells (○) and the viability of the cells (●). The experimental procedure is given under Fig. 1. PHA and A 23187 were both added at the beginning of the experiment. The viability after 45 h of incubation with A 23187 was measured as the percentage of cells which excluded trypan blue.

The critical role of Ca^{2+} in both responses was confirmed by lowering its concentration in the medium (Fig. 4). First, a basic Ca^{2+} free medium was supplemented with 10% (v/v) of foetal calf serum, instead of the usual level of 20%, to give a Ca^{2+} concentration of 0.3 mM. This lowering of Ca^{2+} barely affected the response to PHA but it significantly enhanced the response to the ionophore. Further lowering of Ca^{2+} was effected by addition of sodium citrate at concentrations between 1 mM and 10 mM. The results in Fig. 4 show that there was a sharp drop in response to A 23187 when $[Ca^{2+}]$ fell below 10^{-4} M, close to the dissociation constant of the complex between Ca^{2+} and A 23187[19]. The response to PHA fell when a slightly lower Ca^{2+} concentration was reached (half maximal response at 2×10^{-5} M) in good agreement with the results of Alford[9] and of Whitney and Sutherland[10]. We conclude that A 23187, like PHA, requires Ca^{2+} in the external medium in order to be effective. Addition of a 1 mM excess of Ca^{2+} over citrate (5 mM and 10 mM) restored the response both to PHA and to A 23187 to the level of the controls.

The inhibitory effects of A 23187 on the response to PHA are shown in Fig. 5, together with a curve showing the decrease in viability of the cells. Although the two curves show a rough correspondence it is clear that there is initially a marked inhibition without significant loss of viability and that later, above the normal threshold for stimulus by A 23187, an activating effect is superimposed on the declining incorporation of thymidine. It is not easy to explain this activation if a single population of cells, already fully stimulated by the PHA, is involved, unless A 23187 has some effect in addition to facilitating the influx of Ca^{2+}. Another explanation is that A 23187 can stimulate a subpopulation of lymphocytes which are not affected by the PHA. This would be consistent with the high proportion of cells which enlarge under the influence of the ionophore. Experiments to distinguish between these possibilities are in progress.

It is likely that much of the toxic effect of the ionophore can be explained in terms of its effects on the mitochondria, the morphology of which is grossly disturbed. It is well known that mitochondria have a large capacity for taking up Ca^{2+}, especially in the presence of phosphate and other permeant anions[20] and it is also known that A 23187 stimulates this uptake and diverts the energy from both respiration and from exogenous ATP into Ca^{2+} transport[16]. As inhibitors of glycolysis and of respiration are known to block transformation[21] it is not surprising that A 23187 is also inhibitory. Mouse and rat spleen cells were more sensitive than pig lymphocytes to the toxic effects of the ionophore, only 20% surviving after 40 h at 0.8 μg ml^{-1}, and we have been unable to produce significant stimulation of thymidine uptake by these cells.

Except for its inhibitory effects, A 23187 produces a very similar response in pig lymphocytes to that produced by PHA. In addition to the results described above we have preliminary evidence which shows a stimulus of phosphatidyl inositol turnover and an inhibition of PHA stimulated phosphatidyl inositol turnover by citrate. If the effect of the ionophore is limited to its facilitation of divalent cation movements then those of PHA can be similarly explained We therefore suggest that lymphocyte transformation is the result of a direct effect of the mitogen on the permeability of the plasma membrane to Ca^{2+}

Two interesting questions follow First, how does PHA increase permeability to Ca^{2+} and, second, what are the further effects of Ca^{2+} inside the cell?

The most striking common feature of the action of a variety of mitogens on lymphocytes is the requirement for multivalency[1 3] This generalisation also applies to the release of histamine from mast cells by antibodies to IgE, a response which can also be induced by A 23187 in the presence of Ca^{2+} (ref 22) If the receptor proteins bridge the lipid regions of the membrane then it is plausible to suggest that clusters of receptors might contain polar channels permitting the passage of Ca^{2+} and possibly of other ions into the cell This may be but one example of a general mechanism for transmitting signals across a membrane following the interaction between a specific receptor and the appropriate stimulus

Many intracellular processes are controlled by the concentration of Ca^{2+} (ref 23), at least three of these are involved before DNA synthesis in stimulated lymphocytes Activation of phosphorylase kinase[24] is required for the initiation of glycolysis[21], the microfilament–microtubule system is required for endocytosis[25] and its inactivation blocks transformation[26], lastly and most significantly, the level of cyclic GMP in some cells has been shown to be controlled by Ca^{+2} (ref 27) and its concentration in lymphocytes rises immediately in response to PHA (ref 5) The further effects of cyclic GMP are not yet defined but in other tissues it has been implicated in several hormonal responses[28] and it is clearly an important intermediary

Actions and interactions of colchicine and cytochalasin B on contraction of granulation tissue and on mitosis

It has been shown by Majno *et al*[1] that a strip of growing granulation tissue (GT) cut from the wall of a 2- to 4-week-old granuloma pouch[2] or from the base of an open wound in the rat, contracts *in vitro* in response to 10^{7}–10^{6} concentrations of 5-hydroxytryptamine, angiotensin and other agonists An association between this pharmacological reactivity of GT and the phenomenon of wound contraction has been proposed[1] on the bases that the forces which cause a wound to contract are cellular in origin and generated by GT cells[3,4], and that fibroblasts proliferating *in vitro* and *in vivo* develop a muscle-like cytoarchitecture characterised by an increase in the number of microfilaments[5] Also fibroblasts in culture contain abundant microtubules[6] which can be rapidly destroyed by poisons such as colchicine[6–8] that prevent polymerisation of the tubular protein For example colchicine can prevent microtubules comprising the mitotic spindle from forming and thereby inhibit karyokinesis (separation of chromosomes)[9] The drug seems not to affect the functions of microfilaments, on which various types of contractile activity, including cytokinesis, depend[10], the microfilaments are specifically inhibited by the drug cytochalasin B (ref 11)

We performed a series of experiments using the technique of Majno *et al*[1], primarily to determine the time of onset of contractility of GT after wounding and the effects of X irradiation on contractility We found that when colchicine or other spindle poisons (vincristine, vinblastine or podophyllotoxin) were added to GT in the bath in 10^{-7}–10^{-6} final concentrations, there slowly developed a marked contraction of the tissue, which was shortened by as much as 30–40% of its initial length (Fig 1*a*) Contraction induced by colchicine was dependent on the presence of oxygen and was inhibited by 10^{-4}–10^{-5} 2, 4-dinitrophenol (DNP) (Fig 1*b*) Contraction of GT induced by colchicine and related drugs was also reduced by 10^{-5} KCN and by 10^{-4} papaverine After contraction of GT had been induced by colchicine, the tissue failed to relax after five or more successive washes with fresh Tyrode solution, which did not free the tissue of the drug ATP caused GT to contract and DNP caused relaxation Colchicine failed to cause contraction of GT in the presence of DNP, when the tissue was washed, DNP but not colchicine was removed and the tissue recontracted at the same rate as before the addition of DNP (Fig 1*b*) It was more difficult to reverse the action of papaverine on contraction caused by colchicine by washing in this way

When 10^{-7}–10^{-6} cytochalasin B (dissolved in DMSO[11]) was added to GT, the tissue relaxed slightly, subsequent washing restored the initial base line and the preparation then contracted in the usual way on addition of colchicine When 10^{-6} cytochalasin B was added to the bath, followed (without washing) by 10^{-6} colchicine, the tissue failed to contract, until it was washed with fresh Tyrode solution, this removed cytochalasin B as it removed DNP, and allowed contraction to occur When cytochalasin B was added after contraction had been induced by colchicine, the tissue relaxed completely (Fig 1*d*), further washing caused contraction to re-occur, at the same rate as prior to the addition of cytochalasin B in the same way as shown for DNP (Fig 1*b*)

This reactivity of GT to spindle poisons, metabolically dependent on the presence of oxygen and on oxygen-coupled phosphorylation, and antagonised by cytochalasin B, was shown by strips of GT cut from 7–35-d-old pouches in the rat We have been unable to demonstrate any pharmacodynamic activities of strips of uninjured subcutaneous connective tissue removed from rats by adding colchicine, cytochalasin B, 5-hydroxytryptamine, angiotensin, histamine or other agonists But colchicine caused oxygen-dependent contractions, also inhibited by DNP and cytochalasin B, of rat stomach fundus and of rat and guinea pig ileum, similar to GT

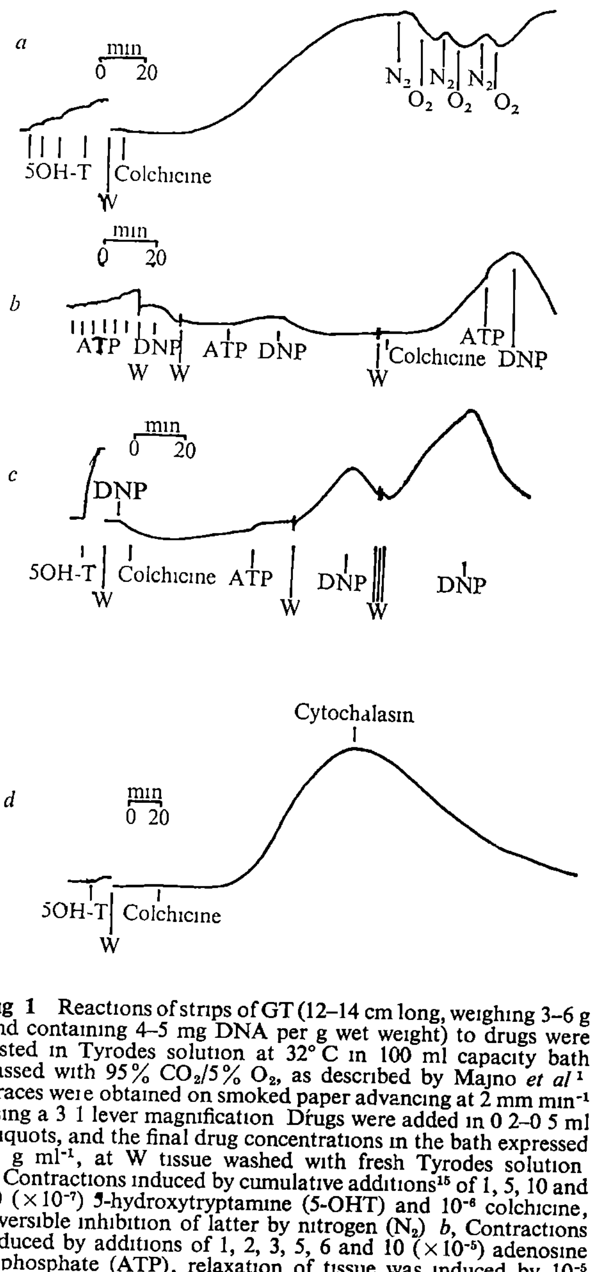

Fig 1 Reactions of strips of GT (12–14 cm long, weighing 3–6 g and containing 4–5 mg DNA per g wet weight) to drugs were tested in Tyrodes solution at 32° C in 100 ml capacity bath gassed with 95% CO_2/5% O_2, as described by Majno *et al*[1] Traces were obtained on smoked paper advancing at 2 mm min^{-1} using a 3 1 lever magnification Drugs were added in 0 2–0 5 ml aliquots, and the final drug concentrations in the bath expressed as g ml^{-1}, at W tissue washed with fresh Tyrodes solution *a*, Contractions induced by cumulative additions[15] of 1, 5, 10 and 50 ($\times 10^{-7}$) 5-hydroxytryptamine (5-OHT) and 10^{-6} colchicine, reversible inhibition of latter by nitrogen (N_2) *b*, Contractions induced by additions of 1, 2, 3, 5, 6 and 10 ($\times 10^{-5}$) adenosine triphosphate (ATP), relaxation of tissue was induced by 10^{-5} 2,4-dinitrophenol (DNP) which also inhibited the contraction due to 10^{-6} colchicine *c*, Shows GT failed to contract to 10^{-6} colchicine in the presence of 10^{-5} DNP until the tissue was washed with fresh medium which removed DNP and caused recontraction due to colchicine *d*, Contractions induced by 10^{-6} colchicine inhibited by 10^{-5} cytochalasin B (DMSO used as solvent for cytochalasin B had no effect on contraction of GT)

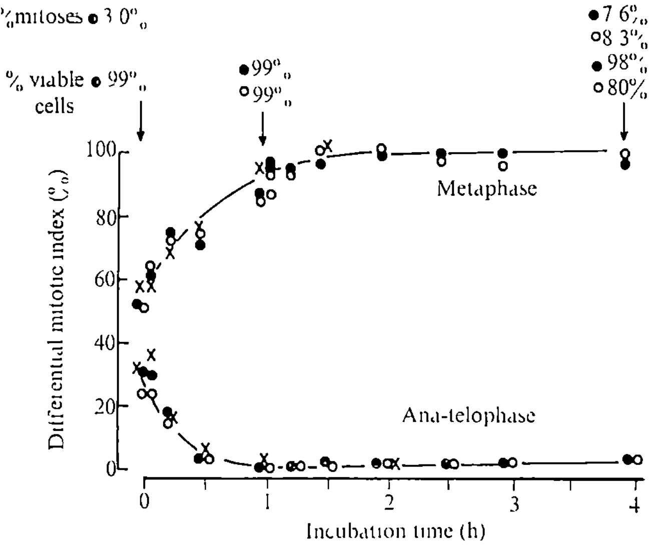

Fig 2 Metaphase arrest induced by 10^{-6} colchicine in freshly collected W-256 cells (~ 10^6 cells ml^{-1}) incubated at 36° C in medium 199 plus 10% horse serum and gassed with 95% O_2/5% CO_2 (●) or N_2 containing < 3 p p m O_2 (○) The presence of 10^{-5} cytochalasin B failed to influence metaphase arrest induced by 10^{-5} colchicine under aerobic conditions (×) Percentage viable cells determined using nigrosin exclusion technique, total mitotic counts based on all mitotic stages present in 500–1,000 cells per sample, differential mitotic counts based on 100 metaphases counted in each aliquot removed after 0–4 h incubation time

We measured the effect of colchicine and cytochalasin B under aerobic and anaerobic conditions on mitotic division of W-256 rat tumour cells cultured *in vitro*, which had been collected from ascites fluid when the tumour was at an exponential phase of growth Differential mitotic counts were made on cell aliquots removed from the cultures at intervals after the drug(s) had been added Two telophase stages were scored cytoplasmic cleavage absent (1), and present (2) to establish cytokinesis During incubation, the cells were bubbled with either 95% O_2/5% CO_2 or with pure N_2 (containing <3 p p m O_2) Colchicine caused metaphase arrest irrespective of the presence or absence of oxygen or cytochalasin B (Fig 2, Table 1) But 10^{-5}–10^{-4} DNP, greatly reduced the effect of colchicine on cell division Cytochalasin B inhibited cytokinesis Neither the absence of oxygen nor the presence of papaverine affected karyokinesis and cytokinesis significantly, but cytochalasin B was significantly less effective in preventing cytokinesis when oxygen was absent or DNP present (Table 1)

Assuming that colchicine and cytochalasin B act specifically on microtubules and microfilaments respectively, the results obtained indicate that both organelles participate in the maintenance of 'tone' of the contractile cells which develop in GT and are present in stomach and ileum It is suggested that in cell contraction a microtubular apparatus functions primarily by regulating the tone of the contractile component (microfilaments), that the destruction of microtubules by colchicine releases the microfilaments from the control exercised by the microtubules and indirectly causes contracture to develop, provided oxygen is present and coupled to phosphorylation, and that cytochalasin B inhibits contracture by a specific direct action on microfilaments

The intracellular movements which take place during mitosis are attributed to successive changes occurring in microtubules (karyokinesis) followed by microfilaments (cytokinesis) The results obtained indicate that neither karyokinesis

Table 1 Differential counts of mitoses in W-256 cells incubated for 100 min in presence of colchicine and other compounds under aerobic or anaerobic conditions

Freshly collected W-256 cells in log growth phase were incubated in medium 199 (plus 10% horse serum) at 36° C. Approximately 10^6 cells were added per ml of medium which had been prewarmed and gassed for 20 min with 95% O_2/5% CO_2 or N_2 before and after addition of the various compounds followed by cells. After incubation, the cells were fixed by adding an excess of methanol–acetic acid (3:1 v/v) and were then stained with acetic orcein. Differential mitotic counts are based on 100 metaphases counted in each preparation.

*Abbreviations: P, prometaphase, M, metaphase, A, anaphase, T, telophase (cytoplasmic cleavage absent (1) or present (2)).

†Based on χ^2 test for T(2)/(A + T1 + T2) in *a* and *c* and for (A + T1 + T2) in *b*.

nor inhibition of spindle synthesis by colchicine require the presence of significant concentrations of oxygen, the considerable energy required for mitosis seems to be supplied from reservoirs built up progressively during the whole cell cycle[12]. It has been found that a slight increase in oxygen consumption occurs at cytoplasmic cleavage of sea urchin eggs[12,13]. We found that anoxia maintained for 100 min caused a 12% decrease in the proportion of type 2 telophase in W-256 cells but this decrease was not statistically significant. DNP caused no significant delays in the progression of the cells through mitosis, but inhibited the actions of colchicine on karyokinesis and of cytochalasin B on cytokinesis. This suggests that uncoupling of phosphorylation by DNP affects active transport of colchicine or possibly its binding to the target protein (microtubule) of the dividing cell. This binding is, however, reversible and does not involve a chemical modification of colchicine[7], it also possibly affects transport and binding of cytochalasin to the contractile microfilaments. Ultrastructural studies have provided some evidence that microtubule subunits may aggregate to form 100 Å filaments[14].

A comparison of the effects of colchicine, cytochalasin, DNP and oxygen on cell division and on contraction of GT shows that these two cellular activities react similarly. Our findings suggest that microtubules are closely integrated with microfilaments in regulating both these processes. The termation of mitosis in telophase may reflect a loss of control of the tubular component over the microfilaments which causes a spontaneous contracture of the latter and results in cell cleavage, in the same way that inactivation of the corresponding tubular component (by colchicine) in the contractile cell produced contracture. Contracture induced by colchicine, and other spindle poisons, was all-or-none in character, it was not possible to regulate the degree of tissue shortening by altering the drug concentration. This is the type of response which would be caused by a drug which destroys the mechanism on which it acts. Cell cleavage appears to be a phenomenon with similar all-or-none characteristics.

Reversibility of morphine tolerance and dependence in guinea pig brain and myenteric plexus

WHEN guinea pigs are exposed continuously to high morphine concentrations, tolerance and physical dependence develop within a few days in both the central nervous system (CNS) and the myenteric plexus. In the plexus morphine tolerance is associated with subsensitivity to the inhibitory catecholamines and supersensitivity to the excitatory neurotransmitter serotonin (5-hydroxytryptamine, 5-HT)[1,2]. We have investigated the following questions about these phenomena. (*a*) After opiate withdrawal in animals made tolerant and dependent, would the altered sensitivities to neurotransmitters in the plexus return to normal? (*b*) If so, would loss of tolerance to morphine in the plexus proceed in parallel with loss of subsensitivity to catecholamines and loss of supersensitivity to 5-HT? (*c*) Would such reversion to normal in the plexus be concurrent with disappearance of CNS indications of tolerance and dependence?

Male guinea pigs (400–450 g) were rendered tolerant and dependent in 3 d by implanting four morphine pellets (75 mg morphine base each) subcutaneously[3] The pellet residues were removed on the third day after implantation and the animals were maintained for 7 d thereafter Implantation and removal were carried out under light ether anaesthesia

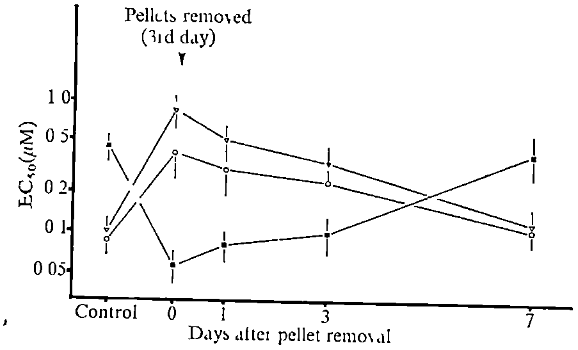

Fig. 1 Changes in sensitivity to morphine (▽), adrenaline (○), and 5-HT (■) of the longitudinal muscle-myenteric plexus preparation of guinea pigs the third day after implantation with four morphine pellets (75 mg morphine base each) and after abrupt withdrawal by pellet removal (third day after implantation) The mean effective dose (EC_{50})± s e m of each drug is plotted against time on a logarithmic scale Each point is based on four to five animals (eight to ten strips)

The longitudinal muscle strip with attached myenteric plexus from the ileum was prepared according to Rang[4] and mounted in a 5-ml tissue bath as described previously[1] The bath contained Krebs bicarbonate Ringer solution (37° C) and was bubbled with 95% O_2/5% CO_2 Electrical field stimulation for maximal twitch tension was applied at 80 V, 0 1 Hz and 0 5 ms pulse duration by means of a Grass S4E stimulator Strips were equilibrated for 1 h with electrical stimulation and washed at intervals of 5–10 min A force displacement transducer (Grass FT 0 03C) connected to a Grass 7B polygraph recorded the isometric twitches (2–4 g tension) Resting tension was adjusted to 1 g

Longitudinal muscle strips of untreated animals were prepared after overnight starvation Morphine-treated animals were killed, and strips were obtained on the third day after pellet implantation, and on the first, third and seventh day after pellet removal When morphine or catecholamines were tested, electrical stimulation was applied continuously The drug was washed out after a maximal effect was established Excitatory compounds, like acetylcholine and 5-HT, were added to the bath 10 s after stopping electrical stimulation Drugs were added to the bath at intervals of 10–45 min The concentration required for morphine or catecholamines to inhibit electrically induced twitches by 50% is called EC_{50} The same term is used for induction of 50% of the preceding electrically stimulated tension by acetylcholine or 5-HT

Tolerance in guinea pigs was measured by the effect of intravenously injected morphine sulphate (50 mg free base ml^{-1}) on the body temperature In controls, 30 min after intravenous injection of 10 mg kg^{-1} morphine, a maximal degree of hypothermia was observed, using a thermistor probe inserted 5 cm into the rectum for 2 min Physical dependence was tested by precipitation of jumping behaviour on intraperitoneal injection of naloxone hydrochloride (50 mg ml^{-1}), as previously described for guinea pigs[1] Each animal was tested only once

Figure 1 summarises the responses to morphine, adrenaline, and 5-HT of longitudinal muscle–myenteric plexus preparations isolated from guinea pigs during and after exposure to morphine After removal of the pellets, tolerance to morphine was gradually lost, as indicated by the decrease of the effective concentration (EC_{50}) required for 50% inhibition of electrically induced twitches Within 7 d the tissue had recovered normal sensitivity to the opiate (EC_{50}=100 nM)

A similar time course of recovery was found for adrenaline, with virtually normal sensitivity restored by the seventh day after pellet removal

Sensitivity to the excitatory effect of 5-HT followed a very similar but inverse course Supersensitivity reached about eight-fold (EC_{50}=55 nM) compared with the non-tolerant preparations (EC_{50}=420 nM) The first day after pellet removal the strips were still six times more sensitive to 5-HT than controls, and even on the third day some supersensitivity persisted (EC_{50}=100 nM) As described for the other drugs, normal sensitivity was established by the seventh day (EC_{50}=400 nM)

The dose-response curve for dopamine inhibition in morphine tolerant strips was very flat, with only 20% inhibition at 100 μM (Fig 2) The same results were obtained the first day after pellet removal, and even after 3 d, 100 μM dopamine only depressed the twitch tension 40% Nevertheless, normal sensitivity had returned within 7 d (EC_{50}=10 μM)

The drugs used in the above experiments produce a common effect, they influence the output of acetylcholine induced by electrical stimulation or by 5-HT Since acetylcholine added to the bath stimulates the longitudinal muscle directly[5], the response to this neurotransmitter may indicate whether or not chronic exposure to morphine affects the sensitivity of the muscle We noticed no change in sensitivity to the excitatory effect of acetylcholine in strips prepared before or after pellet removal as compared with controls (EC_{50}=0 4 nM) Furthermore, no change in twitch tension induced by maximal electrical stimulation was seen at any time in these experiments

To determine tolerance in the CNS, the hypothermic action of morphine was measured 30 min after intravenous injection A dose of 10 mg kg^{-1} caused a fall of rectal temperature of 0 8° C in controls (Table 1) The same dose,

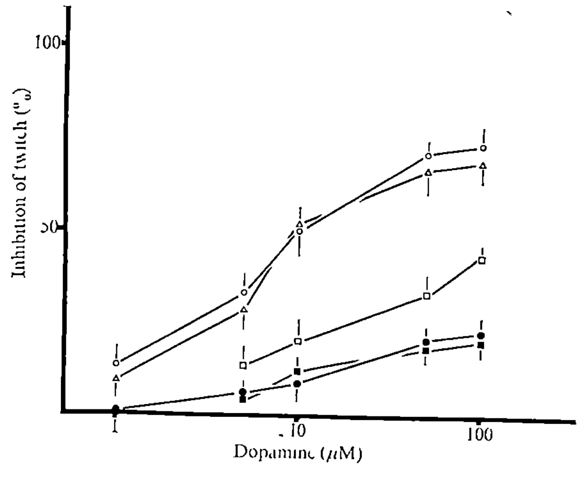

Fig 2 Dose-response curves for dopamine inhibition of the electrically stimulated muscle twitch Control (○) strips, preparations from guinea pigs 3 d after pellet implantation (■), and the first (●), third (□), and seventh (△) day after pellet removal Each point represents the mean depression (±s e m) of the electrically stimulated twitch (N=4–5) For further explanation, see Fig 1

3 d after pellet implantation, depressed the temperature by only 0.3° C. After pellet removal, there was no change in the degree of tolerance after 1 d, partial recovery by the third day and complete recovery by the seventh day.

Physical dependence disappeared at approximately the same rate as tolerance to hypothermic effects. As Table 1 shows, after pellet removal naloxone became gradually less effective in precipitating withdrawal jumping; and after 7 d, no jumping at all was observed, even with doses up to 128 mg kg^{-1}.

The results reported here demonstrate that pharmacological alterations observed during morphine tolerance and dependence in the guinea pig myenteric plexus as well as in the CNS are completely reversible. Within 7 d following abrupt withdrawal, sensitivities to morphine, naloxone, adrenaline, dopamine and 5-HT returned to normal. Thus, these findings support the view that opiate tolerance and dependence can disappear rapidly and completely[6-10]. By the methods used here we were unable to observe any persistence of tolerance or dependence[11-14], or of the associated abnormal sensitivities to neurotransmitters.

Table 1 Effect of morphine pellet implantation and removal on tolerance and physical dependence in guinea pigs

	Temperature fall*			Naloxone ED_{50}‡
		N	*P*†	(mg kg^{-1} ± s.e.m.)
Control	−0.80 ± 0.14	5	—	> 100¶
Third day after pellet implantation	−0.30 ± 0.05	6	< 0.01	2.4 ± 0.9
First day after pellet removal§	−0.32 ± 0.13	6	< 0.01	3.2 ± 1.2
Third day after pellet removal	−0.48 ± 0.07	5	< 0.01	41.0 ± 3.7
Seventh day after pellet removal	−0.89 ± 0.14	5	N.S.	> 128¶

Data show the effect of morphine (10 mg kg^{-1} intravenous) on the rectal temperature and the ED_{50} of naloxone hydrochloride (intraperitoneal) required to precipitate withdrawal jumping.

*Mean °C ± s.e.m., measured at room temperature 20°C.

†Two-tailed *t* test for difference from control.

‡The median effective dose (ED_{50}) ± s.e.m. consists of three to four independently calculated ED_{50} values according to Dixon[18]. Each independent ED_{50} is based on three to four animals.

§Pellet removal on third day after implantation.

¶This dose did not evoke jumping.

Our data show that the time course of recovery after morphine withdrawal is very similar in the myenteric plexus and CNS. This parallelism supports the likelihood of a common underlying mechanism in both nervous tissues. Furthermore, the results obtained in the plexus are in accord with our earlier findings that morphine tolerance is accompanied by supersensitivity to the excitatory neurotransmitter 5-HT[1,2], as first hypothesised by Collier[15]. As discussed[16], this supersensitivity could be a sufficient condition for both opiate tolerance and dependence. The supersensitivity is seen as an adaptive response to chronic inhibition by morphine of nerve pathways containing at least one serotoninergic synapse. Then more morphine would be required to inhibit (that is, tolerance), and a certain amount of morphine would be required to normalise the supersensitive synapses (that is, dependence). When exposure to morphine ends and the ambient morphine concentration declines, the disinhibition of these synapses could account for the abstinence syndrome. In support of the hypothesis is the finding that cyproheptadine, a specific 5-HT receptor blocker in the CNS, abolishes most withdrawal phenomena[17]. The time course of the loss of supersensitivity to 5-HT after morphine withdrawal, which corresponds to the rate of disappearance of tolerance and dependence in the CNS, may reflect the turnover rate of 5-HT receptors.

This investigation was supported by a research grant from the National Institute on Drug Abuse.

Isolation of photoreceptor and conventional nerve terminals by subcellular fractionation of rabbit retina

LITTLE is known of retinal transmitter substances although acetylcholine, dopamine, 5-HT, γ-aminobutyric acid (GABA), glutamate, and aspartate have all been put forward as candidates for such a role[1-9]. In other areas of the central nervous system (CNS), the preparation of isolated nerve-ending particles (synaptosomes) has been extremely valuable in studying central transmitter substances[10-13]. As far as we are aware, however, subcellular fractionation procedures have not previously been applied to the study of retinal transmitter substances.

Here we have subjected the rabbit retina to homogenisation and subcellular fractionation[12,14] and have found that these procedures produce synaptosomes, not only from the conventional type of retinal nerve ending, but also from easily identifiable pinched-off photoreceptor terminals. We have also studied the subcellular distribution in the retina of some endogenous amino acids and of some marker enzymes, particularly those concerned with GABA metabolism. The distribution of exogenously accumulated ^{14}C-GABA and ^{3}H-dopamine was also examined[15]. The results of these experiments support the suggestion that aspartate may be a photoreceptor transmitter and that GABA and dopamine may be transmitters at some of the conventional retinal synapses.

Rabbit retinae were homogenised in 0.32 M sucrose and a crude nuclear pellet (P1) and a crude mitochondrial

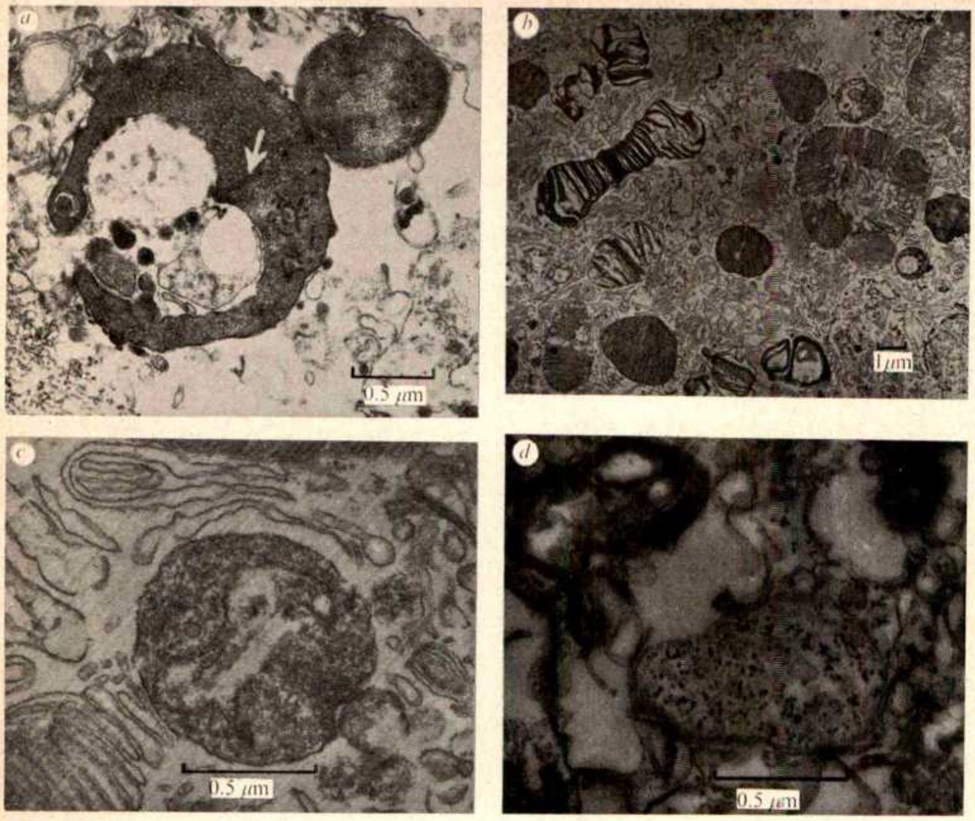

Fig. 1 Electron micrographs of retinal subcellular particles. *a*, Rod photoreceptor terminal: The arrow points to the synaptic ribbon, paired invaginations lie one on each side of the ribbon. Between the ribbon and the invaginations is the arciform density. A sheet of synaptic vesicles lie apposed to the ribbon. *b*, Fragments of photoreceptor outer segment; *c*, synaptosome from a conventional retinal synapse, *d*, particle possibly originating from glia and containing many small electron opaque granules but no synaptic thickening.

pellet (P2) (ref. 12) were obtained by differential centrifugation. For electron microscopy the P1 and P2 pellets were fixed in glutaraldehyde, post-fixed in osmium tetroxide and embedded in Epon–araldite. Sections were stained with methanolic uranyl acetate and aqueous lead citrate and examined by electron microscopy.

The crude nuclear fraction (P1) contained many nuclei, tissue fragments, and a few large mitochondria. Aggregations of smaller mitochondria were frequently seen and these appeared to be derived from sections of photoreceptor inner segments being sheared-off intact during the homogenisation process. In addition, fragmented outer segments were frequently observed. The most striking feature of this fraction, however, was the presence of large numbers of pinched-off rod photoreceptor terminals (Fig. 1*a*). These structures were identified by the presence of densely staining cytoplasm, many synaptic vesicles and a synaptic ribbon with an associated halo of synaptic vesicles. Most of these rod photoreceptor terminals, (diameter 1–2 μm) were sectioned in a plane which revealed the invaginations into which processes from horizontal and bipolar cells normally project[16,17]. Occasionally a much larger cone terminal (diameter 5–10 μm) with less dense cytoplasm was observed. A few nerve endings with light staining cytoplasm (diameter approximately 1 μm) and synaptic ribbon, but no invaginations, were observed in this fraction; these were identified as bipolar terminals.

The crude mitochondrial fraction (P2) contained myelin fragments from the optic nerve, fragmented and partially intact photoreceptor outer segments (Fig. 1*b*), and many free mitochondria. Many conventional nerve ending particles (Fig. 1*c*) from horizontal and amacrine cells were observed, but no pinched-off photoreceptor terminals were identified in this fraction. Bipolar cell terminals containing synaptic ribbons were observed. Many other particles were present which varied in size and shape: these contained numerous small electron-opaque granules (ribosomes) but no mitochondria (Fig. 1*d*) or synaptic thickenings and may have been derived from processes of the neuroglial Müller cells[18].

This preliminary morphological study of the subcellular particles produced by homogenisation of the rabbit retina shows that conventional retinal nerve endings form synaptosomes similar to those previously described for many other areas of the CNS. The photoreceptor terminals, however, are unique in their distinctive morphology and like cerebellar mossy fibre nerve endings[12], but unlike other nerve ending particles, sediment in the P1 pellet. Thus, it should be possible to obtain, for the first time, a preparation containing only isolated photoreceptor terminals. Such a preparation should be of great help in identifying the transmitter substance of the photoreceptors.

It has been proposed that an excitatory transmitter is continuously released from photoreceptors in the dark,

Table 1 Distribution of endogenous amino acids in primary fractions

	% of total recovered in P1 + P2 + SNT.			Relative specific activity (RSA)		
	P1	P2	SNT	P1	P2	SNT
GABA	20.2	10.9	68.8	0.50	0.60	1.68
Aspartate	41.5	13.9	44.5	1.08	0.76	1.03
Glutamate	21.0	6.5	70.9	0.53	0.36	1.71
Glycine	23.8	11.2	64.9	0.58	0.62	1.57

Approximately 70 mg wet weight of rabbit retinae were homogenised in 20 volumes 0.32 M sucrose (6% w/v). Each retinal homogenate was spun at 1,000*g* for 5 min to produce a crude nuclear pellet (P1). The supernatant was then centrifuged at 17,000*g* for 30 min to produce a crude mitochondrial pellet (P2) and SNT (supernatant of latter centrifugation[12]). The amino acids in these fractions were extracted with ice-cold perchloric acid (6%) and allowed to stand overnight. The extracts were taken to *p*H 4.0 with KOH and centrifuged at 0° C to remove the perchlorate precipitate. The supernatant was acidified to *p*H 2.2 with citrate buffer and the amino acids were determined by ion-exchange chromatography using an automatic amino acid analyser (Biocal BC100). Results are expressed as both % of total recovered in P1 + P2 + SNT and relative specific activity (RSA = % total recovered in fraction/% total protein recovered in fraction). Results are means of 4–6 experiments. The s.e. of the means were between 0 and 10%.

but release slows in the light, resulting in hyperpolarisation of the horizontal cell[19,20] Recently, Dowling and Ripps[21] have suggested that the photoreceptor transmitter may be aspartate or glutamate on the basis that increased Mg levels, which would be expected to reduce transmitter release, cause hyperpolarisation of second order retinal neurones Since our experiments suggest that the P1 fraction contains most of the photoreceptor terminals, we have examined the distribution of endogenous aspartate, glutamate, GABA and glycine in the primary fractions produced from the rabbit retina (Table 1) These experiments indicate that the P1 fraction contains more than 40% of the aspartate, whilst only about 20% of the other amino acids are concentrated in this fraction These results are consistent with the suggestion that aspartate may be the transmitter released from the photoreceptor terminals

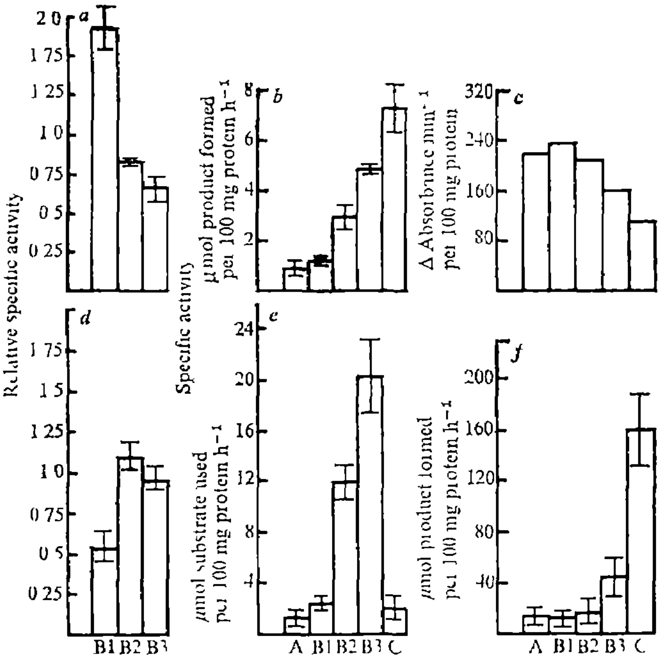

Fig 2 Distribution of enzymes, ^{3}H-dopamine, and ^{14}C-GABA sucrose gradients Retinae were incubated with a mixture of ^{3}H-dopamine (0 1 µM) and ^{14}C-GABA (0 1 µM) for 20 min at 37° C in medium containing pargyline (15 µM), EDTA (25 µM), and ascorbic acid (1 mM) These retinae, and also unincubated retinae for enzyme assays, were homogenised in 0 32 M sucrose and centrifuged at 1,000*g* for 5 min The supernatant was then spun at 17,000*g* for 30 min at 4° C to produce a crude mitochondrial pellet (P2) This pellet was resuspended in 0 32 M sucrose and layered on to the top of a four step discontinuous sucrose gradient (equal volumes of 1 4, 1 2, 1 0, 0 8 M sucrose) which was then centrifuged at 100,000*g* for 90 min at 4° C The five resulting fractions were collected by aspiration Fraction A being that floating on 0 8 M sucrose C sedimenting below 1 2 M sucrose The three intermediate fractions were designated B1, B2 and B3 The results are the means of 4 to 11 experiments, the vertical bars are the s e of the mean *a*, ^{3}H-Dopamine, *b*, MAO, *c*, LDH, *d* ^{14}C-GABA, *e*, GAD, *f*, GABA-T

We have not yet been able to examine the morphology of the particles present in the various fractions obtained by density gradient centrifugation of the crude mitochondrial pellet (P2) The mitochondrial enzymes MAO and GABA-T however were predominantly localised in the pellet (C) (Fig 2) The GAD activity was found predominantly in fraction B2 and B3 Since previous studies have shown that these fractions are rich in synaptosomes, and that GAD is concentrated in nerve endings[22-24], it seems likely that the retinal particles sedimenting in B2 and B3 represent 'gabainergic nerve endings' Particles in these same fractions also accumulated most of the ^{14}C-GABA on the gradients, this coupled with previous electron microscope autoradiographical studies on cortical homogenates which have shown that labelled GABA is accumulated by nerve terminals[25], suggests that GABA-operated retinal nerve endings may also accumulate labelled GABA But we cannot at present exclude the possibility that GABA-containing glial particles also sediment in these fractions

^{3}H-Dopamine seemed to be localised preferentially in the B1 fraction suggesting that it was accumulated by slightly 'lighter' particles than those which accumulated ^{14}C-GABA These particles are also likely to be synaptosomes since autoradiographic studies of ^{3}H-dopamine uptake in the retina have only revealed neuronal uptake[3,4]

Newly synthesised lipids incorporated into influenza virus membranes

USING sequential labelling techniques, I have found that newly synthesised as well as preformed lipids are incorporated into the membrane of the maturing influenza virus, thus contradicting suggestions that only pre-existing phospholipids[1–3] are utilised for the synthesis of enveloped viruses. This is not surprising in the light of reports that a selection mechanism exists for fatty acyl chains[4,5] (in ortho- and para-myxoviruses) and that many phospholipids[6] and neutral lipids[7] turn over rapidly in cultured animal cells.

Influenza virus can be considered a template virus—newly synthesised polypeptides are inserted into the membrane by lateral displacement of existing host cell polypeptides[8]. Studies of the origin of phospholipids have involved the use of ^{32}P-orthophosphate to measure the decay of phospholipids in the virion and infected cells. Although this technique appears to be valid for equilibrium labelling and thus for measuring the lipid composition of the virion[9], attempts to chase ^{32}P-orthophosphate from phospholipids in monolayer cultures have been unsuccessful. Since ^{32}P can exchange rapidly or compartmentalise into organic pools which turn over slowly, data for the turnover of phospholipids in chick embryo fibroblasts[7] obtained with this isotope would seem to be unreliable[8]. Using short pulses of 2-^{3}H-glycerol, Weinstein and I have already shown that the depression of synthesis of host cell lipids in virus-infected chick embryo fibroblasts depended on the multiplicity of infection, suggesting that newly synthesised lipids were incorporated into the virion[11].

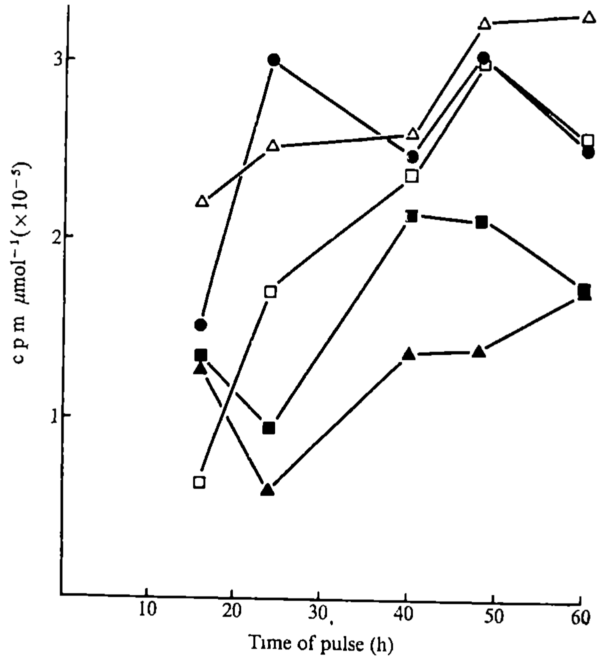

Fig 1 Equilibrium labelling of chick embryo fibroblasts plated in the presence of 0.45 μCi ml^{-1} of 2-^{14}C-glycerol. △, Phosphatidylcholine; ■, phosphatidylethanolamine; ●, phosphatidylinositol; □, phosphatidylserine; ▲, sphingomyelin.

To investigate this question further, secondary chick embryo fibroblasts were seeded on to Falcon flasks (75 cm^2) in Puck's medium containing 10% calf serum and 0.45 μCi of 2-^{14}C-glycerol (ICN, specific activity 16 mCi mmol^{-1}). Individual flasks containing about 10^7 cells were sampled at various times, lipids were extracted and separated by thin-layer chromatography and their specific activity was determined[6]. With the exception of sphingomyelin, all phospholipids were labelled to equilibrium within 48 h (Fig 1). To achieve maximal incorporation of label, confluent cells (at 48 h) were washed with KIR[6] and cells starved for 16 h in minimal Eagle's medium with 0.1% fatty-acid-poor bovine serum albumin (MEM-FAPBSA) containing 0.45 μCi ml^{-1} of 2-^{14}C-glycerol per ml. This step further increased the incorporation of ^{14}C-glycerol by 50% (12–16 h were needed to achieve further equilibrium labelling, in the absence of serum). Monolayers were then washed with ice-cold KIR and infected with 15–20 plaque-forming units (PFU) per cell of influenza virus (Ao/WSN/34 strain) by adsorption at 4° C for 90 min. The virus inoculum was removed and the cells were pulsed with 1 μCi ml^{-1} of 2-^{3}H-glycerol (New England Nuclear Corp., specific activity 8.8 Ci mmol^{-1}) in MEM-FAPBSA for 16 h. Virus was collected after 16 h, the purification of virus and extraction and separation of lipids is described in the legend of Table 1.

Table 1 Incorporation of 2-^{3}H-glycerol into influenza virions derived from prelabelled cells

	Phospholipids c p m μmol^{-1} Pi ^{14}C	^{3}H	^{3}H/^{14}C*
Lysophosphatidylcholine	14.8	10.4	0.7 (±0.1)
Phosphatidylcholine	315	312	1.0 (±0.1)
Phosphatidylserine	132	39	0.3 (NC)
Phosphatidylethanolamine	127	53	0.4 (±0.1)
Phosphatidylinositol	19	12	0.6 (±0.1)
Sphingomyelin	132	34	0.3 (NC)
	Neutral lipids c p m μmol^{-1} ^{14}C	^{3}H	^{3}H/^{14}C*
Monoglycerides	208	83	0.4 (±0.1)
Free fatty acids	137	70	0.5 (±0.1)
Cholesterol	1964	200	0.1 (NC)
Diglycerides	172	241	1.4 (±0.15)
Triglycerides	91	227	2.5 (±0.2)
Cholesterol esters	250	83	0.3 (NC)

Doubly labelled virus was mixed with cold purified egg-propagated influenza virus, containing the equivalent of 300 μg of phospholipid, and purified by adsorption and elution from BaSO$_4$, two cycles of differential centrifugation and by banding (twice) in preformed gradients of potassium tartrate[12]. In a separate experiment, isotope dilution techniques[12] with ^{32}P revealed <0.1% contamination by host cell phospholipids as judged by Čerenkov radiation[13]. The extraction and quantification of labelled virus was as previously described[6,11]. Specific activities were determined after subtraction of the mean values obtained from duplicate runs of individual lipids obtained from cold purified virus from that of labelled virus plus an equivalent amount of cold virus which was separated by thin-layer chromatography. Corrections for background and overlap of channels was done directly in an Intertechnique spectrometer.

NC, no change. Pi, inorganic phosphate. Results represent means of three separate experiments.

*Bracketed figures represent variability of ratios between experiments.

Analysis of neutral glycerides showed that about 55–70% of di- and triglycerides were newly synthesised, whereas phosphatidylcholine contained half preformed and half newly synthesised lipid and in the case of phosphatidylethanolamine, about 30% was newly synthesised. Although glycerol labels cholesterol randomly, most of it appears to be synthesised before infection, confirming that this lipid turns over slowly.

These experiments provide direct evidence that newly synthesised lipids are incorporated into the virus (after infection). Since lipids are synthesised at the endoplasmic reticulum and transported to the cell surface membrane, it would appear that they must be transported to sites of viral membrane biogenesis which are 'hot spots'[14] for the integration of newly synthesised lipids as well as polypeptides coded for by the virus. The mechanism involved is unclear, but the most likely candidates for selective binding and transport of lipids to the sites of viral biogenesis are the envelope polypeptides and/or the 'M' protein[8]. These informational molecules determine the number and species of fatty acyl chains incorporated and provide a system for integration of lipids into membranes[8].

Volatilisation of mercury and organomercurials determined by inducible R-factor systems in enteric bacteria

WE have screened a large number of R plasmid-bearing *Escherichia coli* and obtained a few that confer resistance to the organomercurials phenylmercuric acetate (PMA) and methylmercuric chloride (MMA) Resistance to cationic Hg(II) in *E coli*, *Staphylococcus aureus* and *Pseudomonas aeruginosa* has invariably been associated with plasmids that also mediate resistance to various antibiotics (R plasmids)[1–6] The mechanism of mercury resistance is the enzymatic reduction of Hg(II) to Hg(0), which is volatile[2,7,8] Previously, no organomercurial-reducing *E coli* strains have been reported The only organomercurial-reducing strain studied in detail is a PMA-resistant soil pseudomonad[7–9] As organomercurials including PMA are a human health problem[10], it will be of interest to see if the mercury(ial) resistance of the bacteria in our alimentary canal influences the fate of ingested mercury(ials)

Starting with the Hammersmith Hospital collection[11,12] wherein over 800 enteric plasmids have been isolated and transferred into a common 'host' organism, an *E coli* K-12 strain J53, each of the plasmid-bearing strains was tested by disk assay for resistance to both mercuric chloride (100 nmol per disk) and to phenylmercuric acetate (7 nmol per disk) A series of over 30 mercuric-resistant strains including some also resistant to PMA were tested for the ability to volatilise radioactive ^{203}Hg(II) and ^{203}Hg-PMA

The distinction between sensitive and resistant strains is absolute with regard to volatilisation of Hg(II) and PMA (Fig 1) Sensitive bacteria without plasmids such as strains J53-1 and AB1932-1 show no detectable loss of ^{203}Hg(II) or ^{203}Hg-PMA from the medium during 90 min incubation at 36 C Strains harbouring R-factors that confer Hg(II)-resistance but not PMA-resistance volatilise only ^{203}Hg(II) and not ^{203}Hg-PMA (for example, strain J53(R222)) and strains that are resistant to both Hg(II) and PMA (such as strain J53(471a)) cause the volatilisation of both compounds

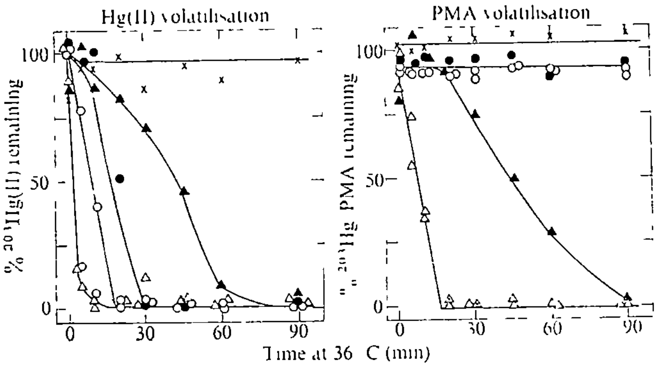

Fig. 1 Volatilisation of ^{203}Hg(II) and ^{203}Hg-PMA Cells were grown overnight at 37° C in tryptone broth (8 g Difco Bacto-tryptone, 5 g NaCl l^{-1} deionised water) or in tryptone supplemented with 10 μM $HgCl_2$ or 1 μM PMA In the morning, the cultures were diluted tenfold into the same medium and when growth reached 75 Klett units turbidity (number 54 filter, Klett-Summerson colorimeter), a third addition of Hg(II) or PMA was made to the induced cultures After growth to 125 Klett units (230 μg dry weight ml^{-1}), the cells were collected by centrifugation at 6,000*g* for 10 min at 20° C and resuspended at 2 3 mg ml^{-1} (dry weight) in 0 01 M $NaPO_4$ buffer, *p*H 7 3 Cells were diluted elevenfold into an assay buffer containing final concentrations of 0 01 M $NaPO_4$ buffer, *p*H 7 3, 5×10^{-4} M Na_2EDTA, 10^{-3} M β-mercaptoethanol, 2×10^{-4}M $MgCl_2$ and either, *a*, 10 μM $^{203}Hg(NO_3)_2$ or *b*, 1 0 μM ^{203}Hg-PMA 20 μl samples were removed periodically and counted by liquid scintillation spectroscopy[2] The reaction mixtures (220 μl) were shaken at 200 r p m in 10 × 75 mm test tubes in a 36° C water bath ×, Uninduced J53-1, ●, uninduced J53(R222), ○, Hg(II)-induced J53(R222), ⊙, PMA-induced J53(R222), ▲ uninduced J53(471a), △ Hg(II)- induced J53(471a), △ PMA-induced J53(471a)

The results of a series of such experiments are summarised in Table 1 along with the antibiotic resistance pattern of each plasmid, the compatibility groups, and the bacterial species from which the plasmids were isolated A small number of R factors from other sources and some hospital isolates were also tested All of the 47 strains with mercury volatilising activity listed in Table 1 are inducible for this activity This is seen in Fig 1, where the initial rate of loss of ^{203}Hg(II) is five to ten times more rapid with bacteria that have been previously exposed to 10 μM $Hg(NO_3)_2$ or 1 μM PMA With the strains harbouring the first eight plasmids that confer activity toward both Hg(II) and PMA, growth on either substrate induced the immediate rapid volatilisation of both—that is, a single system appears to be functioning or there is at least cross induction With 38 of the remaining 39 Hg(II)-resistant strains, growth in the presence of 1 μM PMA induces the rapid volatilisation of ^{203}Hg(II), even though ^{203}Hg-PMA is not volatilised (that is, PMA appears to be a gratuitous inducer but not a substrate for the system)

As well as the two most common patterns (exemplified in Fig 1 by plasmids R471a and R222), we have found a number of exceptional induction-volatilisation patterns, each of which is reproducible in repeated experiments with separate single colony isolates First, strains with R factors R826 and R828 did not induce volatilisation of PMA in the assay conditions, although when pregrown with either Hg(II) or PMA, these strains rapidly volatilised PMA Second, strains J53(R40a), RN180 and RN181 showed low level volatilisation of ^{203}Hg-PMA (±,< 50% of 1 μM PMA volatilised in 90 min at 36° C) as opposed to > 90% loss in 30 min with J54(R471a) (Fig 1) Previous growth on 1 μM PMA induced rapid volatilisation of 10 μM Hg(II) by strains J53(R40a), RN180 and RN181, but little or no activity toward PMA These strains belong to the class of organomercurial-reducing strains, but they are quantitatively very different from the first eight plasmid-containing strains in Table 1 Third, with strain J53(R192) exposure to 1 μM PMA strongly inhibited (to less than one-fifth of the uninduced level) the ability of the cells to volatilise ^{203}Hg(II) Higher levels of PMA (approaching 10 μM) and $Hg(NO_3)_2$ (approaching 20 μM) have this effect on all the strains Fourth, the strains carrying R factors R391 and R705 do not show induction of ^{203}Hg(II) volatilising activity during 90 min at 36° C in the buffer assay conditions

We used phenylmercuric acetate for screening R factor-containing strains for resistance to organomercurials Recently, we have measured the volatilisation of ^{203}Hg and ^{14}C from radioactive methylmercuric chloride when exposed to induced cells of J53(R471a), J53(R286) and J53-1(R831), but not when induced cells of these strains were used, nor with J53 derivatives with plasmids R15, R192, or R391 or the plasmidless J53-1 (all pre-exposed to Hg(II)) Strain RN180 induced with Hg(II) showed low level but significant volatilisation of ^{203}Hg-methylmercuric chloride

Thirty-one of the mercury-resistant strains in Table 1 contain plasmids transferred into the common genetic background of K-12 derivative J53 Plasmids JJ1, U150 and U305 were transferred into another common K-12 derivative AB1932-1 (ref 13) and have been previously shown to volatilise Hg(II)[2,4] In terms of mercury resistance and volatilisation, AB1932-1(R15) is indistinguishable from J53-1(R15) The four RN plasmid-bearing mercury-resistant strains originated from Chabbert[14] in Paris Two of

The plasmids in strains J53 or J53-1 (a derivative of J53 with a chromosomal mutation to nalidixic acid-resistance) come from the Hammersmith Hospital collection[11,12] R factors R15, R28, R52, R192, R222, R312 and R348F have been previously reported[11] as mercury resistant Plasmid RIP69 has been described[16] and was assigned to compatibility class 7, later renamed group M (ref 12) Compatibility groups 'L' and 'S' will be described shortly[18] Plasmid R15 was introduced by conjugation into an acridine-orange 'cured' plasmid-less derivative of AB1932-1 (J31), Su resistance was not tested after transfer Plasmid R100 is a synonym for plasmid R222 [17], Su resistance and compatibility group were not tested with CR34 (R100-1) The symbols for antibiotic resistances are A, ampicillin, Cb, carbenacillin, Cp, cephalothin, Cm, chloramphenicol, Gm, gentamycin, Km, kanamycin, Sm, streptomycin, Sp, spectinomycin, Su, sulphonamide, Tc, tetracycline The antibiotic resistances are those tested in this study and therefore incomplete, the resistance to the penicillin class of antibiotics does not necessitate several enzymic mechanisms these seem identical to our most common class of plasmids conferring only mercury resistance, represented in Fig. 1 by R222. The other two, RN180 and RN181, represent an exceptional class. A series of hospital isolates from Rochester, New York (DG21, DG35 and DG36)[13] and from St Louis (J71, J82, B36 and BU9990) complete our current collection of mercury volatilising *E. coli*. In these strains, the plasmid nature of the mercury resistance has yet to be shown but all are multiply antibiotic resistant. The frequency of mercury resistance amongst the new St Louis isolates was 4/126 (4 of the 25 new antibiotic resistant isolates). Approximately 200 of the 800 plasmids from various enteric organisms that have been transferred into J53 confer resistance to Hg(II). The first seven of the plasmids conferring resistance to PMA and Hg(II) originated in *Serratia marcescens* isolates. Five belonged to the 'L' incompatibility group and came from Boston, Massachusetts; the other two were group 'S' and came from Toulon, France. Recently, however, strain J53 containing plasmid JR211, which belongs to the 'A-C' compatibility group and originated in *Klebsiella aerogenes*, was found to volatilise ^{203}Hg-PMA. Clearly, the frequency of mercury resistance is sufficiently high to make this a useful epidemiological marker and further studies with mercury and mercurial resistance patterns should help in elucidating relationships between plasmids.

This work was supported by grants from the National Institutes of Health and the National Science Foundation. Anne O. Summers started us on studies of mercury resistance. CR34 (R100-1) and RN180, RN181, RN182 and RN184 were obtained from R. P. Novick.

Unidirectional replication of plasmid ColE1 DNA

COLICINOGENIC plasmid E1 (ColE1) has been isolated from *Escherichia coli* both as a supercoiled DNA molecule of 4.2×10^6 molecular weight and as a supercoiled DNA-protein relaxation complex[1]. Treatment with certain agents that denature protein structure induces conversion of the supercoiled ColE1 DNA-protein complex to an open circular (relaxed) DNA form with one single strand break specifically in the poly (U,G) binding or 'Crick' strand[2,3]. It has been shown that the EcoR1 restriction endonuclease cleaves ColE1 DNA at a single site. Using that site as a reference point it was demonstrated that the single strand break in the open circular product of induced relaxation is located at a unique site, approximately 19% of the length of ColE1 DNA from one end of the EcoR1 cleaved molecule[4]. Only certain restriction endonucleases have previously been shown to cleave DNA at a specific nucleotide sequence and the result of their action is a double strand break[5–7].

Replicating ColE1 DNA molecules have been isolated from *E. coli* cells and examined with respect to their physicochemical properties (L. K. Williams S. Sato, R. W. Leavitt, and D.R.H., manuscript in preparation). The parental strands of these ColE1 molecules, like those of replicating SV40 molecules[8,9], are covalently closed as determined by their broad distribution between the densities of supercoiled and open circular DNA in caesium chloride–ethidium bromide density gradients, by their rapid sedimentation in alkaline sucrose density gradients and by their appearance in the electron microscope as partially supercoiled, partially open structures. Fareed *et al.*[10] used the single EcoR1 cleavage site in SV40 DNA as a reference point to determine that SV40 DNA replication proceeds bidirectionally from a unique origin. We describe here an analysis of EcoR1 cleaved replicating ColE1 DNA molecules. Evidence is presented that ColE1 DNA replication proceeds unidirectionally from an origin whose location is indistinguishable from the site of the single-strand break present in the open circular DNA of the relaxed ColE1 complex.

A lysate of *E. coli* JC411 cells, colicinogenic for the plasmid ColE1, prelabelled with ^{14}C-thymine and pulse labelled with ^{3}H-thymidine was centrifuged to equilibrium in a caesium chloride–ethidium bromide density gradient. The pulse labelled DNA was separated into two pools, one comprising ^{3}H-DNA of a density intermediate between that of supercoiled ColE1 DNA and open circular or linear DNA and the second comprising ^{3}H-DNA of a density equal to that of open circular or linear DNA. ColE1 replicating intermediates in the less dense pool consist of molecules that have replicated to a greater extent than the replicative forms in the intermediate density pool of DNA (L. K., P. H. Williams, S. Sato, R. W. Leavitt and D.R.H., manuscript in preparation). Similar observations have been made for replicating SV40 molecules[8,9]. To purify the ColE1 DNA further, each pool was centrifuged on preparative sucrose density gradients and the ^{3}H-DNA which sedimented as rapidly or more rapidly than 23S DNA (the sedimentation coefficient of supercoiled ColE1 DNA) from each preparative gradient was pooled separately.

A sample of each of the two pools was treated with the EcoR1 endonuclease and analysed by centrifugation through 5–20% sucrose density gradients. Figure 1*a* shows that before cleavage the ^{3}H-thymidine-labelled pool of DNA originally derived from the intermediate density peak in the caesium chloride–ethidium bromide density gradient sedimented with coefficients of 23–34S. There is a peak of the prelabelled ^{14}C-thymine-labelled DNA at the 23S position, presumably arising by contamination from the supercoiled peak in the preparative dye–caesium chloride density gradient. After cleavage (Fig. 1*b*) much of the ^{14}C-DNA was found in the 15S position expected for the linear ColE1 DNA. The pulse labelled ^{3}H-DNA sedimented with sedimentation coefficients between 15S and 23S after cleavage. Figure 1*c* shows that before cleavage the pool of ^{3}H-DNA derived initially for the lowest density peak in the caesium chloride–ethidium bromide density gradient sedimented rapidly between 23S and 42S with most of the ^{3}H-DNA counts between 38S and 42S. Again much of the prelabelled ^{14}C-DNA sedimented in the position of 23S supercoiled ColE1 DNA. After cleavage with the EcoR1 endonuclease (Fig. 1*d*) most of the ^{14}C-DNA sedimented at 15S while most of the ^{3}H-DNA sedimented with coefficients between 17S and 23S. The rapid sedimentation through neutral sucrose density gradients, characteristic of replicating ColE1 DNA before and after cleavage, is consistent with the observations in the electron microscope that before cleavage with EcoR1, replicating ColE1 molecules exhibit a partially supercoiled, partially open structure and that after cleavage with EcoR1 linear molecules are observed containing an internal loop of replicated DNA and two unreplicated branches. Figure 2 represents typical EcoR1-cleaved ColE1 DNA molecules in various stages of replication.

The total lengths of the linear molecules with internal loops derived from EcoR1-cleaved DNA of the intermediate and light density pools, were determined by electron microscopy. The linear molecules with internal loops were found to be of the same length as the contour length of open circular ColE1 DNA spread on the same grid to a 95% confidence level. An analysis of the changes in relative lengths of the unreplicated branches as the extent of replication changes is shown in Fig. 3 for 124 ColE1 DNA molecules that were between 3 and 70% replicated. It is clear that as replication proceeds, one unreplicated arm of the molecule, designated U_1, remains constant in size and the other unreplicated arm, U_2, progressively decreases in size. This is as expected for a unidirectional mode of replication from a fixed origin. In contrast, if replication proceeded bidirectionally from a fixed origin, both U_1 and U_2 would decrease in size with an increasing extent of replication. Extrapolation of U_1 and U_2 to 0% replication permits a determination of the position of the origin of ColE1 DNA replication. As Fig. 3 shows, the origin is calculated to be 18.3±0.9% of unit length from one EcoR1 end and 81.7% from the other.

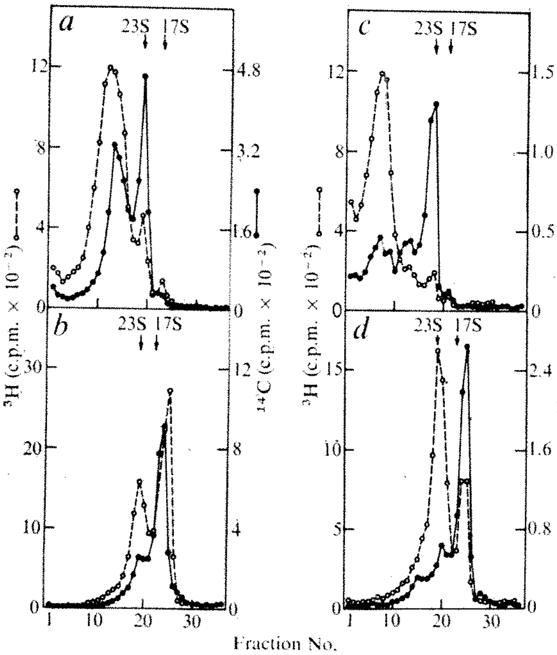

Fig. 1 Neutral sucrose sedimentation analysis of replicating ColE1 DNA molecules untreated and treated with the EcoR1 restriction endonuclease. A 500 ml culture was prelabelled uniformly with ^{14}C-thymine (0.1 μCi ml^{-1}) to a density of 5×10^8 cells ml^{-1}, collected and resuspended in medium lacking thymine and containing 3 mM cyclic AMP. After 30 min, the cells were pulsed for 30 s with ^{3}H-thymidine (10 μCi ml^{-1}) and 0.3 μg ml^{-1} of unlabelled thymidine. The cells were collected by centrifugation and lysed by the SDS-salt method[11]. The pulse label was purified by neutral sucrose gradient sedimentation and caesium chloride–ethidium bromide density gradient centrifugation (L.K., Williams, Sato, Leavitt and D.R.H., manuscript in preparation). Two peaks from the dye-buoyant density gradient containing replicating ColE1 DNA molecules, one banding at the intermediate density (*a* and *b*), the other at the light density (*c* and *d*) were sedimented through neutral 5–20% sucrose density gradients before (*a* and *c*) and after (*b* and *d*) treatment with the EcoR1 restriction endonuclease. Approximately 1 μl of an EcoR1 enzyme preparation was used for each 100 μg of ColE1 DNA in 0.1 M Tris, *p*H 7.5, 50 mM NaCl and 10 mM MgCl$_2$. After 5 min at 37° C the reaction was stopped by the addition of EDTA (final concentration of 25 mM).

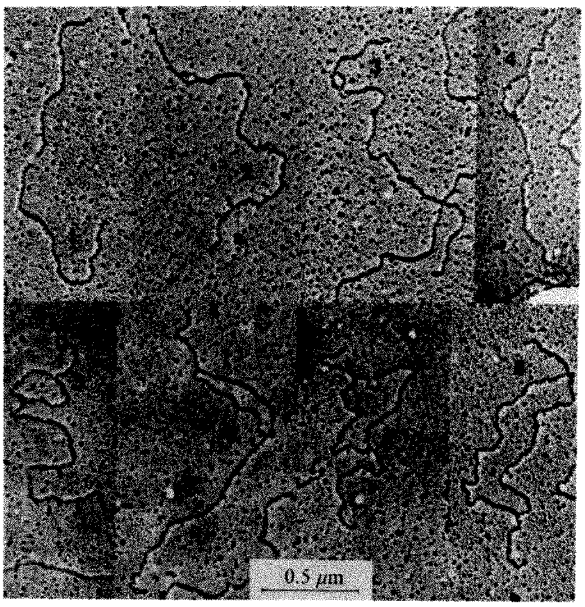

Fig. 2 Replicating ColE1 DNA molecules treated with the EcoR1 restriction endonuclease. DNA was spread by the aqueous technique of Davis *et al.*[12], rotary shadowed with platinum–palladium, and examined in the Phillips 200 electron microscope. Micrographs of selected molecules are arranged in order of increasing extent of replication. Panel 1 represents an unreplicated linear molecule.

Since replication proceeds unidirectionally, molecules greater than 81.7% replicated would be expected to have a double-Y appearance after cleavage with EcoR1. Several double Y molecules have been found in the ^{3}H-DNA derived from the light density peak in the preparative dye–caesium chloride density gradient and representative molecules are shown in Fig. 4. One of the forks of these molecules has two branches of equal size of approximately 82% of the total length of ColE1 DNA joined by a short segment to a fork with two smaller branches of equal size. As the size of the two smaller branches increases, the length of the short segment decreases. The structure of these double Y molecules is consistent with a unidirectional mode of replication from a fixed origin.

A consequence of unidirectional replication of a circular DNA molecule from a unique origin is that the origin and the termination point for replication are juxtaposed. The position of the origin-terminus for ColE1 DNA replication, 18.3±0.9% from one end of the EcoR1 cleaved molecule, is indistinguishable from the location of the single strand break present in the open circular DNA of the relaxed ColE1 DNA-protein complex (approximately 19% of unit length from one end of the EcoR1-cleaved molecule). While these data do not distinguish between the two ends of the EcoR1-treated molecule, the apparent correspondence of the nicked site and the origin-terminus implies a direct involvement of the protein components of the relaxation complex in ColE1 DNA replication.

Other plasmids studied in *E. coli*, including several different sex factors, Col, and R plasmids, have also been isolated in the form of DNA-protein relaxation complexes[13]. The relaxation event has been shown to be strand specific for ColE2 (ref. 3), F1 (ref. 14) and R6K (Y. Kupersztoch, M.A.L. and D.R.H., submitted for publication) as well as for ColE1, and it has been demonstrated that the single strand break found in the open circular DNA after induced relaxation of the ColE2 and PSC101 (ref. 4) and R6K (Y. Kupersztoch, M.A.L. and D.R.H., manuscript submitted for publication) complexes is located at a unique site in each case. The replicon hypothesis of Jacob *et al.*[15] advanced the idea that DNA replication is regulated by the action of a protein, the initiator, at the origin of replication, the replicator locus. It is possible that these specific complexes of plasmid DNA and protein reflect the basic organisation of plasmids in *E. coli* as autonomous units of replication.

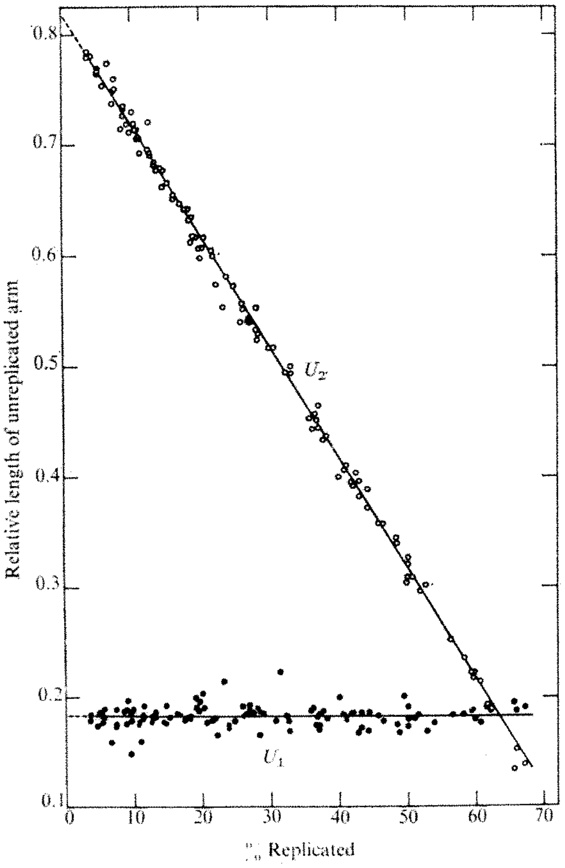

Fig. 3 Analysis of the length of the two unreplicated segments of replicating ColE1 DNA molecules after cleavage with EcoR1 as a function of the extent of replication. Replicating ColE1 DNA molecules purified and treated with the EcoR1 restriction endonuclease as described in Fig. 1 were used in this analysis. U_1 and U_2 are the unreplicated branches joining an internal loop comprised of R1 and R2. The relative lengths of U_1 and U_2 for each molecule was determined from the formula $T = U_1 + U_2 + 1/2(R_1 + R_2)$, where T = total length. The percentage replicated = $1/2\ (R_1 + R_2)/T$.

Since the strand specific break found as a result of induced relaxation is at the origin-terminus of ColE1 DNA replication, it is conceivable that the protein components of the relaxation complex could be involved in the initiation of DNA synthesis and/or in its termination. At least in the case of the ColE1 DNA-protein relaxation complex it has been shown that the protein components of the complex have novel properties that could be consistent with a direct role in DNA synthesis. The supercoiled ColE1 complex has three major protein components, whose molecular weights are approximately 60,000, 16,000 and 11,000 (M.A.L. and D.R.H., manuscript in preparation). After the induction of relaxation by treatment with sodium dodecyl sulphate (SDS), the 16,000 and 11,000 molecular weight proteins are completely released from the open circular DNA and the 60,000 molecular weight protein is found in an association, proposed to be covalent, with the broken strand (M.A.L. and D.R.H., manuscript in preparation) at its 5′ terminus (D. G. Guiney and D.R.H., manuscript in preparation). Such nicking and covalent joining *in vivo*, augmented by a capability to reseal the nicked DNA, could provide the swivel mechanism thought to be necessary to facilitate the unwinding of the parental strands of replicating DNA. Activity as a swivel mechanism might be required both before and after the initiation of DNA synthesis. A nicking and resealing mechanism could also be active at the termination point of DNA synthesis to facilitate the separation of two completed but interlocked molecules.

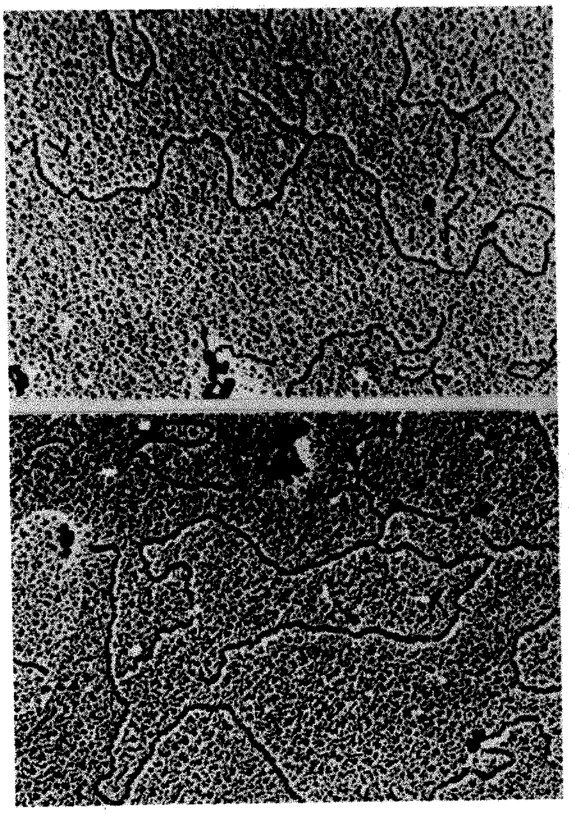

Fig. 4 Double Y structures derived from EcoR1 treatment of replicating ColE1 DNA molecules. Replicating ColE1 DNA molecules were purified and treated with EcoR1 as described in Fig. 1.

It remains to be determined whether or not unidirectional replication is an obligatory feature of the plasmid state (perhaps reflecting an essential role for relaxation complex in initiation and termination of DNA synthesis). The identification of a plasmid with the property of bidirectional DNA synthesis coupled with knowledge of the location of the site nicked by the relaxation complex could resolve the question of the action of the relaxation complex at either the origin or at the terminus of DNA replication.

Rifampicin-resistant replication of coliphage N4 DNA

IT has recently been reported that rifampicin-sensitive RNA synthesis participates in the replication of bacterial[1,2], episome or plasmid[3–8] and phage[7–11] DNA, presumably in a primer role during initiation. A more complex model of DNA replication may, however, be provided by the development of coliphage N4 (ref. 12). Transcription of N4 chromosome is unusual in that the virus uses two new rifampicin-resistant polymerising activities[13]. Expression of the early and delayed-early genes is therefore unaffected in rifampicin-pretreated cells although infection is abortive since transcription of the late N4 genes requires the functioning of the rifampicin-sensitive *Escherichia coli* RNA-polymerase (ref. 14). Here we show that initiation and continuation of N4 DNA replication take place in conditions in which the host RNA polymerase is totally inactive and give an account of the nature of the products that are synthesised in rifampicin-pretreated cells.

As shown in Fig. 1, rifampicin (200 μg ml^{-1}) added to Hfr 3300 cells 10 min before infection, did not prevent host DNA shut-off and subsequent phage DNA replication. N4 DNA synthesis was always initiated with a 3–5 min delay and the rate of ^{3}H-thymidine incorporation reached from 50–60% of that observed during normal infection. The bulk of the newly produced DNA is viral, since all of the DNA-negative *amber* mutants[15] tested failed to induce DNA synthesis. The effect on phage-coded macromolecular syntheses of adding rifampicin at different times before infection suggests that the reduction in the rate of DNA synthesis is caused by the decreased protein synthesis rather than by a direct effect of the drug on DNA replication (Fig. 2). As practically no incorporation of ^{3}H-uridine into RNA was observed in uninfected cells pretreated for 10 min with rifampicin it can be concluded that N4-directed DNA production can occur in the total absence of transcription by the host RNA-polymerase. It should be stressed, however, that N4-infected rifampicin-pretreated cells do synthesise large amounts of RNA (Fig. 2). Rothman-Denes and Schito have demonstrated that this rifampicin-resistant RNA hybridises specifically only to N4 DNA (ref. 13).

The nature of the DNA synthesised in the presence of rifampicin was subsequently investigated. Earlier studies showed that N4 parental DNA rapidly attaches to the cell membrane and that most of the ^{3}H-thymidine incorporated in a 1 min pulse administered at any time after the onset of phage DNA synthesis is complexed to fast sedimenting bacterial sites[16] where replication takes place (intermediate I)[17]. Maturation of the replicated DNA to the 40S molecule contained in the virion[18] requires the expression of late phage functions. Infection performed in rifampicin-pretreated cells resulted in the association of approximately 85% of the ^{32}P-labelled parental N4 chromosome with the cell membrane (not shown) implying that RNA synthesis mediated by the host RNA polymerase is not required for attachment. The sedimentation profile of the pulse-labelled DNA synthesised in the presence of the drug is furthermore undistinguishable from that observed under normal conditions, indicating that rifampicin does not prevent the parental genome from replicating in association with the correct bacterial site (Fig. 3*a* and *b*). When the fate of the

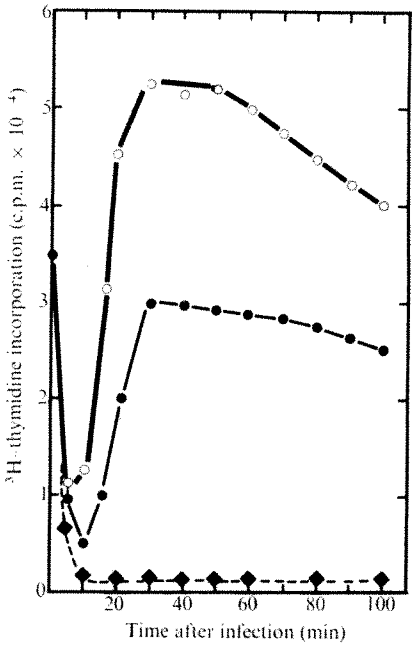

Fig. 1 Effect of rifampicin on N4 DNA synthesis. *E. coli* K12 strain Hfr 3300 was grown at 37° C in M9S casamino-acids-glucose medium[12] to a density of about 2×10^8 cells ml^{-1}. The culture was divided into several portions of equal volume (10 ml). One portion served as a control while 200 μg ml^{-1} of rifampicin (Lepetit) was added to the other portions. After shaking at 37° C for 10 min, wild type or *amber* 8, 12, 15, 23 or 25 DNA-negative (DO) N4 mutants were added separately at a multiplicity of infection of 10. At specified times thereafter 0.2 ml aliquots were removed and incubated for 2 min with methyl-^{3}H-thymidine (10 μCi ml^{-1}, 14 Ci mmol^{-1}, Amersham, England). At the end of the pulse 0.05 ml samples were precipitated with trichloroacetic acid and counted in toluene PPO as previously detailed[15]. ○, N4 wild-type-infected culture, untreated; ●, N4 wild-type infected culture, pretreated with rifampicin; ◆ DO-*amber* mutant-infected cultures, pretreated with rifampicin.

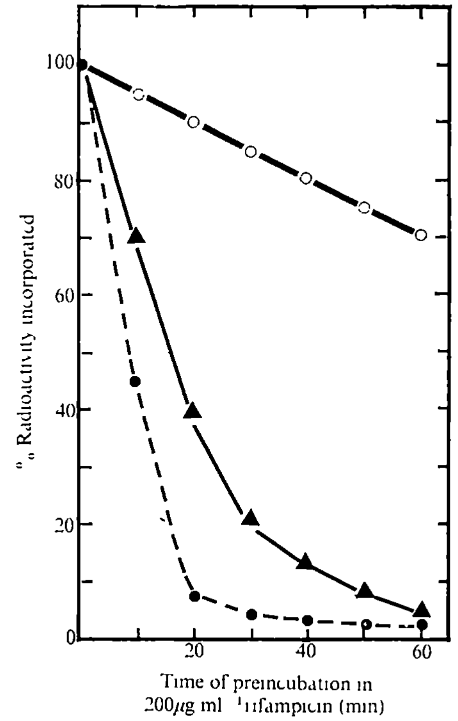

Fig 2 Rate of macromolecular syntheses in Hfr 3300 cells incubated with rifampicin for different lengths of time and infected with coliphage N4 Cells were grown according to the procedure described in the legend of Fig 1 Rifampicin (200 μg ml^{-1}) was added to different cultures 0, 10, 20, 30, 40, 50 and 60 min before infection with N4 at a multiplicity of 10 To measure incorporation of labelled precursor into DNA, 0 2 ml samples were removed 20 min after the addition of the phage and pulsed for 2 min with methyl-^{3}H-thymidine (10 μCi ml^{-1}) RNA synthesis was assessed by pulsing 0 2 ml aliquots from 6–8 min postinfection with ^{3}H-uridine (5 μCi ml^{-1}, 41 Ci mmol^{-1}, Amersham) and protein synthesis was determined by labelling for 3 min 0 2 ml portions, taken 5 min after infection, with ^{3}H-leucine (20 μCi ml^{-1}, 0 125 Ci mmol^{-1}, Amersham) The TCA-insoluble radioactivity incorporated was measured as described[15] Values are plotted as a percentage of the radioactivity incorporated by Hfr 3300 cells treated with rifampicin at time zero of infection On the ordinate 100 corresponds to 41,400 c p m for ^{3}H-thymidine, 67,000 c p m for ^{3}H-uridine and 8,300 c p m for ^{3}H-leucine ▲, Isotope incorporation into DNA, ○, into RNA, ●, into protein

DNA contained in intermediate I was analysed by chasing the radioactivity incorporated during the pulse with an excess of unlabelled thymidine, strikingly different results were observed depending on whether intermediate I was formed in the presence of rifampicin or not As shown in Fig 3*c* in normal conditions most of the pulse-labelled DNA in intermediate I was released as material sedimenting with a rate characteristic of mature N4 DNA after a chase of 20 min, whereas none of the DNA species synthesised in drug-pretreated cells could be chased into slowly sedimenting material (Fig 3*d*) Analysis by neutral or alkaline sucrose density gradient centrifugation of the DNA accumulated during continuous labelling of infected cells confirmed that upon expression of late phage functions the newly replicated DNA gives rise to molecules possessing the same hydrodynamic properties shown by N4 mature polynucleotide chains (Fig 4*a* and *c*) Detachment and maturation of N4 DNA are possibly interdependent events since in rifampicin-pretreated cells not only did detachment from the bacterial site fail to occur (Fig 4*b*) but the polynucleotide chains accumulated in intermediate I, upon denaturation by alkali migrated as an heterogeneous peak with much of the material sedimenting faster than single strands of mature DNA (Fig 4*d*) The lack of transcription, in the presence of the antibiotic, of the late phage genes[13] which code for maturing factors could explain the accumulation of the fast sedimenting DNA species

The extended synthesis of viral DNA in cells pretreated with rifampicin (Fig 1) indicates that the host RNA-polymerase is not required in the initiation and elongation reactions of N4 chromosome replication These findings are in contrast with those obtained with other host–phage systems in which rifampicin-sensitive transcription has been shown to be a prerequisite for at least the initiation of replication[7–11] One might therefore assume either that RNA synthesis in general is dispensable for N4 DNA replication or that RNA priming is required for initiation but is carried out by a system distinguishable from the host RNA-

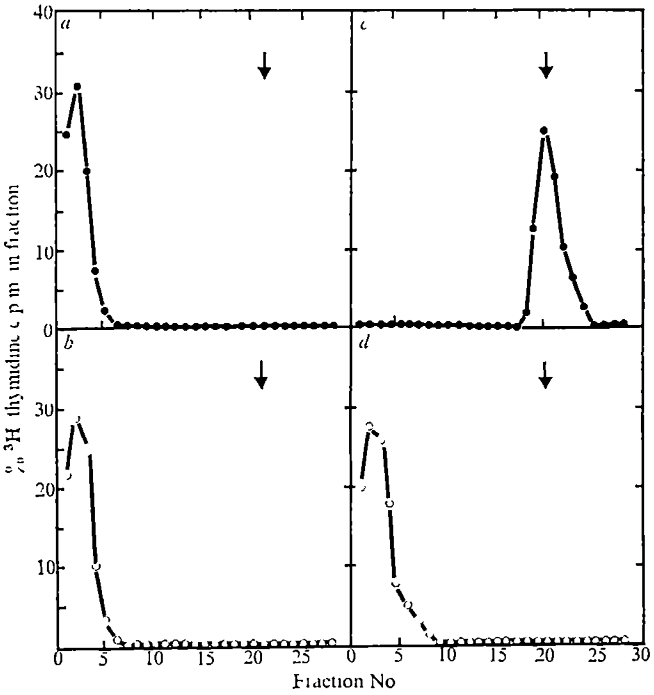

Fig 3 Sedimentation analysis of N4 DNA synthesised in control cells and in cells pretreated with rifampicin *E coli* Hfr 3300 was grown at 37° C in M9S with shaking When the cell density reached 2 5 × 10^8 cells ml^{-1} the culture was divided into two portions One portion was left untreated and served as a control and 200 μg ml^{-1} of rifampicin was added to the other aliquot After 10 min incubation at 37° C N4 was added at a multiplicity of 10 Newly synthesised phage DNA was labelled from 20–22 min after infection by the addition of methyl-^{3}H-thymidine (14 Ci mmol^{-1}) to a final concentration of 20 μCi ml^{-1} At the end of the labelling period a 2 ml sample was taken and processed as described below To the remaining culture unlabelled thymidine was added to a final concentration of 2 0 mg ml^{-1} At 40 min after infection a sample of cells was centrifuged and gently lysed by the Tris-lysozyme-EDTA-detergent method described by Hallick Boyce and Echols[21] Portions of the cell lysates (0 15 ml) were mixed with ^{32}P-N4 DNA (ref 17) and centrifuged in a 4 2 ml of 5–20% sucrose gradient overlaying a 0 3 ml 1 7 g ml^{-1} caesium chloride shelf Sucrose solutions were made up in 0 02 M Tris-HCl, *p*H 8 0, containing 0 01 M EDTA Centrifugation was in the Spinco SW50 rotor for 60 min at 35,000 r p m and 5° C Fractions (about 0 15 ml) were collected from the bottom of the tube and the acid-insoluble radioactivity in a 0 05 ml sample was determined Overall recoveries of ^{3}H were greater than 85% Labelled N4 DNA found at the CsCl-sucrose underlayer is defined as Intermediate I The arrows indicate the position to which marker ^{32}P-N4 DNA sediments *a*, Sedimentation pattern of pulse-labelled N4 DNA, control cells, *b*, sedimentation pattern of pulse-labelled N4 DNA cells pretreated with rifampicin, *c*, fate of pulse-labelled N4 DNA after a 20 min chase with unlabelled thymidine untreated cells *d*, fate of pulse-labelled N4 DNA cells pretreated with rifampicin

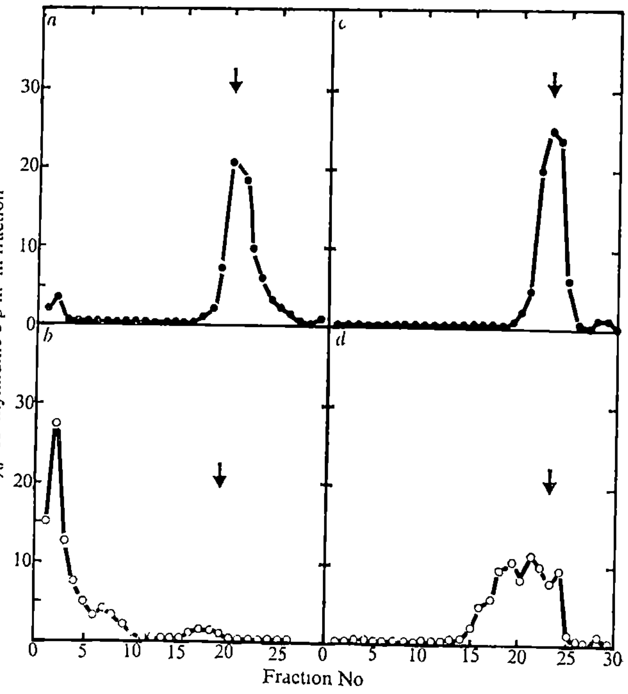

Fig 4 Sedimentation analysis of N4 DNA labelled continuously in control cells and in cells pretreated with rifampicin Hfr 3300 was grown as described in the legend of Fig 1 At a cell density of 2×10⁸ cells ml⁻¹ the culture was divided into two aliquots One portion served as a control while 200 μg ml ⁻¹ of rifampicin was added to the other portion After 10 min incubation at 37° C N4 was added at a multiplicity of 10 Phage DNA was continuously labelled from 20 to 40 min after infection by the addition of methyl-^{3}H-thymidine (14 Ci mmol^{-1}) to a final concentration of 5 μCi ml $^{-1}$ At the end of the labelling period, samples were taken and DNA was gently extracted as specified in the legend of Fig 3 Portions of the cell lysate (0 15 ml) were mixed with ^{32}P–N4 DNA and centrifuged in neutral or alkaline sucrose gradients Alkaline sucrose solutions were made up in 0 001 M EDTA and 0 3 M NaOH Conditions of sedimentation and analysis were the same as those described in Fig 3 *a* and *c*, Patterns of sedimentation of N4 DNA labelled continuously from 20–40 min after infection in control cells *a*, Neutral sucrose gradient, *c* alkaline sucrose gradient Patterns of sedimentation of N4 DNA labelled continuously for the same period of time in rifampicin-pretreated cells *b*, neutral sucrose gradient, *d*, alkaline sucrose gradient The position to which marker ^{32}P-N4 DNA sediments is indicated by the arrows

polymerase The rifampicin-resistant mode of initiating Okazaki pieces[19], the replicative form of phage ΦX 174 (ref 20) and the λ*dv* plasmid dimer[8] could, in principle, be used by N4 DNA for priming the next round of replication More likely, one or both of the phage-related RNA-polymerising activities[13] may be involved in a drug-resistant transcription both at the origin and during elongation of N4 DNA Finally, an altogether different mechanism of DNA strand initiation and elongation cannot be ruled out on the basis of present data Isolation of a ribopolynucleotide covalently attached to a growing viral deoxypolynucleotide chain may place the mode of N4 DNA replication in a more usual frame and may render this system amenable to further investigation

This research was supported in part by funds from the Italian Ministry of Public Health We thank Dr L G Silvestri (Gruppo Lepetit, Milan) for rifampicin and Claudio Casoli for assistance

Poly(C) in animal viral RNAs

A TRACT of approximately 100 nucleotides, containing 80–90 cytidylic acid residues (poly(C)) has been found within the genome of encephalomyocarditis virus[1] (EMCV) We have sought to establish whether this unusual structural feature is also present in other animal picornaviruses, including those of human and veterinary importance, such as rhino-, foot-and-mouth disease and swine vesicular disease viruses The composition and extent of occurrence of poly(C) in a variety of picornaviruses might indicate whether it has a role in any of the processes which are common to all of these viruses, such as penetration, replication and assembly[2] Furthermore, if poly(C) is a virus-specific feature, it might prove feasible to devise antiviral chemotherapeutic strategies based upon its presence

Picornaviruses (family Picornaviridae) have been classified[3,4] into five subgroups on the basis of physicochemical evidence, namely the enteroviruses, cardioviruses, foot-and-mouth disease viruses (FMDV), and human and equine rhinoviruses We have examined representative viruses from four of these genera for the presence of poly(C) using methods similar to those previously employed with EMCV RNA, in which the poly(C) tract was detected as a very large T_1 RNase digestion product in polyacrylamide gels[1] All the cardioviruses and FMD viruses examined were found to possess a poly(C) region, we did not detect poly(C) in representatives of the entero- and human rhinoviruses

The viral RNAs were labelled by cultivating the viruses in medium containing ^{32}P-orthophosphate Figure 1 shows autoradiographs of polyacrylamide gel slabs in which the products of total T_1 RNase digestion of various ^{32}P-labelled RNAs isolated from the purified viruses were fractionated by electrophoresis. In those cases where very large products (≥50 nucleotides) were encountered, the fragments were analysed by further digestion with pancreatic RNase to determine whether they consisted largely of C residues (Table 1). The methods used in the further digestion of the C-rich tracts and in the fractionation and identification of their products are described in the legend to Table 1.

The RNAs of all examples of the cardioviruses and foot-and-mouth disease viruses studied yielded very large products on T_1 RNase digestion, containing mainly C (Table 1). In contrast, none of the six enteroviruses examined gave rise to any such C-rich products, although some seemed to contain A-rich tracts (ref. 5 and our unpublished observations). Similarly, the RNAs of three different rhinovirus strains yielded no large C-rich T_1 RNase digestion products. We have examined only one virus outside the picornavirus family, the togavirus, Semliki Forest virus[6]. T_1 RNase digestion of the virus 42S RNA and the virus-induced 42S and 26S RNAs gave rise to several A-rich products, but no C-rich oligonucleotides (I. Kennedy, A. P., C. N. and P. F., unpublished).

Table 1 Occurrence and analysis of C-rich fragments from total T_1 RNase digestion of various viral RNAs

Genus*	Virus	No. of analyses	Large C-rich T_1 RNase digestion products (Fig. 1)	Estimated size (nucleotides)	% C	Pancreatic RNase digestion products
Cardio	EMC	5	A_0	~100	80–90	1AAC, 1AC, 4U, 80–90C, 1G
	Mengo	3	M_0	~100	80–90	1AAC, 1AC, ~4U, 80–90C, 1G
			M_A	~150	> 75	mainly C
	Maus-Elberfeld	3	ME_0	~150	80–90	1AAAAC, 1AAU, 1AAC, ~2AU, ~4AC, ~6U, 90–110C, 1G(?)
Foot-and-mouth disease	A-61	3	A-61_0	~150	80–90	mainly C (some AC and U also present)
	O-V1	3	O-V_0	~150	80–90	$1A_3X$, 1AAC, 1AU, ~4AC, ~8U, 90–110C, 1G(?)
			O-V_B	⩾200	70–80	$1A_3X$, $1A_3C$, 1AAC, 5–10AC, 10–15U, ~150C, 1G(?)
	C-GC	2	C_A	⩾200	75–85	$1A_3X$, $1A_2C$, 1AU(?), ~10AC, ~17U, ~150C, 1G(?)
			C_B	⩾200	75–85	$1A_3X$, $1A_2C$, 1AU(?), ~10AC, ~17U, ~150C, 1G(?)
	C-997	1	not shown	~150	80–90	mainly C

* The RNAs of the following viruses did not give rise to large C-rich T_1 RNase oligonucleotides: the enteroviruses, polio (type 1, ts^+); Echo (type 12); coxsackie Faulkner; coxsackie 8068; bovine entero- and swine vesicular disease: the human rhinoviruses, types IA, 2 and 14: the togavirus, Semliki Forest.

The poly(C)-containing fragments, shown in column 4, were completely digested with pancreatic RNase, and the resultant oligonucleotides (column 7) were separated by electrophoresis on paper, quantitated and identified as previously described[1]. These compositions are calculated from different numbers of experiments (column 3) and enable the lengths of the fragments (column 5) to be estimated. These lengths are consistent with the mobilities of the fragments in 10% polyacrylamide relative to the electrophoretic front (Fig. 1). The C content of the large T_1 RNase-resistant fragments (column 6) is calculated from their pancreatic RNase digestion products. In those cases where there is uncertainty about whether G is molar, the yields of oligonucleotides are calculated assuming AAC is present once.

The large C-rich products arising from the cardioviruses and foot-and-mouth disease viruses shown in Table 1 fall into three size classes. The RNAs of EMCV and mengovirus each yielded products of about 100 nucleotides in length, containing at least 90% C (Fig. 1 and Table 1). It is clear that the nucleotide sequences of these viral RNAs are similar, since not only the Poly(C)-containing products A_0 and M_0, but also the smaller oligonucleotides A_1–A_3 (Fig. 1 and ref. 1) and M_1–M_3 (Fig. 1) gave rise to the same products upon subsequent pancreatic RNase digestion; however, two products were observed in mengovirus RNA which were not observed in EMCV RNA. The first was a large product, M_A, which occurred as a broad, possibly heterogeneous band in polyacrylamide gels (Fig. 1). It contained about 150 nucleotides as judged from its electrophoretic mobility, and from its intensity seemed submolar relative to M_0. Like M_0, the band M_A seemed to contain mainly C (Table 1). Its presence is noteworthy, since it is of similar size to the poly(C)-containing products arising from some of the other viruses examined (see below). The second T_1 RNase product, M_x, found in mengovirus but not in EMCV, also seemed rich in C (see Table 1). Its composition precludes it arising as a result of oversplitting of M_0.

Maus-Elberfeld virus (MEV) and the FMDV strains, A-61 and C-997, yielded C-rich products of about 150 nucleotides, as indicated both by their electrophoretic mobilities and their compositions. They each contained about 30–40 more C residues than the poly(C)-containing bands A_0 and M_0, respectively in EMCV and mengovirus RNA (see Table 1).

Finally, the RNAs of the FMDV strains O-V1 and C-GC gave rise to very large T_1 RNase digestion products containing at least 200 nucleotides. Strain C-GC yielded two large C-rich bands with very similar mobilities, apparently in equimolar amounts, which were barely separated in the 10% polyacrylamide gel. These bands (C_A and C_B) were almost identical in electrophoretic mobility to the large C-rich product (OV_B) from O-V1 RNA (Fig. 1). An additional C-rich band (OV_0) was encountered in O-V1 RNA with an electrophoretic mobility identical to that of the poly(C)-containing products from MEV and A-61 RNAs. The compositions of the poly(C) tracts set out in Table 1, however, do not preclude relationships between the larger digestion products of some of these viral RNAs, that is, the smaller products might have arisen by oversplitting of larger ones.

We are uncertain whether the C-rich products from MEV and the FMDV strains yielded molar amounts of G on subsequent pancreatic RNase digestion (Table 1). If these products lack G, they might be expected to arise from the 3′-terminus of the viral RNA. At this stage, however, our analyses of these products are insufficiently precise to enable us to discuss this possibility further.

The results described show that the presence of large tracts of poly(C) is not limited to EMCV RNA, but also occurs in the two other cardioviruses and three FMDV types examined. Similar tracts were not found in the RNAs of the other picornavirus genera. But if the poly(C) tract is involved in replication, for example as part of a recognition site for a viral replicase[7], it would be surprising if it is not conserved at least to some extent throughout the Picornaviridae, since the replication processes are believed to be similar for all these viruses[2]. The methods we have used here cannot resolve this question.

It is clear, however, that the grouping of the picornaviruses according to whether or not large C-rich oligonucleotides arise on digestion of their RNAs is in accord with a classification based on their physicochemical properties. For example, our results support the conclusion that the cardioviruses should be regarded as a genus distinct from the enteroviruses[3,8]. It is also of interest that EMCV and mengovirus, originally isolated from primates[9,10], gave identical poly(C) tracts, whereas the closely related Maus-Elberfeld virus (MEV), which was of murine

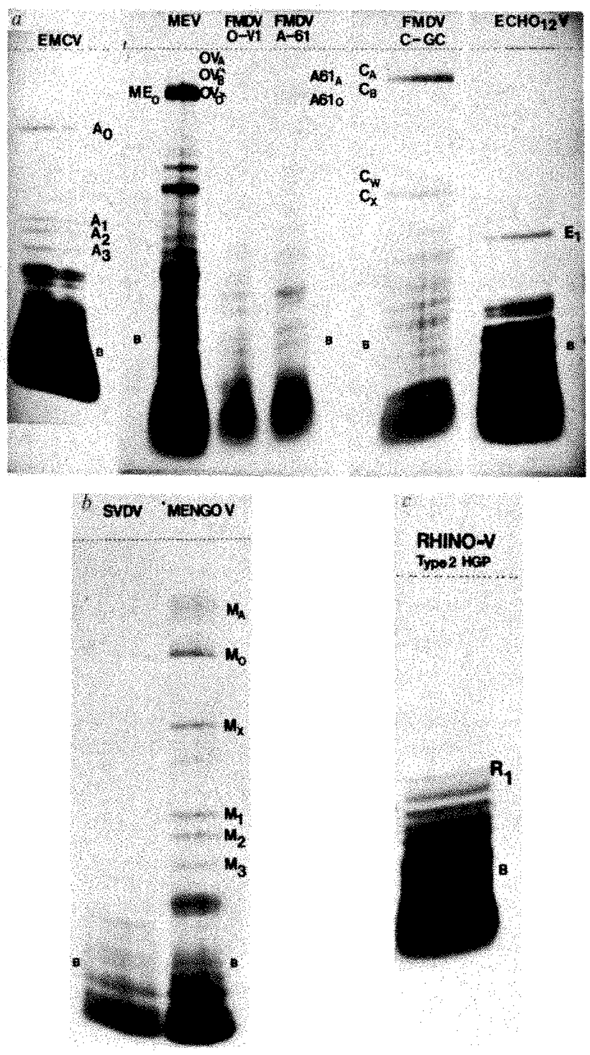

Fig. 1 The following viruses were grown in monolayers of the cell cultures indicated in parentheses in phosphate-free Earle's saline containing ^{32}P-orthophosphate: foot-and-mouth disease virus, strains O-V1, A-61, C-997 and C-GC (BHK-21); the cardioviruses, MEV and mengovirus (BHK-21); bovine enterovirus, VG-5-27 (BHK-21); swine vesicular disease virus, Italy 1/66 (IB-RS-2); coxsackie B5 virus, Faulkner strain and isolate 8068 (HeLa). The viruses were purified according to the method described for foot-and-mouth disease virus[12] and their RNAs extracted with phenol-SDS. Echo virus, type 12 (LLC-MK$_2$); poliovirus type 1, strain ts^{+} (HeLa S3); and the rhinovirus types 1A, 2 and 14 (L-132) were also grown in monolayers of cell cultures, except that they were purified and their RNAs extracted according to the method used for EMCV, given in ref. 1. Each sample of ^{32}P-labelled viral RNA (0.1×10^6–20×10^6 c.p.m. and containing 50–200 μg unlabelled carrier RNA) was dissolved in 0.02 M Tris-HCl *p*H 7.5; 0.002 M EDTA containing T$_1$ RNase (Sankyo, Japan) at an enzyme:substrate (w/w) ratio of 1:40. Digestion was complete in 1 h at 37° C. The resultant oligonucleotides were fractionated by electrophoresis in 10% polyacrylamide gel slabs as described previously (see Fig. 2 of ref. 1). The radioactive bands were located as shown by autoradiography, and excised using the autoradiograph as a guide. RNA was eluted electrophoretically from each numbered gel band on to DEAE-cellulose paper disks. Subsequent elution of the labelled fragments from the disks was performed using freshly prepared 30% triethylammonium carbonate, *p*H 10.0, as described by Sanger *et al*[13].

origin[11], gave a substantially longer tract of poly(C).

Thus, the occurrence of poly(C) regions in the picornaviruses seems to be genus specific. Furthermore, the lengths of the poly(C) tracts in the RNAs of individual members of the same genus, and even more significantly of subtypes of one serotype of an individual virus, can differ considerably. These findings emphasise the value of this type of analysis in the classification of viruses. Although clearly falling short of what could be achieved by complete nucleotide sequencing, the methods used here could lead to the elucidation of the variations in RNA primary structure which account for strain and serotype differences.

We thank Dr M. L. Fenwick, Sir William Dunn School of Pathology, University of Oxford, for HeLa S3 cells and poliovirus, type 1; and Dr A. J. Hale for providing research facilities.

Two functional states of the RNA polymerases in the rat hepatic nuclear and nucleolar fractions

IN eukaryotic cells, the DNA-dependent RNA polymerase is known to be bound to chromatin[1]. As it is known that chromatin is a restricted template[2,3], the question is whether all or only a fraction of the RNA polymerases bound to the chromatin is functionally active. The experiments reported here provide evidence that only a fraction of the RNA polymerases present in both nuclei and the nucleolar fraction is functionally active on chromatin.

It was noticed previously[4], when nuclei or nucleoli were treated *in vitro* with actinomycin D (10 μg ml^{-1}) to block the endogenous DNA-template function, that the RNA polymerase activity could be measured independently *in situ* in the same reaction vessel with a synthetic template, such as poly(dC) or poly(dA-dT). These synthetic templates are effective in directing RNA synthesis in the presence of actinomycin D, because they do not contain the deoxyguanosine moiety and hence do not react with the actinomycin D (ref. 5). As Fig. 1 shows when endogenous nuclear RNA synthesis was effectively blocked by actinomycin D, the incorporation of ^{14}C-UTP into RNA was an almost linear function of the concentration of poly(dA-dT). Fur-

Table 1 Functional independence of the engaged and free nuclear and nucleolar RNA polymerases

Incubation conditions	RNA polymerase activity pmol of labelled precursor incorporated per mg DNA ^{14}C–UTP	%	^{14}C–GTP	%
Nuclei	706	100	943	100
Nuclei + poly (dA–dT)	2,274	322	1,098	116
Nucleoli	995	100	1,535	100
Nucleoli + poly (dA–dT)	2,901	292	1,595	104
Nuclei	866	100	1,057	100
Nuclei + poly (dI–dC)	1,068	123	8,930	845
Nucleoli	6,599	100	11,686	100
Nucleoli + poly (dI–dC)	7,692	116	52,761	451

RNA polymerase activity was assayed as described in the legend to Fig. 1. When indicated, 25 μg poly(dA-dT) or 12.5 μg poly(dI-dC) (Boehringer Mannheim) was used as the exogenous template.

thermore, when nuclear or nucleolar suspensions were incubated *in vitro* in the absence of actinomycin D, the addition of poly(dA-dT) stimulated the incorporation of ^{14}C–UTP into RNA threefold (Table 1). If the RNA polymerases bound to chromatin were all functionally active toward the endogenous chromatin template, then all or part of the RNA polymerase would have to leave the chromatin and transcribe the poly(dA-dT) in order to account for increased ^{14}C–UTP incorporation into RNA after addition of the synthetic template. But, as the right hand columns of Table 1 show, when ^{14}C–GTP was used to monitor RNA synthesis, the addition of poly(dA-dT) did not enhance or antagonise incorporation. These results clearly indicate that the endogenous chromatin template retained all of the functionally active RNA polymerase (engaged form) for ^{14}C–GTP incorporation in the presence of the poly(dA-dT) synthetic template. Consequently, the RNA polymerase population that transcribed the poly(dA-dT) template had to be derived from a population of RNA polymerase, which was functionally inactive toward the endogenous chromatin template (free enzyme). The same conclusion was reached when poly(dI-dC) was used as the exogenous template. Where ^{14}C–GTP incorporation into RNA was stimulated several fold, again the endogenous template function, as indicated by ^{14}C–UTP incorporation data, was not significantly affected by the addition of the synthetic template (bottom part, Table 1).

Table 2 Effect of α-amanitin on the engaged and free nuclear RNA polymerase activity measured with endogenous and exogenous template

Incubation conditions	RNA polymerase activity pmol of ^{14}C–UMP incorporated per mg DNA	%	α-Amanitin sensitivity % Inhibition
Nuclei	790	100	30
+ α-Amanitin	551	70	
+ Actinomycin D poly(dA–dT)	931	118	30
+ Actinomycin D poly(dA–dT) α-amanitin	657	83	
+ Poly(dA–dT)	2579	326	52
+ Poly(dA–dT) α-amanitin	1244	157	
+ Actinomycin D	133	17	
+ Actinomycin D α-amanitin	105	13	
Solubilised nuclear enzyme			
+ Native calf thymus DNA	265		47
+ Native calf thymus DNA α-amanitin	141		

Assay conditions were the same as described in Fig. 1. When required, 2 μg α-amanitin (Henley, New York), 10 μg actinomycin D, and 25 μg poly(dA-dT), were added, singly or in combination, to the standard reaction mixture at time zero. Nuclear RNA polymerase was solubilised by the method of Roeder and Rutter[13]. Fraction 4 of the solubilised nuclear enzyme was used for the assay. Calf thymus DNA (25 μg) was used as template. Its activity was expressed as pmol of ^{14}C–UTP incorporated per mg protein.

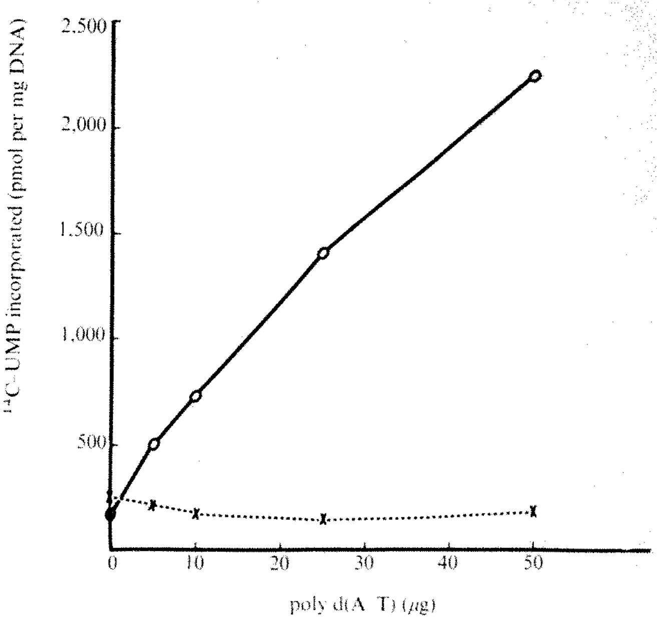

Fig. 1 Male Sprague-Dawley rats, about 200 g body weight, were used. Rat liver nuclei and nucleoli were isolated as described before[4]. RNA polymerase activity was assayed *in vitro* with a standard reaction mixture of 0.65–0.75 ml total volume containing (μmol): Tris-HCl (*p*H 7.9 at 23° C), 50; MnCl$_2$, 1; 2-mercaptoethanol, 14; (NH$_4$)$_2$SO$_4$, 40; and ATP, CTP, UTP and GTP, each, 0.1; with 0.1 μCi of either 2-^{14}C–UTP (Schwarz/Mann, specific activity 42 Ci mol^{-1}) or 8-^{14}C–GTP (Schwarz/Mann, specific activity 39 Ci mol^{-1}) as indicated. When required, 10 μg of actinomycin D (Nutritional Biochemicals) and an indicated amount of poly(dA-dT) (Miles) were also added to the incubation mixture at time zero. The reaction was initiated by the addition of 0.1 ml nuclear or nucleolar suspension in 0.34 M sucrose derived from 0.1 and 0.6 g of liver, respectively, and incubated for 10 min at 37° C with shaking. The reaction was stopped by transfer of the reaction tubes to chipped ice, followed by immediate addition of 5 ml of cold 10% trichloroacetic acid containing 1% sodium pyrophosphate. The acid-insoluble material was collected on Whatman GF/C filters and washed seven times with 5 ml of 5% cold trichloroacetic acid containing 1% sodium pyrophosphate, and once with 5 ml of 60% ethanol. The filters were air dried in liquid scintillation vials and counted in 10 ml of Bray's solution[10]. The specific activity of RNA polymerase was expressed as pmol of labelled ^{14}C–UMP or ^{14}C–GMP incorporated per mg DNA. DNA concentrations were determined as described by Burton[11]. Protein was measured by the method of Lowry *et al.*[12] with bovine serum albumin as standard. Nuclei + actinomycin D (×); nuclei + actinomycin D + poly(dA-dT) (○).

Several species of RNA polymerases are known to exist in eukaryotic nuclei[6]. Since α-amanitin specifically inhibits nucleoplasmic RNA polymerase II (refs 7–9), it was decided to use it as a probe to determine whether the chromatin bound RNA polymerases in both the 'engaged' and 'free' states represent the same enzyme. The results presented in Table 2 show that both the 'engaged' and 'free' nuclear RNA polymerases were similarly inhibited by α-amanitin. For example, the activity of the 'engaged' enzyme on the

Table 3 Effect of α-amanitin on the engaged and free nucleolar RNA polymerase activity measured with endogenous and exogenous template

Incubation conditions	RNA polymerase activity pmol of ^{14}C–UMP incorporated per mg DNA	%	α-Amanitin sensitivity % Inhibition
Nucleoli	1,434	100	
+ α-Amanitin	1,289	90	10
+ Actinomycin D poly(dA–dT)	2,411	168	
+ Actinomycin D poly(dA–dT) α-amanitin	2,534	177	0
+ Poly(dA–dT)	4,614	322	
+ Poly(dA–dT) α-amanitin	3,928	274	15
+ Actinomycin D	0	0	
+ Actinomycin D α-amanitin	0	0	

Conditions were the same as described in the legend to Table 2.

endogenous chromatin template was inhibited 30% by α-amanitin, whereas the 'free' polymerase, which utilised the exogenous poly(dA-dT) template, was also inhibited 30% under conditions where the endogenous chromatin template activity was inhibited by actinomycin D. In the absence of actinomycin D, the inhibition was 52%. This level of inhibition agrees very well with the inhibition of the solubilised RNA polymerase whch was 47% when calf thymus DNA was used as template.

Table 3 presents data which indicate that this toxin had no effect on both the 'engaged' and 'free' nucleolar RNA polymerases, as has been reported[7-9]. These data suggest that the 'engaged' and 'free' forms of RNA polymerase in nuclei most probably represent the same enzyme, and similarly the 'engaged' and 'free' forms present in the nucleolus also are derived from a single population of RNA polymerase molecules.

I thank Julia Lee for technical help. This study was supported in part by a grant from the US Public Health Service.

Location of human satellite DNAs on the Y chromosome

THE technique of *in situ* hybridisation of radioactively labelled DNA or RNA to the denatured DNA in metaphase chromosomes provides a powerful and popular method for identifying the chromosomal location of specific repeated DNA sequences[1,2]. In man, this technique has been used to map the ribosomal cistrons (ref. 3 and H.J.E., M. L. Pardue, and R.A.B., in preparation) and to examine the chromosomal location of three of the four known satellite DNAs[4-8]. Satellite II (ref. 6) was found in the centromeric heterochromatic regions (C band) of chromosome 1 and in the C bands of one C group (chromosome 9) and one E group chromosome pair (tentatively identified as chromosome 16). Satellite III (ref. 8) was found mainly in the C band of chromosome 9, with some in the centromere/short arm regions of the D and G group chromosomes, and possibly in the C bands of chromosomes 1 and 16. The satellite DNA investigated by Saunders *et al.*[7] (which is probably identical to satellite IV of Corneo *et al.*[5]) was only positively identified in the C band of chromosome 9, although other regions of hybridisation were noted. In all these studies on satellite DNAs, the autoradiographic observations were limited because no general chromosome identification was possible. Thus, only major sites of hybridisation could be detected and in some instances the locations of these sites were in doubt.

We have now investigated the chromosome location of the four human satellite DNAs by *in situ* hybridisation using dual karyotype analysis (ref. 9 and J.R.G., R.A.B., R. P. Clayton and H.J.E., in preparaton) (see legend to Fig. 1). This involves quinacrine fluorescence and karyotype analysis of the chromosomes, followed by *in situ* hybridisation and comparison of the autoradiographs with the corresponding fluorescence karyotype. The method allows unequivocal identification of each site

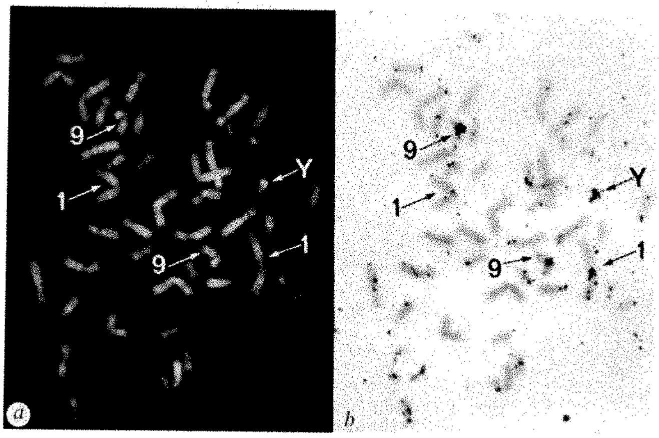

Fig. 1 DNA was prepared from placentae of male babies by the method of Marmur[11]. Satellite DNAs were isolated by centrifugation in Ag^+–Cs_2SO_4 or Hg^{2+}–Cs_2SO_4 density gradients[4,5] and buoyant densities and purity checked in neutral CsCl gradients. ^{3}H-labelled cRNAs were prepared *in situ* hybridisation performed as described elsewhere (J.R.G., R.A.B., R. P. Clayton and H.J.E., in preparation). The cRNAs were hybridised to blood lymphocyte chromosome preparations from various normal, and chromosomally abnormal males and females. Chromosomes were first stained with quinacrine and selected well spread metaphase cells showing good Q banding under fluorescence photographed. Following removal of the stain by washing, hybridisation, autoradiography and staining with Giemsa or Crystal Violet, these cells were again located, re-photographed and dual karyotypes constructed (ref. 9 and J.R.G., R.A.B., R. P. Clayton and H.J.E., in preparation). *a*, Fluorescence photograph of quinacrine stained chromosomes before *in situ* hybridisation. *b*, Giemsa stained autoradiograph of same cell after hybridisation with cRNA prepared from DNA satellite II. Note the concentration of grains over both chromosome 9 and the Y chromosome and that the differences in grain count between homologous chromosomes of pairs 1 and 9, parallel differences in the sizes of their respective C bands.

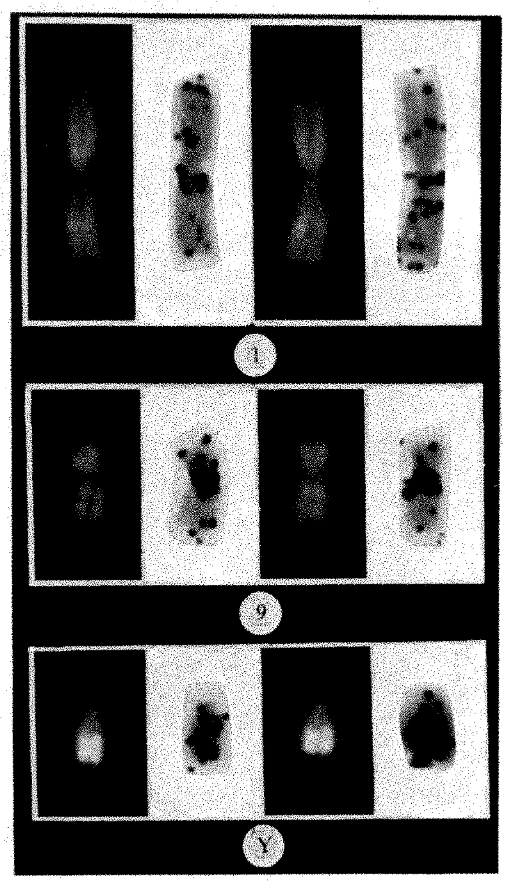

Fig. 2 Partial dual karyotype of chromosomes (1, 9 and Y) prepared from a blood lymphocyte of a 47,XYY male and hybridised with cRNA prepared from DNA satellite IV. All methods were as described in the legend to Fig. 1.

of hybridisation. Full details of these methods and results will be published elsewhere (J.R.G., A.R.M., R.A.B., R. P. Clayton, and H.J.E., in preparation), but we would like to comment here on one important aspect of our findings.

Although our results differ in several minor respects from those previously published, one major location of satellites II, III and IV seems to have been completely overlooked. We find that a substantial portion of all three of these satellites, and also of satellite I, is located in the human Y chromosome, in particular in the brightly fluorescent region of the long arm (Fig. 1)—the region that stains intensely with Giemsa with the C-banding technique. This specific hybridisation to the Y chromosome is a consistent finding, made in numerous experiments using cells from normal males and from males with a 47,XYY chromosome constitution. In the latter case, hybridisation is found on both Y chromosomes and an example is illustrated in Fig. 2.

The apparent discrepancy between our finding and those previously published cannot be accounted for by errors in observation, since the Y chromosome can be identified without recourse to fluorescence analysis, and the amount of cRNA hybridised is large. Saunders *et al.*[7] hybridised cRNA to cultured fibroblast metaphase cells and there is no mention of the Y chromosome or the sex of the donor(s) of these cells. The cRNAs from satellites II and III, however, were hybridised to cells containing a Y chromosome, but no specific hybridisation to the Y was noted[6,8]. The difference is unlikely to be in the origins of the template DNAs used by the different groups, but may be a consequence of differences in techniques used in the hybridisation process.

We have found that the Y chromosome contains a considerable proportion of repetitious DNA, and that some of this is in a satellite-free fraction (J.R.G., R.A.B., R. P. Clayton, and H.J.E.; J.R.G. and A.R.M., in preparation). The present studies show that the human Y chromosome also contains repetitious sequences from all four of the human satellite DNA fractions. Previous cytochemical results have suggested that the human Y chromosome may contain highly repetitious DNA[10], but this is the first direct demonstration of this fact.

Murine leukaemia virus RNA transcription from chromatin of normal and infected BALB/c spleen

STUDIES on Rous sarcoma virus (RSV), murine leukaemia virus (MuLV) and mammary tumour virus (MTV) systems have shown that at least parts of viral genomes are present in multiple copies in the natural host DNA. RSV-specific nucleotide sequences have been detected in various chick cells, including Rous sarcomas and embryos with or without RSV gs antigens and chick helper factor[1,2]. Similarly, normal and virus-transformed mouse and rat cells contained equivalent amounts of MuLV-specific DNA sequences[3]. MTV-specific DNA genomes have been detected in equal numbers in mouse strains with both high and low incidences of mammary tumours[4]. In addition, induction of leukaemia viruses from apparently uninfected mouse and chicken cells indicates that complete, 'endogenous' viral genomes are present in these cells[5-8]. But the integration of 'exogenous' viral genomes, upon infection with an oncogenic RNA virus, cannot be proved in an homologous system because of the lack of specific markers which could distinguish between exogenous and endogenous MuLV genes. Actual integration was demonstrated in the case of some heterologous systems, upon infection of duck and of mouse cells with RSV[9].

Evidence exists that partial transcription of MuLV genomes occurs in a virus-free cell line, but to a lesser extent than in some of its transformed derivatives[10]. A similar observation was reported in the case of MTV-RNA transcripts in tumours, lactating mammary glands, spleens and livers from high and low incidence mouse strains[11]. More direct evidence for transcription of integrated viral genes was obtained by studying DNA-containing tumour virus systems. Polycistronic RNA molecules containing both cellular and viral base sequences were reported in adenovirus and in simian virus 40 (SV40) transformed cells[12,13]. Moreover, Astrin[14] and Shih *et al.*[15] demonstrated that chromatin isolated from SV40-transformed mouse cells can synthesise SV40 RNA transcripts *in vitro*. Here

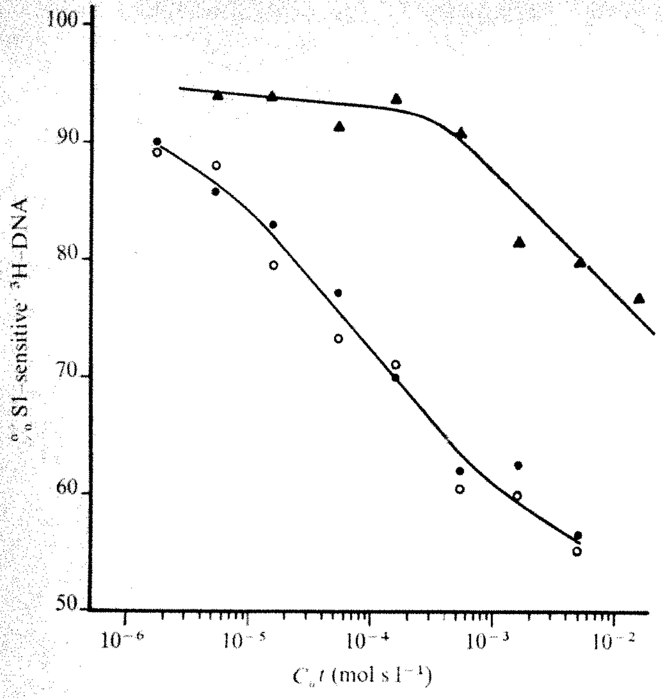

Fig. 1 Annealing curves of RLV–^{3}H–DNA in the presence of 15 mg ml^{-1} of either salmon sperm DNA (▲), normal BALB/c spleen DNA (●), or RLV-infected BALB/c spleen DNA (○). RLV was obtained from Electronucleonics. The virus (approximately 1 mg protein) was incubated for 18 h at 37° C in a 8 ml standard reaction mixture and the ^{3}H–DNA product was purified as described[21]. Non-radioactive DNA was extracted from isolated spleen nuclei of normal and RLV-infected BALB/c mice. The extraction procedure was essentially that of Marmur[22]. It is included two 30 min incubations at 37° C in the presence of 100 μg ml^{-1} RNase and two 30 min incubations at 37° C in the presence of 400 μg ml^{-1} pronase. Salmon sperm DNA (Sigma) was treated with RNase and pronase, and deproteinised before use. DNA fragments were prepared by sonication (Mullard sonifier) and their molecular weight, as determined by analytical ultracentrifugation (Beckman model E), ranged from 130,000 to 160,000 daltons. The DNA samples to be annealed were denatured for 15 min at 100° C in 30 mM Tris, *p*H 7.6. After rapid chilling at 0° C, NaCl was added to a final concentration of 0.6 M. Fifteen microlitre duplicate samples, containing each 4,500 d.p.m. of viral ^{3}H–DNA (Sigma). One of the duplicate samples contained 80 ng 67° C in sealed glass capillaries (Drummond microcaps) for periods of time ranging from 1 min to 6 d. After incubation, the content of each capillary was chilled and poured into 0.6 ml 30 mM sodium acetate, *p*H 4.6, 50 mM NaCl, 1 mM ZnSO$_4$, 5% glycerol and 50 μg ml^{-1} native thymus DNA (Sigma). One of the duplicate samples contained 80 ng ml^{-1} (8 activity units ml^{-1}) of *Aspergillus oryzae* SI-nuclease (prepared according to ref. 23). The mixtures were incubated for 15 min at 45° C, chilled, precipitated in the cold by 1.2 ml 10% perchloric acid (PCA) and filtered through Whatman GF C filters. The filters were washed with 10 ml 5% PCA, dried under a heat lamp and counted in a Packard scintillation counter. The percentage of reannealed ^{3}H–DNA refers to the ratio of SI-nuclease-resistant radioactivity to the total radioactivity in the samples that were not submitted to SI-nuclease treatment. No loss of total PCA-precipitable radioactivity was observed after incubation periods up to 6 d. The results presented in the graphs were not corrected for the presence of nonreannealing ^{3}H–DNA present in the viral product.

we report that MuLV-DNA copies are present in equal amounts in spleen DNA from both normal mice and mice infected with Rauscher leukaemia virus (RLV), but that the viral genomes are expressed to a much larger extent in leukaemia mouse spleen chromatin than in normal spleen chromatin.

RLV-infected BALB/c mice were killed 15 d after virus inoculation. Infected and non-infected spleens were both processed in the same way for DNA extraction, as described in the legend to Fig. 1. The unlabelled cellular DNAs were tested for virus-specific nucleotide sequences by their capacity to accelerate the reassociation kinetics of labelled DNA, synthesised *in vitro* by partially disrupted RLV virions. The apparent reduction in the C_0t values (product of initial concentration of DNA, in mol of nucleotide per l, and time (s)), showed that the reassociation rate of the ^{3}H-DNA product was, in the presence of either infected or uninfected BALB/c spleen DNA, increased about 300-fold over the rate observed in the presence of salmon sperm DNA (Fig. 1). At these concentrations of cellular DNA and viral ^{3}H-DNA product, this degree of acceleration is consistent with the presence of about 40 copies of viral sequences per diploid mouse genome. This result is in good agreement with those of Gelb *et al.*[3], who reported 50 leukaemia virus-specific DNA copies per diploid BALB/3T3 cell.

Subsequently we determined the level of *in vivo* expres-

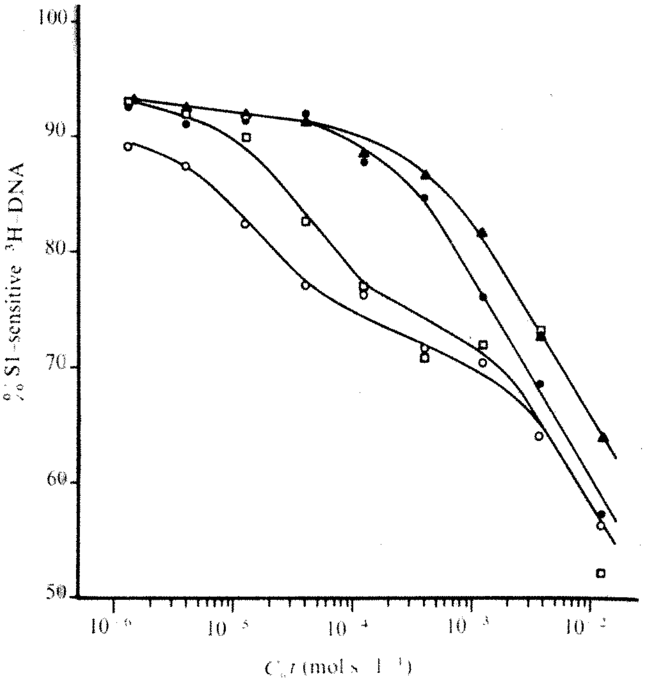

Fig. 2 Annealing curves of RLV–^{3}H–DNA in the presence of 1.4 μg ml^{-1} 70S RLV-RNA (□), 200 μg ml^{-1} endogenous RNA from normal BALB/c spleen chromatin (●), 600 μg ml^{-1} endogenous RNA from RLV-infected BALB/c spleen chromatin (○), or no chromatin nor viral RNA (▲). High molecular weight (70S) RLV-RNA was purified from infected plasma virions according to ref. 24. Chromatin was purified from spleens as described[25], except that the ultimate centrifugation step was omitted to avoid the possible loss of a preferential DNA fraction. It was suspended at a concentration of 150 μg DNA ml^{-1} in 50 mM Tris, *p*H 8.0. NaCl and SDS were added to a final concentration of 0.4 M and 1%, respectively. Deproteinisation was performed on 100 ml volumes (15 mg chromatin DNA) at room temperature by two extractions with an equal volume of phenol-cresol (7:1) and one extraction with chloroform-isoamyl alcohol (24:1). Nucleic acids were ethanol-precipitated, dissolved in 6 ml 10 mM Tris, *p*H 7.6, 0.1 M NaCl and 5 mM MgCl$_2$, and incubated for 60 min at 37° C after addition of 250 μg DNase I (Sigma). Deproteinisation in the presence of SDS and NaCl, and ethanol precipitation were repeated as before. The resulting precipitate was suspended in a minimal volume of 10 mM Tris, *p*H 7.6, and the sample was passed over a 1.6 cm × 100 cm Sephadex-G-50 (medium) column equilibrated with 10 mM Tris, *p*H 7.6. The RNA eluting in the excluded volume was ethanol-precipitated and used for annealing experiments with viral ^{3}H-DNA. The annealing reactions were performed in 20 μl duplicate samples containing 4,500 d.p.m. RLV-^{3}H-RNA, 200 μg yeast RNA (Sigma) and RNA to be tested. The procedure was the same as for annealing in the presence of DNA, except that the SI-nuclease reaction mixtures contained 150 μg ml^{-1} calf thymus DNA and that precipitation was performed with TCA (trichloroacetic acid) instead of PCA.

sion of the viral DNA genomes in chromatin isolated from normal and RLV-infected BALB/c spleens Chromatin from both normal and infected spleens was purified and processed for RNA extraction as described in legend to Fig 2 RLV-^{3}H-DNA was again used as a probe for virus-specific nucleotide sequences in chromatin RNA High molecular weight (70S) RLV-RNA was used as a viral RNA standard Leukaemic spleen chromatin RNA accelerated the reassociation kinetics of the probe ^{3}H-DNA to a much higher degree than did uninfected spleen chromatin RNA (Fig 2), but only over a limited *C₀t* range The latter observation might be explained by the possible presence of nonviral nucleotide sequences in the ^{3}H-DNA product The acceleration rates, when compared with the acceleration effect of the 70S viral RNA, are consistent with the presence of 0 7 and 0 06% viral sequence in the RNA population of leukaemic and normal spleen chromatin, respectively

Endogenous chromatin RNA might consist mainly, if not exclusively, of newly *in vivo* synthesised molecules If so, *in vitro* transcription of chromatin by RNA polymerase would not result in a measurable enrichment of the total RNA population in virus-specific sequences On the contrary, chromatin might contain appreciable amounts of associated RNA, considered as a distinct, structural and/or regulatory component, which does not seem very likely[16–18] In the latter case, the *in vitro* RNA transcripts would contain a higher proportion of viral sequences than the endogenous chromatin RNA Our experiments favoured the first hypothesis we incubated infected and uninfected spleen chromatin in the presence of all four unlabelled ribonucleoside triphosphates Bacterial enzyme was used because, besides the fact that it is easier to prepare in large amounts, it displays a good fidelity in chromatin transcription[14] The incubation resulted in a fivefold increase of the RNA content in the reaction medium This RNA accelerated the reassociation of the probe ^{3}H-DNA to the same degree as did the corresponding, endogenous chromatin RNA In the case of RNA from leukaemic spleen chromatin, the acceleration occurred throughout the observed *C₀t* values, in contrast with the effect of either 70S RLV-RNA or endogenous leukaemic spleen RNA This observation suggests that *in vitro* chromatin transcription yields RNA sequences that are not present, either in the endogenous chromatin RNA population, or in the high molecular weight RLV-RNA These additional sequences are, however, complementary to the ^{3}H-DNA probe Hence the probe should be considered as only partially virus specific

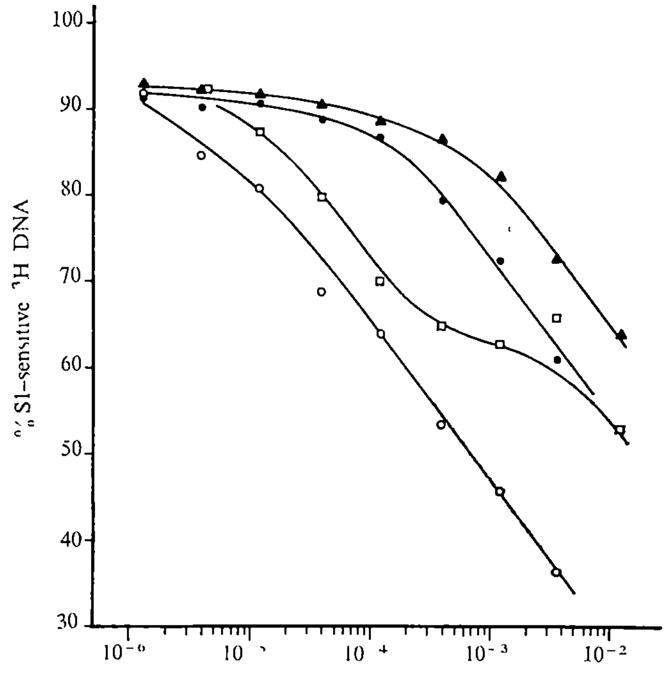

Fig 3 Annealing curves of RLV-^{3}H-DNA in the presence of 1 4 μg ml^{-1} 70S RLV-RNA (□), of 1 1 mg ml^{-1} *in vitro* RNA transcripts from normal BALB/c spleen chromatin (●), of 1 3 mg ml^{-1} *in vitro* RNA transcripts from RLV-infected BALB/c spleen chromatin (○), or neither chromatin nor viral RNA (▲) *E coli* RNA polymerase was purified according to Burgess[26], using the alternate method of gel filtrations on Bio Gel A-5m and Bio Gel A-1 5 m columns *In vitro* synthesis of RNA was performed as follows a 100 ml reaction mixture, containing 50 mM Tris, *p*H 8 0, 100 mM NaCl, 4 mM MgCl$_2$, 1 mM MnCl$_2$, 0 1 mM DTT, 0 2 mM of each unlabelled ATP, CTP, GTP and UTP, 150 μg ml^{-1} DNA in the form of chromatin, and 150 μg ml^{-1} RNA polymerase, was incubated for 45 min at 37° C The reaction was terminated by addition of NaCl and SDS to a final concentration of 0 4 M and 1%, respectively All subsequent operations were performed as described in legend to fig 2

This work clearly demonstrates that endogenous chromatin RNA from RLV-infected spleens, as well as *in vitro* RNA transcripts from the same spleen chromatin, contains very significantly more virus-specific sequences than the corresponding RNAs from the non-infected spleen chromatin Thus, our experiments provide direct evidence that the viral genomes, present in the natural host DNA, are largely expressed in RLV-infected spleen A much lesser degree of expression occurs in the normal tissue

Whether the transcription from leukaemic spleen chromatin occurs at the level of pre-existing or of newly integrated viral genes cannot be discussed here because of the lack of specific markers Finally, we feel that our experimental approach is more direct than those consisting of the detection of viral sequences in cytoplasmic[11,19], polyribosomal[20] or even nuclear[11] RNA populations

We thank Mr C Baes for technical assistance and the Fonds de Cancérologie de la Caisse Générale d'Epargne et de Retraite, Brussels, Belgium for financial support

Detection of cell-dependent cytotoxic antibody to cells infected with herpes simplex virus

The killing or damage of virus-infected cells by immune processes may play a significant role either in host defence or in the production of pathological lesions during virus infections[1] These immune processes are believed to be directed at virus-induced antigens on the membranes of infected cells On the basis of *in vitro* experiments, several mechanisms have been proposed as possibly operative *in vivo* These include the cytolytic action of antibody and complement[2,3], the interaction of antibody, complement and leukocytes[4], and the destruction of infected cells by immune lymphocytes[5–7] Another mechanism described in non-viral systems is the cytotoxicity demonstrated by the synergistic effect of antibody and nonimmune effector cells[8–10] The following experiments demonstrate a similar process operative with viruses in which heat-inactivated immune serum augments the damage of herpes simplex virus-infected cells *in vitro* by human mononuclear cells

Blood from human donors, whose sera contained or lacked neutralising antibodies[11] to herpes simplex virus type 1 (HSV-1), was used Mononuclear cells (MC) were purified from heparinised blood by centrifugation on a layer of Ficoll-Hypaque[12], washed four times in Hanks balanced salt solution (BSS), counted and diluted in Eagle's growth medium containing 10% inactivated foetal calf serum (EGM) Ninety-five per cent of the cells were mononuclear, about 90% of which were lymphocytes, cell viability exceeded 90% All human or rabbit sera to be tested were heat inactivated at 56° C for 30 min The γ-globulin and purified human IgG described below were not heat inactivated

Table 1 Absorption of augmenting factor by HSV-1-infected BHK-21 cells

Added to MC	Absorption with	% cytotoxicity	% augmentation
PHI 1/500	Not absorbed	36 1±1 8	22 8
PHI 1/500	HSV-1-infected BHK	13 4±1 2	0 1
PHI 1/500	Control BHK	32 1±1 7	18 8
Culture medium	- - -	13 3±2 8	0 0

2 0 ml of a 1/50 dilution of pooled HSV-1 immune serum (PHI) in BSS was mixed with an 0 3 ml pellet of either BHK-21 cells previously infected with HSV-1 or control BHK cells The mixture was agitated for 120 min at room temperature and then centrifuged The resulting supernatant was absorbed with a second pellet of infected or control cells for 24 h at 4° C and centrifuged before testing for the presence of augmenting factor Augmentation is defined as the difference between MC+test substance and the MC control (line 4)

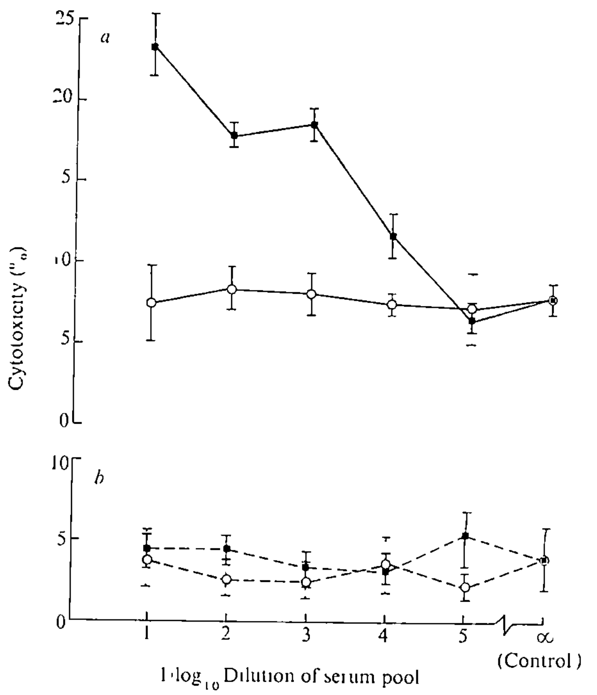

Fig 1 Augmentation of cell mediated cytotoxicity by antibody-positive pooled human sera MC plus dilutions of the seropositive pool (■) are compared with MC plus dilutions of the seronegative pool (○) 5 × 10^5 human MC (obtained from a seropositive donor) with or without positive or negative serum were added per well An effector target cell ratio of 50 1 was found to be optimal in separate experiments The positive and negative pools comprised sera taken from five positive and negative donors, respectively *a*, HSV-1 infected HEp 2 target cells *b*, uninfected HEp 2 target cells

HEp-2 cells (3 × 10^6) were exposed simultaneously to 100 μCi ^{51}Cr and 3 × 10^6 plaque-forming units (PFU) of the Heard strain of HSV-1 in a final volume of 1 0 ml of Eagle's maintenance medium containing 2% inactivated foetal calf serum (EMM) Cells were incubated for 150 min at 37° C and washed four times, 1 × 10^4 cells diluted in EMM were then added to each well of a Falcon Micro Test II plate Control HEp-2 cells were treated in a similar fashion except that no virus was added The sealed plates were incubated at 37° C in a CO_2 incubator and used 24–32 h later when approximately 50% of the infected cells showed cytopathic effects (CPE) At this time, the EMM was removed from each well by aspiration with a Pasteur pipette, and discarded MC, sera or EGM, alone or in combination, in a total volume of 0 25 ml, were added at 37° C for another 8–12 h, unless stated otherwise (see below and Fig 2) The bathing medium was then aspirated carefully with a Pasteur pipette, the monolayer lysed with 1 M NaOH, and the medium and cell lysate transferred to tubes for counting separately in a Nuclear–Chicago gamma counter All determinations were performed in quadruplicate Cytotoxicity was defined, following the practice of Holm and Perlmann[13], as the percentage of ^{51}Cr release observed with lymphocytes and other immune factors less the percentage ^{51}Cr released spontaneously from HSV-1-infected or control HEp-2 cells

During the 8–12 h incubation after the addition of MC and serum, the CPE in the infected cultures increased to involve approximately 90% of the cells Nevertheless, most cells remained attached to the well surface for at least another 12 h Assessment of cell viability after the 12 h incubation revealed that only ~15% of the attached cells stained with Erythrocin B as compared with ~5% of the cells in the control cultures During this incubation, infected and control HEp-2 cells showed 17–37% (mean 29)

Table 2 Titration of human commercial γ-globulin and purified IgG

Added to MC	Dilution	Infected cells % cytotoxicity	Infected cells % augmentation	Control cells % cytotoxicity	Control cells % augmentation
γ-globulin	1/500	45.1±2.9†	26.2	12.3±1.2	−2.3

Hyland γ-globulin (TA No 0442R011A7), dialysed to remove preservative, and lyophilised human IgG (Mann, V-3122) were tested. In addition to IgG, the γ-globulin contained 1.7 mg ml^{-1} of IgM as assessed by radial immunodiffusion[14]. At 4 mg ml^{-1}, the IgG material gave only the typical arc of IgG on immunoelectrophoresis against rabbit anti-human serum, it contained no IgM by radial immunodiffusion (sensitivity < 8 μg ml^{-1} IgM). Neither γ-globulin nor IgG in the absence of MC was more cytotoxic than culture medium for the infected target cells.

* Dilution is expressed in relation to the usual IgG concentration of pooled normal adult sera of about 11.5 mg ml^{-1}

§ $P < 0.05$

and 16–30% (mean 22) spontaneous ^{51}Cr release, respectively, within a given experiment, infected cells showed 5–8% more background ^{51}Cr release than the control cells. Centrifugation (1,500 r.p.m. for 15 min) of the aspirated bathing medium taken from the infected cultures, however, revealed that about 10% of the total c.p.m. were sedimentable, as compared with 3% for control cultures. Therefore the increased ^{51}Cr release of the HSV-1-infected cells appeared to reflect an increment in the relatively small number of loose or dead cells shed into the aspirated medium rather than an increased loss of ^{51}Cr-labelled cellular macromolecules.

Figure 1 presents data typical of four experiments. Cell-mediated cytotoxicity was augmented by the presence of pooled HSV-1 antibody-positive human serum but not by pooled serum with no detectable HSV-1 antibodies. The increments in cytotoxicity were apparent at dilutions 1/10 to 1/10,000 and were statistically significant at $P < 0.001$ (Student's *t* test). The serum pools alone (without MC) had no effect on ^{51}Cr release. The increment due to the addition of serum was reproducible but varied in magnitude from experiment to experiment (range 8–30%). In separate experiments, rendering the aspirated bathing medium cell free by centrifugation did not reduce the difference in leakage observed between infected HEp-2 cells incubated with MC and positive serum and infected HEp-2 cells incubated with MC alone. This implies that the augmenting effect of positive serum was on ^{51}Cr release *per se* and not on the sloughing of cells into the culture medium. There was also a small but consistent cytotoxic effect of MC alone on the infected as compared with the control target cells (Fig. 1). The results from additional experiments showing that this effect can be obtained with MC from either seropositive or seronegative donors, however, would indicate that cell-mediated cytotoxicity conveyed by sensitised effector cells alone is not involved.

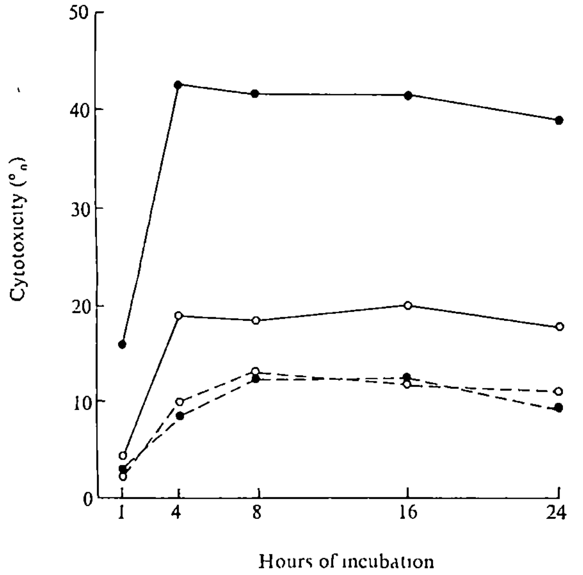

Fig. 2 Effect of time of incubation on augmented cytotoxicity. ———, HSV-1-infected cells; – – – –, control cells; ●, mononuclear cells (from a seropositive donor) (5 × 10^5 per well and 1/500 antibody-positive serum; ○, mononuclear cells alone.

At a 1/500 dilution of the positive serum, a dilution at which no cytolytic (complement-dependent) antibody could be detected, the augmented cytotoxicity was readily apparent 1 h after the addition of the MC and was maximal at 4 h (Fig. 2). In subsequent study of this phenomenon, an 8–12 h incubation was used.

Nine human immune sera and eight nonimmune sera were tested individually at a 1/500 dilution for augmentation of cytotoxicity. All sera containing HSV-1 neutralising antibody augmented cytotoxicity, in contrast the sera with no detectable HSV-1 antibody failed to do so. In addition, serum from an HSV-1-immunised rabbit showed augmentation, whereas nonimmune rabbit serum did not. The ten immune sera showed augmentation of 11.0 ± 1.8% compared with 0.5 ± 1.3% for the nonimmune sera ($P < 0.001$).

The augmenting factor could be removed by absorption of antibody-positive human serum with HSV-1-infected BHK-21 cells but not by uninfected BHK-21 (Table 1). It was also present in high titre both in pooled human γ-globulin (1/50,000) and in highly purified pooled human IgG (1/15,000) (Table 2). These findings taken together strongly suggest that the factor is an antibody of the IgG class.

The fact that the augmenting antibody was found not only in heat-inactivated serum, but at serum dilutions far in excess of those detected by complement-dependent cytolytic antibody assay (not greater than 1/100 in our laboratory), indicated that the classical complement sequence is not necessary for expression of activity. The participation either of complement proteins produced by the MC in our assay system[15,16] or of an alternative pathway using complement components[17] cannot, however, be excluded. It is interesting that Wunderlich *et al*[18] found that addition of exogenous human complement does not enhance antibody-dependent cell-mediated cytotoxicity (ADC) in an allogeneic target cell system.

Because ADC has been shown in other systems to be mediated by effector cells obtained from either nonimmune or immune individuals[8], it was interesting to compare the degree of augmentation by MC from HSV-1 immune and nonimmune donors. In the presence of a 1/500 dilution of pooled γ-globulin, cells obtained from five seropositive human donors and three seronegative donors showed $12.4\pm4.6\%$ and $13.3\pm2.2\%$ augmentation, respectively. Thus, the presence or absence of neutralising antibodies in an individual does not appear to influence the ability of his or her mononuclear cells to demonstrate the augmentation phenomenon.

The effector cell in our heterogeneous Ficall-Hypaque-purified MC population is unknown. The similar cytotoxicity of nonimmune and immune mononuclear cells in our system as well as the augmentation rather than blocking of cytotoxicity by immune serum suggest that it is not the T lymphocyte. Furthermore, in a nonviral system, the effector cells for ADC in the rat are thymus-independent[19]. The monocyte[20], an adherent cell, is a possibility, however, in other models of ADC, the effector cell is a nonadherent cell[19,21], and preliminary experiments in our laboratory also indicate that the effector cell in our system is nonadherent to a plastic surface. The likely non-adherent effector cell, therefore, probably is a B lymphocyte or the recently described null lymphoid cell[22]. Attempts are now being made in our laboratory to identify the specific effector cell.

The cytotoxic effect of mononuclear cells and immune serum on HSV-1-infected cells is similar to the synergistic or antibody-dependent cytoxicity models described for unsensitised or antigen-coated chicken erythrocytes[8], Chang liver cells[9], allogeneic cells[18,23] and animal tumour cells[10]. These findings therefore extend the possible role of serum arming factors[10] to the immune damage of cells undergoing acute virus infection.

We thank Drs S. Sprecher-Goldberger and L. Thiry for suggesting the use of herpes-infected cells as targets. This work was supported by grants from the National Foundation, the National Cancer Institute and the Center for Disease Control.

Cyclic GMP stimulates lymphocyte nucleic acid synthesis

AGENTS that trigger proliferation of lymphocytes[1] and other cultured cells[2] have also been reported to stimulate increases in intracellular guanosine 3′,5′-monophosphate (cyclic GMP). These observations raise the interesting possibility that endogenous cyclic GMP acts as the intracellular mediator of some of the effects of mitogenic agents. If so, then it might be possible to demonstrate experimentally that cyclic GMP, introduced exogenously, has a mitogenic effect. We tested this possibility in mouse splenic lymphocytes and compared the mitogenic effects of cyclic GMP and two of its synthetic derivatives, 8-bromo-cyclic GMP (8-Br cyclic GMP) and N^2 O^2-dibutyryl-cyclic GMP (dibutyryl cyclic GMP), with that of concanavalin A (con A), a mitogenic lectin reported[1] to increase the cyclic GMP content of human lymphocytes. Our results indicate that, like con A, cyclic GMP and its derivatives can stimulate RNA and DNA synthesis in lymphocytes.

Splenic leukocytes from BALB/c mice were prepared as previously described[3] and cultured in serum-free RMPI-1640 medium, at 37° C in an atmosphere of 5% CO_2, 95% air. After addition of nucleosides or con A to the cultures, stimulation of

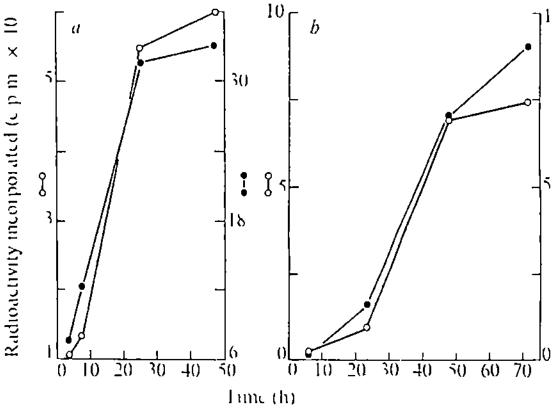

Fig 1 Time course of incorporation of (*a*) ^{3}H-uridine (26 Ci mmol^{-1}, New England Nuclear Corp.) and (*b*) ^{3}H-thymidine (15 Ci mmol^{-1}, New England Nuclear Corp.) into acid-precipitable macromolecules of spleen cells exposed to 8-Br cyclic AMP (Sigma), 1×10^{-3}M (○), or con A (Miles-Yeda), 0.5 μg ml^{-1} (●). Cells (2×10^6 per tube) were incubated in 0.5 ml RPMI-1640 medium (Grand Island Biological Co.). At the times indicated on the abscissa, 2 μCi of ^{3}H-labelled precursor was added to the culture and incubation was continued for an additional hour (for uridine) or 2 h (for thymidine), then 2.5 ml 5% TCA was added. The cells were centrifuged and washed two times with 5% TCA, then dissolved in 0.2 ml NaOH, and counted in liquid scintillation solution. Each point represents the mean of triplicate cultures, differing by not more than 10%, the quantity of radioactivity incorporated into cells in parallel cultures not treated with drugs has been subtracted (3,500 c.p.m. for uridine, 600 c.p.m. for thymidine).

Table 1 Effect of cyclic nucleotides and con A on thymidine incorporation

Additions	Control*	Dibutyryl cyclic AMP, 2 × 10^{-4}M
None	2 4	3 4
8-Br cyclic GMP, 1 × 10^{-3} M	13 2	12 3
Con A, 0 5 μg ml^{-1}	89 1	16 2
Con A + 8-Br cyclic GMP	107 3	34 0

Culture conditions and assay are described in the legend to Fig 1 Thymidine incorporation was measured in triplicate at 44 h Figures are c p m × 10^{-3}

*In these experiments dibutyryl cyclic AMP was omitted

nucleic acid synthesis was assessed at intervals by measuring the incorporation of pulses of radioactive uridine or thymidine into trichloroacetic acid (TCA)-precipitable material

8-Br cyclic GMP caused time-dependent increases in RNA and DNA synthesis, as indicated by uridine and thymidine incorporation, respectively (Fig 1) Stimulation by 8-Br cyclic GMP paralleled temporally that produced by con A, although the lectin produced quantitatively greater effects Uridine incorporation increased early with both 8-Br cyclic GMP and con A, and reached a plateau at about 25 h (Fig 1*a*) The increase in thymidine incorporation, which was initially detectable at 20 h, plateaued at about 46 h (Fig 1*b*)

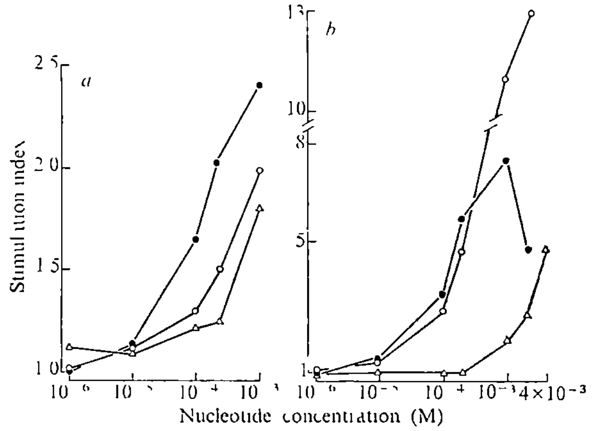

Fig 2 Stimulation of ^{3}H-uridine (*a*) and ^{3}H-thymidine (*b*) incorporation into TCA-precipitable macromolecules by various concentrations of guanosine 3′,5′-cyclic nucleotides △, cyclic GMP, ●, dibutyryl cyclic GMP, ○, 8-Br cyclic GMP Stimulation index (ordinate) is the ratio of incorporation by nucleotide-treated cultures to that by cultures without adding drug (4,100 c p m for uridine and 1,200 c p m for thymidine) Incorporation was measured at 20 h for uridine and 44 h for thymidine Triplicate points agreed within 10% The incorporation assay and culture conditions are described in the text and the legend to Fig 1 Viability of cells (assessed by exclusion of trypan blue) was not affected by the nucleotides at concentrations shown The spleen leukocytes in these experiments were 90–95% lymphocytes, contaminated with 5–10% macrophages and some erythrocytes Identical results were, however, obtained if erythrocytes were removed by osmotic lysis and macrophages removed by adsorption to Petri dishes or glass wool

The stimulatory effects of 8-Br cyclic GMP, dibutyryl cyclic GMP, and cyclic GMP itself, were dose dependent (Fig 2) At 1 × 10^{-3} M the cyclic GMP derivatives produced a 2 to 2 5-fold stimulation of uridine incorporation and an 8 to 11-fold increase in thymidine incorporation Cyclic GMP was less potent and produced mitogenic effects at high concentrations only (4 6-fold stimulation of thymidine incorporation at 4 × 10^{-3} M) 5′-Guanosine monophosphate did not stimulate thymidine incorporation at concentrations between 10^{-4} and 4 × 10^{-3} M (results not shown)

Since endogenously synthesised adenosine 3′,5′-monophosphate (cyclic AMP) and exogenous $N^6,O^{2'}$-dibutyryl cyclic AMP (dibutyryl cyclic AMP) have been reported to inhibit the lectin-induced mitogenic activation of lymphocytes[4,5], we asked whether dibutyryl cyclic AMP could inhibit the stimulatory effects of 8-Br cyclic GMP The dibutyryl cyclic AMP derivative was used at a concentration (2 × 10^{-4} M) that maximally inhibited con A-stimulated thymidine incorporation without reducing cell viability (measured by exclusion of trypan blue) Dibutyryl cyclic AMP did not affect the stimulation of thymidine incorporation caused by 1 × 10^{-3} M 8-Br cyclic GMP although it did inhibit stimulation by con A by 80% (Table 1) In addition 8-Br cyclic GMP did not protect con A-stimulated cells from inhibition by dibutyryl cyclic AMP (Table 1) In fact the stimulation of thymidine incorporation by 8-Br cyclic GMP appeared to be approximately additive to that caused by con A (at a concentration found in preliminary experiments to be maximally effective) whether or not dibutyryl cyclic AMP was present It appears likely that the cyclic GMP derivatives stimulate a subpopulation of splenic lymphocytes smaller than that stimulated by con A

It has been proposed that cyclic AMP and cyclic GMP act in opposite directions in biological systems, so that the ratio of the two nucleotides within cells regulates many cell functions, including growth[6] Cyclic AMP inhibits the growth of cells in culture[7], as well as the lectin-induced transformation of lymphocytes[4,5] We have found that exogenous cyclic GMP and two of its chemical derivatives can stimulate resting mouse spleen lymphocytes to synthesise RNA and DNA, with a time course similar to that caused by con A

Do immunoglobulins have proteolytic activity?

As more and more proteins are sequenced, the search for sequential and structural interrelationships among them is becoming a major activity, even though it is still in its infancy compared with investigations dealing with ancestral relationships[1,2] For our study of homologous regions found among ancestrally unrelated proteins we have modified McLachlan's double matching method[3] and used it to find the statistically significant homologies The method, the details of which are being published elsewhere[4], enables a computer to perform a sliding match between two proteins, either when both proteins are aligned from N-terminal to C-terminal, which we call 'normal matching', or when one is aligned from N-terminal to C-terminal while the other is aligned from C-terminal to N-terminal, which we call 'reverse matching' At each step during this sliding match, some amino acids will be found to be identical between the two proteins being matched and some others will be different Based on similarities found among ancestrally related proteins the probability of each amino acid being substituted by another is calculated—the *M* score of similarity[3]—and printed The scores reach from 0, a non-match, all the way to 8 and 9 both of which stand for exact matches, 9 being assigned to phenylalanine, cysteine, tyrosine and tryptophan For ease of detection, the printout has a stop ( ) for a score of 8 and a prime (′) for a score of 9 (ref 4) The same molecule can also be matched against itself to reveal the presence of repeating subsequences and symmetry patterns[5]

During this study it was observed that the serine-containing active site fragment of bovine trypsin as well as of *S griseus* proteolytic enzyme matched the variable region of Bence Jones protein λ SH with an exceptionally high *M* score corresponding to a gaeat statistical significance (Tables 1 and 2) More than one homologous region was observed between the histidine, aspartic acid and serine-containing active site fragments of trypsin and Bence Jones λ human SH, in other words there were multiple copies of each trypsin active site fragment with varying degrees of significance, in Bence Jones λ human SH This suggests to us the possibility for the repeating sequences found in many proteins[6] to be related to a limited number of primordial subsequences from which all proteins could have evolved[5] We are not aware of any report which links any proteolytic activity with immunoglobulins The level of significance that was obtained between Bence Jones λ human SH and serine-containing active site fragments of various proteolytic enzymes, however, is so great that we decided to compare the distances between the serine, aspartic acid and histidine active site fragments of trypsin with the distances between various homologues of these fragments on Bence Jones λ human SH

Table 1 Significant homologies found between the Bence Jones λ human SH and serine-containing active site fragment of various proteolytic enzymes

Target protein	Position number	Matching sequences Individual scores	*M* score	Double matching probability
S grieseus enzyme	*	TCQGDS ′	49	8 8 × 10^{-9}
Trypsin, bovine	183	SCQGDS 5′	46	8 8 × 10^{-8}
Chymotrypsin A & B, bovine	195	SCMGDS 5′ 3 .	41	5 7 × 10^{-6}
Key protein				
Bence Jones λ SH	20	TCQGDS		

Target represents the protein(s) matched and key the protein which is used to find the matching sequences among the target proteins Position number indicates the position along the protein, of the sequence being matched, numbered contiguously from the amino terminal of the protein Contiguous numbering is used to avoid confusion arising from many different groups introducing gaps into their sequences for various reasons The numbers, periods and primes below the target sequences represent the individual similarity scores between the amino acids of the target and the amino acid of the key directly below it *M* score shows the cumulative score for the span length of the key, which is obtained by summing of the individual scores Double matching probability gives the probability for such a matching occurring by chance The f_A used in this matching represents the composition of amino acids of the key[3] and f_B the composition of the universe of proteins given in ref 1 according to ref 4

The single letter amino acid alphabet is used[1], for the sake of indisputable clarity, when alignments are given S, serine, C, cysteine, Q, glutamine, D, aspartic acid, T, threonine K, lysine, N, asparagine, A, alanine, F, phenylalanine, R, arginine, M, methionine

* Not known since only fragments have been sequenced

Table 2 Significant homologies found between serine-containing active site fragment of trypsin and different Bence Jones proteins

Target protein	Position number	Matching sequences Individual scores	*M* score	Double matching probability
Bence Jones λ human SH	20	TCQGDS 5′	46	8 8 × 10^{-8}

Legend as Table 1

A close examination of the three dimensional model of an immunoglobulin made it possible to eliminate many of these possibilities leaving only two regions where the sequences found homologous to the three active site fragments of trypsinogen are reasonably close to each other One of these regions is located at the amino-terminal end of the light chain (the variable region) completely exposed to the outside The distances between the three amino acids serine aspartic acid and histidine are given in Table 3 The other area is in the constant region of the light chain but completely buried inside the molecule (Table 3)

The distances between trypsin active site fragments, calculated from atomic coordinates, is also given in Table 3 Whether any immunoglobulin molecule would exhibit proteolytic activity can only be determined experimentally We speculate that the area in the variable region of the immunoglobulin exposed to the outside might be the site for proteolytic activity, which would possess very little selectivity Perhaps a peptide would be needed to bind to this area and bring the distances between the indicated amino acids closer to the distances found between serine, histidine and aspartic acid fragments of trypsin

Table 3 Distances (in Å) between the active site residues of trypsin and homologous residues of Bence Jones λ human SH

Trypsin	$S_{188}-H_{46} = 8\ 7$	$S_{188}-D_{90} = 11\ 0$	$H_{46}-D_{90} = 6\ 1$
Bence Jones	$P_7-S_{71} = 16$	$P_7-S_{26} = 22$	$S_{26}-S_{71} = 7$
Bence Jones	$H_{176}-S_{198} = 14$	$H_{176}-D_{200} = 18$	$S_{198}-D_{200} = 4$

The distances for trypsin were calculated from its atomic coordinates The distances for Bence Jones λ human SH were measured from its model The first set represent the homologous sites at the variable region of the immunoglobulin molecule and the second set the constant regions (see text) Numbers indicate the position of the amino acid contiguously from the N-terminal of the protein

A recent study[7] has demonstrated that mutants of *Escherichia coli* K12 with deletions of *lac Z* gene can re-acquire the ability to hydrolyse β-galactosides Full lactose competence was restored through a sequence of at least five mutations The enzyme evolved differed from the *lac Z* β-galactosidase of the wild type *E coli* in its immunological, kinetic and sedimentation characteristics The authors suggested that the adaptation of a gene not involved in lactose utilisation to a form capable of specifying a β-galactosidase is similar to evolution by natural selection

We believe that the gene(s) coding for the protein whose active site fragment(s) has a three dimensional conformation closest to the active site fragment(s) of the wild type β-galactosidase is the one which underwent five or so mutations to yield the new enzyme[5]

We thank Dr R J Poljak for the use of his molecular model of the immunoglobulin molecule, Drs R M Stroud and R E Dickerson for sending the atomic coordinates of trypsin and Drs J P Glusker and H M Berman for providing help to obtain interatomic distances between active site fragments of trypsin

Specificity of antigen receptors for cytochrome *c* in delayed hypersensitivity

The specificity of receptors on thymus-derived cells (T) and bone marrow-derived cells (B) for the same antigen is of interest if the various immune responses directed towards protein antigens[1] are to be understood Detailed molecular studies of such specificities can only be undertaken with protein antigens of known structure Following a large body of detailed work on the antigenic structure of cytochrome *c* for determinants related to antibodies[2], we report here the beginnings of a similar approach to an analysis of the determinants in cytochrome *c* related to delayed hypersensitivity

Female albino Hartley guinea pigs (400–450 g) were immunised with 1 0 mg of horse cytochrome *c* in 0 2 ml phosphate buffered saline (PBS) (emulsified with an equal volume of Freund's complete adjuvant (FCA)) by the injection of 0 1 ml into each footpad Two weeks later the animals were skin tested with 0 1 mg of horse cytochrome *c* in 0 1 ml PBS The sites of injections were assessed for thickness with a caliper (Schnelltaster, System Kroplin AO2T, Kroplin, Schluchtern, Germany) at 2, 4, and 24 h, as was the diameter of erythema No significant reactions were noted at 2 or 4 h and injection of unimmunised guinea pigs had no significant effects at any time interval In addition to the absence of 'immediate' type skin reactions, a search for specific antibody was made by several methods and in every case found to be negative, as has previously been reported[3] The sera for testing were taken 4 d following the skin test dose in 15 consecutive animals Passive haemagglutination using the glutaraldehyde method for coupling[4] the cytochrome *c* to sheep erythrocytes was used and titrations were carried out in microtitre plates All 15 sera had a zero titre while a positive control rabbit antihorse *c* (cytochrome *c*) serum containing 0 1 mg antibody protein ml^{-1} had a titre of 1 160 with such cells Passive cutaneous anaphylaxis (PCA) was carried out with three serum pools from groups of five animals 0 1 ml of such pooled sera at a 1/5 dilution gave negative PCA reactions Finally, all 15 sera were tested by a radioimmunoassay double antibody method[5] A potent rabbit anti-guinea pig γ globulin serum was used as second antibody In all 15 sera, 2 μl of immune guinea pig serum bound less than 5% of a tracer dose of 20 ng of ^{131}I-horse cytochrome *c* We thus concluded that in these animals at the time of testing no detectable circulating antibody was present

On the other hand, all animals had significant delayed reactivity at 24 h with erythema averaging 1 3 cm (± 0 5) in diameter and in duration averaging 0 65 mm (± 0 3) The specificity of this reaction was then studied by skin testing horse *c* immunised animals with various heterologous cytochromes *c* The results are illustrated in Fig 1 Skin thickness relative to the activity of horse *c* is plotted as a function of the number of amino acid differences existing between horse *c* and the heterologous *c* used for skin testing The specificity of the reaction is quite restricted Kangaroo, turkey, human, and tuna cytochromes *c* which differ from horse *c* by 7, 11, 12 and 17 amino acids, respectively, give no detectable skin responses in animals immunised with horse *c* Donkey, bovine, and sheep (the latter two cytochromes *c* have an identical primary sequence) cytochromes which differ from the horse protein by one, three and three amino acids, respectively, are indistinguishable from horse *c* in skin tests while whale *c* (which differs by five residues from horse *c*) is about one half as effective in the skin tests Dog and rabbit cytochrome *c* which differ by six residues from the horse protein are even less active than the whale protein As bovine cytochrome *c* exhibits all the skin reactivity of the horse protein, the three sequence differences between them are not the residues conferring specificity in this reaction The relevant sequence comparisons are listed in Table 1

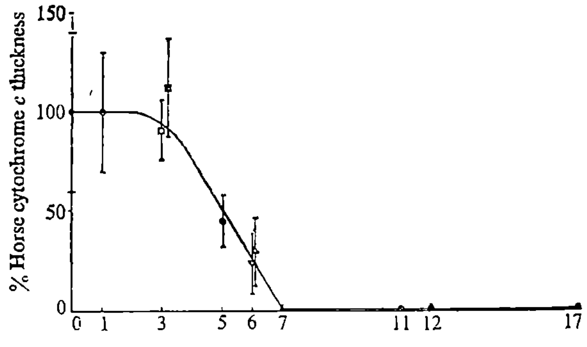

Fig. 1 Cross reactions of various heterologous cytochromes *c* in horse *c* immunised animals Horse (●), donkey (half filled circle,) bovine (half filled square), sheep (□), whale (diagonal crossed circle), dog (▽), rabbit (△), kangaroo (▲), turkey (diagonal crossed square), human (vertical crossed circle), and tuna (■) The vertical line through the symbol represents one standard deviation of the mean of the skin thicknesses, 24 h after skin test Sequence data from Dayhoff[16]

The two sequence differences between whale and bovine *c* are important, however, as are the two differences between the whale and rabbit proteins Sequence position 92 is of special interest since bovine and horse *c* both carry glutamic acid there, while the whale and rabbit proteins carry alanine In the same region at position 89, rabbit *c* carries aspartic acid while the bovine and whale proteins carry glycine Thus, there is an order of sequence similarity and differences which parallels the quantitative changes in specificity In the region encompassing sequence positions 89 and 92, bovine *c* is most like the horse protein, rabbit *c* is the most distantly related and whale *c* is intermediate in structure There are also amino acid differences at positions 44 and 62 which could contribute to the specificity differences exhibited by the bovine and whale proteins and between the whale and rabbit proteins, respectively

Table 1 Cytochrome *c* sequence comparisons

	44	62	89	92
Horse	Pro	Glu	Thr	Glu
Bovine	Pro	Glu	Gly	Glu
Whale	Val	Glu	Gly	Ala
Rabbit	Val	Asp	Asp	Ala

Sequence data from Dayhoff[16]

This structural specificity is related to these sequence differences in the context of the three-dimensional structure of cytochrome *c* The evidence for this is that the cyanogen bromide fragments of cytochrome *c* which comprise the sequences 1–65, 1–80, 66–80, and 81–104 are all inactive in eliciting delayed skin reactions in animals immunised with horse cytochrome *c* Such data suggest that the determinants responsible for the skin reactivity are very conformation dependent, a situation which is extremely common with antigenic determinants in globular proteins[6,7] The cross reactions in this delayed-hypersensitivity system are quite limited and, in fact, exhibit a narrower specificity than do the comparable cross reactions carried out with rabbit antibody to horse cytochrome *c* (ref 2)

This high specificity for the immunogen in cross reactions of delayed hypersensitivity is not restricted to the horse protein Guinea pigs immunised with either human or turkey cytochromes *c* do not cross react with horse *c* in skin tests The strength of the homologous reactions is comparable to that of horse *c*-immunised animals and no circulating antibody was demonstrable in either human or turkey *c*-immunised guinea pigs

Such high specificity has often been demonstrated in delayed hypersensitivity reactions involving the dinitrophenyl-oligolysine system[8] and a number of other systems involving haptenated autologous proteins[9,10] On the other hand, cross reactions of delayed hypersensitivity to proteins have generally shown a very broad specificity and frequently exhibit good to excellent cross reactions between antigens that do not measurably cross react with specific antibody[11–15] Thus, the cytochrome system exhibits the type of exquisite specificity more characteristic of delayed reactivity to haptenes than of the type generally characteristic of protein antigens

The cytochrome system would seem to be an ideal one for the study of the molecular relationship of those structures responsible for interaction with receptors of the two kinds of lymphocytes involved in immune responses

This work was supported in part by a United States Public Health Service grant to M R Horse cytochrome *c* was purchased from the Sigma Chemical Co, St Louis, Missouri and all other cytochromes *c* were supplied by Dr Emanuel Margoliash of Northwestern University, Evanston, Illinois The cyanogen bromide fragments of horse cytochrome *c* were supplied by Dr Lucille Smith of Dartmouth University, Hanover, New Hampshire

Hepatitis B and serum DNA polymerase activities in chimpanzees

THE association of hepatitis B antigen (Australia antigen, HBs Ag) in human serum with DNA polymerase activity was first reported by Hirschman *et al*[1] This has been confirmed and extended by Kaplan *et al*[2] who found DNA polymerase activity in preparations of concentrated human hepatitis B antigen which were rich in Dane particles The DNA polymerase activity previously described by Hirschman *et al*, however, was considered to be dependent on an RNA template, whereas the DNA polymerase reported by Kaplan *et al* appeared to be a DNA-dependent DNA polymerase

No studies have been reported on serum levels of DNA polymerase activity in subjects experimentally infected with aetiological agents of hepatitis B We have infected chimpanzees with hepatitis B viruses[3] to study the temporal relationship between DNA polymerase activity in serum and the appearance of HBs Ag Four susceptible chimpanzees were inoculated intravenously with sera containing hepatitis B antigen Each chimpanzee was monitored for serum HBs Ag and corresponding antibody (anti-HBs) during the course of infection by a solid-phase direct radioimmunoassay (RIA) system[4] Liver damage was assessed by measuring serum glutamic pyruvate transaminase (SGPT) activity and by histological examination of liver biopsy tissue Serum samples were obtained under anaesthesia three times weekly, and assayed for DNA polymerase and HBs Ag or anti-HBs For DNA polymerase we used a modification of the method of Robinson and Robinson[5]

Of four animals inoculated, three developed infections characterised by the occurrence of transient HBs Ag followed by anti-HBs production In all three hepatitis B was confirmed enzymatically and histologically The fourth animal did not develop HBs Ag or evidence of hepatitis but produced late-occurring anti-HBs 70 d after inoculation

In all four animals we found spikes of DNA polymerase activity, the first increases being uniformly observed between the 20th and 40th days after inoculation In the three animals who experienced antigenaemia and hepatitis, first spikes in DNA polymerase either closely preceded or paralleled the first appearance of HBs Ag and always occurred before first increases in transaminase levels Figure 1 shows these relationships for one of the three animals (Ike), and reveals a second DNA polymerase peak post-dating the bulk of the antigenaemia and closely preceding the transaminase peak In the other two animals experiencing hepatitis, increases in DNA polymerase activity clearly preceded the first appearance of HBs Ag (by 20 d in one animal, and by 25 d in the other) and similar secondary

Table 1 Effect of reaction conditions on DNA polymerase activity (Ike) in two serum pools

	Complete, no additions	−NTPs	+Act D	+DNase	+RNase	+poly (dA-dT) poly (dA-dT)
Day 26 Pool	129*	36	23	79	121	77
Day 33 Pool	411	137	50	128	405	304

*Net c p m (gross c p m less background and zero-time c p m)

Pools of serum obtained on days corresponding to DNA polymerase peaks occurring on days 26 and 33 were tested for the effects of various additions and deletions on the incorporation of ^{3}H-dTTP into a TCA-insoluble product Final reaction-mixture concentrations of the additions were actinomycin D, 10 µg ml^{-1}, DNase (EC 3 1 4 5), 10 µg ml^{-1}, 30 min at 37° C, RNase (EC 2 7 7 16), 10 µg ml^{-1}, 30 min at 37° C, poly(dA-dT) poly(dA-dT), 25 µg ml^{-1}

polymerase peaks appeared in both and coincided with increases in transaminase levels

As Fig 2 shows, the serum of the fourth animal (Jay) showed spikes in DNA polymerase activity between the 20th and 40th days and the 50th and 70th days after inoculation in the absence of detectable HB$_s$ Ag or increases in transaminase activity Anti-HB$_s$ was first detectable on day 70

Characterisation of the two DNA polymerase activities found in Ike's serum is summarised in Table 1 Both were inhibited by actinomycin D (10 µg ml^{-1}) or poly(dA–dT) poly(dA–dT) (25 µg ml^{-1}), indicating that these activities do not depend on an RNA template Preincubation of the day 26 pool and the day 33 pool reaction mixtures (Table 1) with ribonuclease did not affect the incorporation of ^{3}H-TMP into trichloroacetic acid (TCA)-precipitable products, further suggesting that these polymerase activities do not depend on an endogenous RNA template The products of the polymerase reactions, however, were partially sensitive to DNase Omission of nucleoside triphosphates from either of the reaction mixtures resulted in decreased incorporation of ^{3}H-dTTP into acid insoluble products

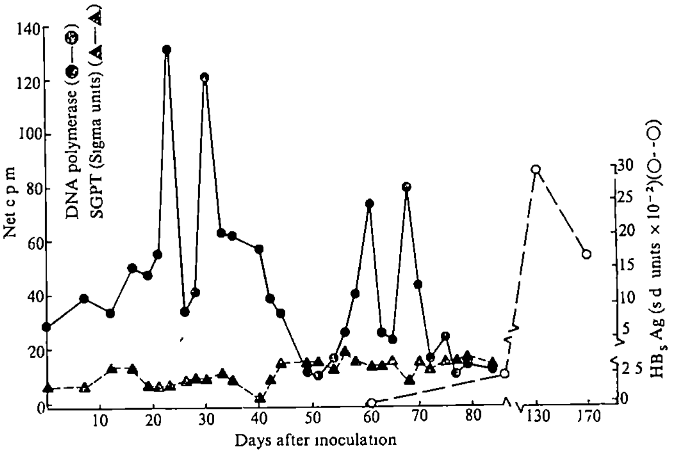

Fig 2 Chimpanzee Jay Serum assays are identical to those in Fig 1, except that 15 mM Mg^{2+} was substituted for 5 mM Mg^{+2}, the final assay was 0 1% in Triton X-100

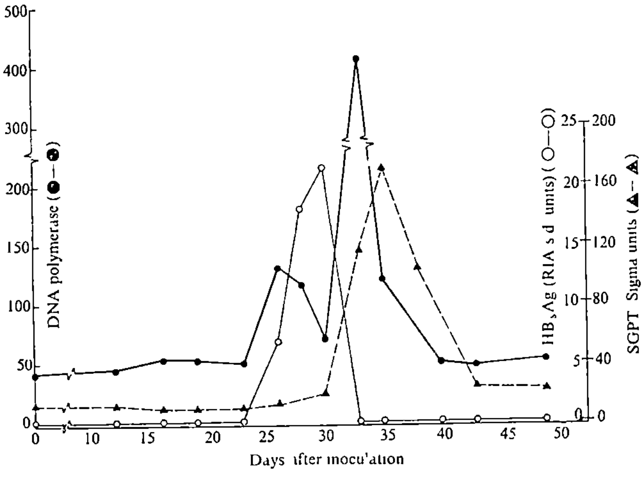

Fig 1 Chimpanzee Ike DNA polymerase activity in serum was determined by a radioisotopic method which measures the incorporation of ^{3}H-dTTP into TCA-insoluble product The polymerase assay contained in a volume of 0 300 ml 50 µl serum, 200 µl 0 1 M Tris-HCl buffer, pH 8 3, the balance of the reaction mixture contained (final assay concentrations) mercaptoethanol (2 5 mM), dATP, dCTP, dGTP (0 25 mM each), MgCl$_2$ 6H$_2$0 (5 mM, unless otherwise noted), KCl (40 mM), and ^{3}H dTTP (0 93 µM) The reaction mixture was incubated for 60 min at 37° C, 100 µl of the mixture was pipetted into 5 ml of ice-cold 5% TCA+2% pyrophosphate solution to precipitate the labelled product The precipitate was collected on a Millipore filter (EAWPO2500) and washed repeatedly with 5% TCA+2% pyrophosphate, 80% ethanol and dried with diethyl ether The disk was placed in 10 ml of toluene PPO-POPOP cocktail for counting Background and zero-time assays c p m were subtracted to yield net c p m Serum glutamic pyruvate transaminase (EC 2 6 1 2) was measured by colorimetric Sigma procedure Serum HB$_s$ Ag was determined by a solid-phase direct radioimmunoassay (AusRIA, Abbott Laboratories) Results for HB$_s$ Ag are expressed in standard deviation (s d) units Preinoculation chimpanzee serum polymerase activity averaged 24 c p m

Based on the results of our study of DNA polymerase activity in four chimpanzees infected with hepatitis B viruses, we believe two preliminary conclusions can be drawn First, for animals experiencing hepatitis, DNA polymerase activity appears in the serum before the onset of antigenaemia and liver damage and may represent replication of viral DNA Second, the postulated viral DNA polymerase activity (in Ike) seems to depend on a DNA template rather than on an RNA template—this idea is consistent with the findings of Kaplan *et al*, who demonstrated that DNA polymerase activity associated with the Dane particle was inhibited by actinomycin D and daunomycin Furthermore, the detection of increased DNA polymerase activity in an infected animal (Jay) who showed no clinical, enzymatic (SGPT) or immunological (HB$_s$ Ag) evidence of hepatitis during the first 70 d after inoculation suggests the DNA polymerase assay may be useful in screening potentially infective sera

Release of enzymes from cell walls by an endopectate-*trans*-eliminase

THE cell walls of higher plants were long regarded as essentially inert structures which functioned mainly as mechanical barriers to the expansion of protoplasts under turgor pressure and as skeletal supports in tissues It is now known, however, that they contain a number of hydrolytic enzymes at least one of which is a hydroxyproline-rich protein[1] These enzymes are often of types associated with the dynamic recycling functions of intracellular lysosomes[2-4] They have usually been detected by the activity of cell wall preparations after comminution of tissues and removal of contaminating cytoplasm by washing[1,2,5] or by the activity of intact or excised roots[3,6] We now report on the release of wall bound enzymes from living cells by a pectic enzyme

An endopectate-*trans*-eliminase (PTE) was obtained from 3-d-old soft rots of cucumbers caused by the bacterium *Erwinia carotovora* (NCTC 1747) One volume of rot was extracted with one volume of 0 85% NaCl and made cell-free by centrifuging Ammonium sulphate was added to 61–80% saturation, the precipitate collected, dissolved in, then dialysed against water, and fractionated by elution from Sephadex G75 superfine with 0 1 M NaCl in 0 005 M Tris buffer, *p*H 9 0 Fractions containing most of the PTE activity were subjected to isoelectric focusing between *p*H 7 0 and 10 0 for 52 h at 4° C Fractions containing PTE were combined, dialysed and gave a single band after electrophoresis on polyacrylamide gel The preparation did not degrade any of a wide range of cell wall and other polymers other then those based largely on anhydrogalacturonic acid residues One unit of activity of this PTE gave an increase in absorbance at 550 nm of 0 1 in 30 min at 25° C in the following assay 1 ml enzyme solution, 2 5 ml 1% sodium polypectate (Sunkist Growers Inc), 0 5 ml $CaCl_2$ (final 0 001 M), Tris buffer, *p*H 9 0 (final 0 1 M), left at 25° C Then 7 5 ml of a mixture of 5 ml thiobarbituric acid (0 04M) and 2 5 ml HCl (1M) was added and the red colour produced estimated at 550 nm against a reagent blank

Table 1 Effect of endopectate-*trans*-eliminase (PTE) on release of K^+ and enzymes from potato tuber tissue

Activity†	Treatment*					
	a	*b*	*c*	*d*	*e*	*d*+*e*
K^+	625	17	685	715	60	775
Acid phosphatase	0 132	0 059	0 056	0 040	0 121	0 161
Phenoloxidase	0 13	0 032	0 059	0 046	0 12	0 166
Peroxidase	0 10	0 060	0 023	0 008	0 083	0 091
Malic dehydrogenase	0 132	0 082	0 115	0 052	0 22	0 272

Values shown are corrected for slight changes caused by autoclaved enzyme

* *a*, 3 ml water containing 14 8 units PTE, 0 001 M $CaCl_2$, 0 02 M Tris buffer (*p*H 9 0) for 3 h at 22° C, *b*, as *a* but in 0 5 M sucrose as plasmolyticum, *c*, as *b*, then liquid removed, disks washed in 0 5 M sucrose, added 3 0 ml water for 10 min, *d*, 3 ml, frozen at −20° C, thawed and kept for 10 min, *e*, liquid removed, disks then treated as *a*

† K^+ activity by flame photometry (p p m) Acid phosphatase by estimating *p*-nitrophenol liberated from *p*-nitrophenyl phosphate at 400 nm (ref 7), activity was expressed as mg *p*-nitrophenol liberated per 0 2 ml enzyme solution Phenoloxidase by estimating oxidation of catechol[8], activity was expressed as Δ *OD* 495 nm min^{-1} per 0 2 ml enzyme solution Peroxidase by estimating oxidation of pyrogallol in the presence of H_2O_2 (ref 9), activity was expressed as Δ *OD* 420 nm min^{-1} per 0 01 ml enzyme solution Malic dehydrogenase by estimating oxidation of NADH in the presence of oxalacetic acid[10], activity was expressed as Δ *OD* 340 nm min^{-1} per 0 1 ml enzyme solution

Samples of 48 disks (0 5 × 7 0 mm diameter) from medulla of turgid potato tubers (cv Majestic) were treated in various ways

At the end of each treatment, the ambient liquid was collected and assayed for K^+, acid phosphatase, phenoloxidase, peroxidase and malic dehydrogenase

The 3 h treatment of tissues with PTE caused cell separation and death of protoplasts in the sense that they did not plasmolyse in hypertonic solutions, treatment with enzyme in a plasmolyticum still caused cell separation but protoplasts remained plasmolysed and intact

Table 1 summarises the effects of the different treatments and also shows in column *d* + *e* the total of K^+ and enzymes liberated from frozen tissue after thawing and released from residual tissue after treatment with PTE for 3 h Comparison of columns *d* and *e* show that K^+ liberated by PTE treatment of residual tissue was only about 10% of that liberated by freezing followed by thawing The corresponding figures for the enzymes were 72–91%

Similarly, although very little K^+ was released from tissues treated with PTE in a plasmolyticum, large amounts of peroxidase acid phosphatase and malic dehydrogenase and smaller though substantial amounts of phenoloxidase were liberated in these conditions There were corresponding differences when plasmolysed protoplasts in PTE treated tissue were rapidly deplasmolysed

Because PTE is believed to act only on substrates in cell walls and middle lamellae, the results suggest that large proportions of the four enzymes in cells are bound to cell walls and are liberated when these are exposed to PTE This confirms earlier work which showed that cell walls contain substantial amounts of peroxidase[1] and acid phosphatase[5] but is unexpected for malic dehydrogenase (which is known to occur as different isoenzymes in mitochondria, chloroplasts and cytoplasm[11] but not, so far as we know, outside the plasmalemma)

We have considered the possibility that our results could be explained, at least in part, by adsorption by cell walls of cytoplasmic enzymes released when cells are broken during preparation of the potato tuber disks or by residual cytoplasm on cut surfaces But this seems unlikely because preliminary washing of disks in 0 2 M NaCl did not decrease release of acid phosphatase or malic dehydrogenase when disks were later treated with PTE in a plasmolyticum It seems, therefore, that these four enzymes are released from cell walls by the action of PTE which is highly specific and is believed to be confined to the rupture of α-1,4-D-glycosiduronic linkages This poses the question of the relationship between polymers based on these linkages and wall-bound protein and, of course, the function of wall-bound enzymes particularly such as malic dehydrogenase hitherto regarded as essentially cytoplasmic

Simple guide to welfare economics

In Defence of Economic Growth By Wilfred Beckerman Pp 287 (Cape London, June 1974) £3 95

THIS book is precisely what it claims to be a defence of economic growth It is written with wit and verve, in a forensic style which would do credit to a barrister defending a criminal before a jury The prosecution witness (the mass media, fuddy-duddy scientists, young radicals, and the middle classes) are battered by facts, arguments and ridicule It is, as Beckerman frankly warns his readers, a one sided contribution to a debate The issue is familiar enough Should economic growth be curtailed or even phased out as a deliberate social policy, in order to prevent pollution and to conserve resources for future generations? And, to anyone interested in this issue, Beckerman's views are familiar enough too Market forces, either working naturally or modulated by a system of taxation, will continue, as they do at present, to regulate the level of pollution and the use of resources Zero growth would exacerbate the inequalities between rich and poor, it would be of dubious benefit to future generations, and in any case it would be politically impossible to achieve in a democratic society

Many people, including some scientists, do not realise that the economist, dealing with the theory of choice in the allocation of resources, is (or tries to be) as neutral over value judgements as the chemist is when he deals with the theory of valency It is not the economist's professional business to moralise about how the national product should be allocated among such items as present consumption, investment in the future, and conservation of the environment His business is to say what the economic consequences will be for different patterns of allocation Thus in the mind of the economist pollution is not 'good' or 'bad' any more than arsenic is 'good' or 'bad' in the mind of a chemist The notion that conservationists have to defend the environment against hordes of economists, hell-bent on maximising economic growth, is, as Beckerman convincingly argues, nonsense The economist is interested in the logic, not the ethics, of choice

A clear distinction has to be made between two dimensions of choice one is how to allocate resources at any moment of time (for example, as between public and private transport), the other is how to allocate resources over a period of time (for example, as between 1975 and 1995) The controversy over economic growth lies in the second of these two dimensions It is, crudely, the choice between on the one hand, more consumption now and possibly (though Beckerman disputes this) less for our grandchildren and, on the other hand, some sacrifice of present consumption and (again only possibly) more for our grandchildren

The evidence of history is that improvement in economic welfare has been accompanied by improvement in social welfare As nations have become more affluent their citizens have, on the whole, become more healthy, enjoyed greater security, shared more fully those immaterial benefits we associate with 'quality of life' So, argues, Beckerman continued economic growth is in the best interests both of today's poor and of posterity As for the social costs of economic growth, for example pollution and disfigurement of the landscape, the economists have an elegant formula as a guide to policy Pollution (which Beckerman selects to exemplify his views) should not be minimised it should be optimised at the level above which the marginal cost of more abatement would exceed the marginal cost of the damage done if it were not abated And to ensure that the cost of disposing wastes into the environment is internalised, just as the cost of labour is, Beckerman proposes a hit-or-miss taxation system which would aim at optimising pollution

The trouble about the economists' elegant formula is that they cannot quantify it in a way which would command the confidence of anyone accustomed to the rigours of scientific method The costs of abating pollution can be measured But estimates of the damage done by pollution which try to quantify the disamenity of fogs and dirty rivers and smells are (to my mind) totally unconvincing Beckerman himself emphasises that economic welfare is only part of social welfare The task of politicians is to promote the whole of social welfare The issue which his book raises is a fundamental one Is social welfare so conditioned by economic welfare that politicians can exclude the unquantifiable components of social welfare? Or—and this is Beckerman's view—should one go on trying to quantify the whole of social welfare, in money terms because money is a convenient symbol of value? After all, he says, it was a long time before physicists learnt how to measure heat Or are the unquantifiable components in the cost-benefit equations of social welfare so important that this whole quasi-scientific approach to social policy ought, for the time being, to be regarded as under suspicion?

Beckerman, quite rightly, withers with criticism the specious precision of computer simulations about the prospects for mankind But is he not himself exposed to a somewhat similar, though much milder, criticism? There is growing evidence that social welfare includes much more than economic welfare and that in affluent societies the correlation between the two (let alone causation) cannot be assumed to be strong Much of what social welfare means cannot be quantified Is there not a risk that the value-free approach to welfare economics will over estimate the quantifiable components and under estimate the others and, in doing so, distort the issues instead of clarifying them?

One puts this challenging book down with the impression that economists, just because they are liable to become involved in social policy, cannot remain as disengaged from value judgements as scientists can The scientist can exclude from consideration phenomena he cannot quantify He would discard an equation for which he could not supply data The economist analysing social choice is tempted to go on using the equation even though he cannot supply the data Beckerman has not altogether resisted this temptation

E ASHBY

Physics and Chemistry from Longman

X-rays in Atomic and Nuclear Physics
Norman A Dyson
An account, drawn from several different branches of physics, of the physical aspects of X-ray production "The book is economically written, well illustrated and carefully produced It should be made available in all scientific libraries, and should find a place on the shelves of any individual who is interested in the production, properties and applications of short wave-length radiation"
P J Wheatley Nature £8 00 net

Radiation Chemistry An Introduction
A J Swallow
Intended for final year undergraduate students of chemistry, for those taking graduate courses in the appropriate subjects, for those beginning research in radiation chemistry, and for specialists in related fields who wish to obtain a general knowledge of the subject A general knowledge of chemistry and especially chemical kinetics is assumed, at approximately second year B Sc level £5 50 net

Stereochemistry
G Natta and M Farina
This book starts with a review of stereochemistry from Pasteur to the present day and follows by describing the shapes of molecules, molecular symmetry and the dynamic aspects of reactions It then continues with a consideration of macromolecular stereochemistry, biological macromolecules and the structure of chemical compounds It closes with a review of optical activity £2 40 net

Tables of Physical and Chemical Constants
G W C Kaye and T H Laby
A classic reference work with extensive tables of conversion factors from older systems into SI units Parts of the book have been completely rewritten, while others have been revised New sections have been included £3 95 net

Silent synapses

Memory and Nerve Cell Connections By Richard Mark Pp x+15 (Criticisms and Contributions from Developmental Neurophysiology) (Clarendon Oxford, Oxford University London, June 1974) £2 95

IN this very interesting book Richard Mark (well known for his work on selective neuromuscular reinnervation in fish and newts, in which he has shown that, in certain circumstances, neuromuscular synapses in lower vertebrates may become functionally switched off without apparent morphological change) extends his arguments on "silent synapses" to the central nervous system and attempts to provide thereby a skeletal framework for a theory of memory and learning The book is well organised, well written and should be read

The nature of the audience at which the book is aimed is not clear, since though the introductory outlines of the structure and function of neurones, glia, synapses, brain codes and so forth are somewhat elementary the arguments introduced later are fairly sophisticated This does not really matter, however, and students and research workers alike will find this book, which is organised rather like a detective story, highly readable After a brief survey of some relevant aspects of neurophysiology the author takes the reader on a tour of various possible mechanisms of memory (with their attendant disadvantages) and finally, eight pages before the end of the book, Dr Mark's own hypothesis, the component parts of which had previously been introduced, is put together The hypothesis essentially suggests that, in the highly convergent (and initially redundant) neural network of the central nervous system, the less used pathways may become functionally suppressed Used pathways may become more efficient and this increased usage is held to be associated with increased synthesis of specific marker proteins, leading to long term changes in functional connectivity

The general argument presented by Dr Mark is interesting and plausible He makes the good point that "it is not reasonable to abstract the verbal or logical representation of each component of a particular behavioural situation that can be used to demonstrate learning and then demand a physiological explanation for all these abstractions at the same biological level Yet many physiologically inclined workers have simply taken each of the parameters of a conventionally accepted learning paradigm such as classical conditioning and assumed that there is a cellular explanation for each of them" The point being made here is that the phenomena of learning and memory are highly complex and that simplistic attempts to identify individual structures with these functions are unlikely to be fruitful From a somewhat similar viewpoint Dr Mark briefly reviews the popular work on memory transfer ('memory molecules') and comes to the tentative conclusion that, although some of the experimental observations may be valid, the hypothetical frameworks associated with this sort of work have so far been inadequate "It would be imprudent to deny that chemically transmissable behaviour exists One has the uneasy feeling from all this literature, contradictory and incomplete as it is, that something is there"

Dr Mark makes the interesting criticism that, since the result of memory transfer experiments, even if valid, cannot be fitted into the present framework of biological understanding, the lack of coherence of these experiments with the other brain studies may rule out scientific progress along these lines "The most telling criticism of chemical memory transfer experiments is not to deny the possibility of the effects, or to denigrate the investigators, but to say that they are before their time This is just as serious a scientific criticism as to say the work is old-fashioned and repetitive It means that even if research stumbled upon something of real significance, which perhaps it already has the finding could not be exploited because of the surrounding chasms of ignorance as to other aspects of brain function"

Taking his example from the study of nerve regeneration in amphibians and fishes, Mark instances work on plasticity of synaptic connections which seems to be due to a competitive suppression of transmission in some terminals In these cases the final pattern emerges not because the best fitted connections improve but because the inappropriate are eliminated It is proposed that a mechanism akin to this developmental shaping of the nervous system may continue into adult life and work there to modify brain connections into a more appropriate form for current experience, that is, as a basis for learning

The details provided by Dr Mark to support this idea are, naturally somewhat scanty, and it may well turn out that the whole approach is misleading It is certainly true, however, that the existence of "silent synapses" peripherally, taken along with the recent evidence for functionally induced plasticity of central connections in the visual system, provokes very interesting speculations This may not be the most direct route to the mysteries of memory and learning, but the search for silent synapses in the CNS is now on •

R M GAZE

Materials in use

Metals, Ceramics and Polymers An Introduction to the Structure and Properties of Engineering Materials By Oliver H Wyatt and David Dew-Hughes Pp xiv+640 (Cambridge University London, May 1974) £12 00 boards, £4 95 paper

Of books on Shakespeare's plays, the Malaise of Western Man, and materials science, there is no end No blinding new insights are to be expected on any of these topics selection, clarity and economy must be our touchstones Anyone with a shelf-full of such books must be tempted to pluck out some of them and follow Prospero's heroic resolution "And deeper than did ever plummet sound I'll drown my book"

The volume under review is not for drowning It is one of the very best of the many English-language texts on materials that have appeared in recent years Unlike some of these, the new book has a pronounced engineering bias the fact that Dr Wyatt worked for years in an engineering school which prepares its students for what used to be called a Mechanical Sciences Tripos shows in the special emphasis on mechanical behaviour which is evident in many parts of the book Thus, although there is a sound summary of the present understanding of dislocation behaviour, macroscopic plasticity theory gets exceptionally thorough treatment, the application of this theory to metalworking processes is unusual in a materials textbook Ceramics and polymers each receive a good concise presentation, including for the former an informative account of the setting of concrete glasses are rather too much compressed (a state possibly natural to the material) There is an excellent chapter on steels, particularly thorough on the problem of heat-treating objects of various sizes The electrical and magnetic chapters are also well presented, with more emphasis than normal on superconductivity (one of Dr Dew-Hughes's special interests) and dielectric materials Magnetic materials place much more emphasis on domain behaviour than intrinsic magnetism—a good test of fitness for engineering purposes

The treatment of particular materials is underpinned by a fairly conventional introduction to topics such as crystallography, diffusion, phase diagrams (including a good treatment of ternaries) and band theory As so often, the thermodynamic treatment is too concise for real clarity, in particular, the statistical basis for entropy has to be taken on trust, which must tinge the crucial concept of an equilibrium population of vacant lattice sites with a touch of black magic But on the whole, the theoretical underpinning is very clear and sufficiently comprehensive

It is easy enough to pick out individual small inadequacies and as always these largely reflect the reviewer's predilections there is almost nothing on the important subject of recrystallisation, the intriguing explanation of how doping with an impurity permits the removal of pores in sintered alumina is muffed, the crucial importance of crystalline states in polymers receives only the most glancing recognition But the list of these shortcomings (which another reviewer might deem of little consequence) is short and the positive achievement of balance and clarity is very considerable

Each chapter has a collection of questions, partly numerical and partly purely verbal, designed to test conceptual understanding, and each has an excellent bibliography

As a basis for a comprehensive course on materials for engineering students, or as a foundation for the much smaller tribe of material specialists, this book can be warmly recommended The paperback version in particular is excellent value

R W Cahn

Valence calculations and molecular orbital theories

Ab Initio Valence Calculations in Chemistry By D B Cook Pp ix+361 (Butterworth London, March 1974) £7 50

This is a book which describes the technical aspects of computing wave functions and energies of electrons in molecules as approximate solutions of the Schrodinger equation It is concerned only with the *ab-initio* method, that is, the approximations contained in such calculations arise from the termination of series expansions of the wave functions rather than the use of a model Hamiltonian In addition to the technical aspects of the book the author gives a personal justification for the place of such calculations in chemistry which may be summarised as follows Many of the important concepts of valence theory are not observables, but in order to maintain contact with and influence the main stream of chemical thinking, quantum chemistry must apply itself to the analysis, criticism and quantitative investigation of these concepts In other words the book is not written just for chemists who want numbers, but also for those interested in ideas

The book fills a gap in the current literature It does not set out to present a broad view of quantum theory or valence theory and therefore assumes a fair amount of basic knowledge in these areas It is elegantly written and printed and I believe it will be widely accepted as a very useful book

Molecular Orbital Methods in Organic Chemistry—HMO and PMO An Introduction By William B Smith Pp xi+161 (Studies in Organic Chemistry, vol 2) (Dekker New York, April 1974) $14 50 £6 00

It is thirteen years since the first books on molecular orbital theories in organic chemistry appeared and one must admire the courage of both author and publisher in adding another volume to this crowded market About half the book is devoted to an elementary account of Huckel theory (HMO) and its perturbative approximations (PMO) The remainder gives a wide coverage of organic reactivity including the recently popularised symmetry rules As an elementary account of the subject it is quite acceptable but it is hardly value for money when compared with other books that are available

Buffers for pH and Metal Ion Control
D D PERRIN and BOYD DEMPSEY
September 1974 184 pages illustrated hardback 412 11700 2 £3 50

Practical Manuals Series
This is a practical book designed to meet the varied needs of those scientists who require pH or metal ion buffers having specified values Information has been gathered together into numerous pH buffer tables, and these include details of zwitterion buffers Through the use of worked examples the reader is enabled to calculate the composition of buffers for particular conditions, and small computer programmes are included which facilitate these calculations

Second Edition
Practical Inorganic Chemistry
Preparations, Reactions and Instrumental Methods
G PASS and H SUTCLIFFE
Second edition September 1974 256 pages illustrated 412 12690 7 hardback £2 60

This second edition of a successful textbook is now in SI units and new experiments involving ion-exchange and solid-liquid chromatography have been added
The experiments described are complemented by suitable structural and analytical studies with follow-up exercises which require the study of listed references

Second Edition
The Spectroscopy of Flames
A G GAYDON, F R S
Second edition September 1974 420 pages illustrated hardback 412 12870 5 £8 00

This book deals primarily with the use of spectroscopic observations to interpret combustion processes in flames and flame structure It represents a total revision of the author's earlier work so that it now incorporates the latest refinements in techniques as well as some important related advances

Further information on these titles and a list of stockists is available from the publishers on request

Impact of climate

Climatic Resources and Economic Activity A Symposium Edited by James A Taylor Pp 264 (David and Charles Newton Abbot and London, June 1974) £6 50

THIS volume is the latest in a series emanating from the Aberystwyth Symposia, hardy annual gatherings from 1958 to 1973 These have focused attention usefully on what is broadly termed "applied climatology" Inevitably this volume overlaps the contents of certain of its predecessors in such an amorphous field, notably *Weather and Agriculture* (Oxford, 1967), *Weather Economics* (Oxford, 1970), and *Weather Forecasting for Agriculture and Industry* (David and Charles, 1972)

It claimed in the preface that this book is timely in reviewing relationships between climatic resources and some of their social and economic usages this is indisputable, although the range of papers it contains is broad rather than all-embracing, and the depth is distinctly moderate Many workers may take greater exception to the unqualified assertion that the volume is "representative of current research trends and achievements" in environmental science There are other kinds of trends and achievements too, several arguably of greater significance in the long run Perhaps the most unnecessary aspect of the introductory keynote is its attempt to justify this collection of articles in terms of current geographical philosophy One wonders whether the three-quarters of the contributors who are employed outside academic geography welcome being seen in this perspective If applied climatology and meteorology are fields worthy of investigation, they may be explored best if the directions from which they are approached are totally unprejudiced

The contents include a broad introduction to the concept of the atmosphere as a global resource, and five chapters of bioclimatic interest, almost wholly concerned with weather, plants, and crop husbandry Two further chapters—more helpful and interesting than most—appraise water resources in the United Kingdom, and mathematical models designed to facilitate the planning of their exploitation Two chapters follow on air pollution, then a rare, thought-provoking essay on weather and road accidents The two last contributions are concerned with modelling influences of atmospheric behaviour on general and national economical activities

Several chapters suffer from the current abuse of statistical methods for environmental analysis Correlations are based on tiny populations, and rakish linear regression lines are employed where curvilinear relationships even of only quadratic or cubic forms would have yielded much more significant values of r^2 Why weaken a potentially important argument if the chosen "best fit" statistical statement does it less—even much less—than justice?

As an ardent disciple of the school which prefers its scientific books to be more akin to disposable paper cups than presentation clocks, I am bound to think that the circulation of this book will be restricted by its style and cost It is too lightweight and piecemeal to serve as a worthy reference volume on the library shelves, meanwhile, it is too wasteful in production and design to recommend itself to the college student or the weather-conscious layman Presumably, therefore, it is aimed at the business market, where its value will depend on the nature of the enterprise A paperback version could have been recommended to students

Both front and back cover pictures are from the 1960s, which perhaps might just be forgiven But the satellite photograph of South America on the back cover would look considerably better—and make more sense to the amateur—if it were not upside down

E C BARRETT

Climate and Life By M I Budyko English edition edited by D H Miller Pp xvii+507 (International Geophysics Series, vol 18) (Academic New York and London, April 1974) $35, £16 45

THIS book provides the most complete account in English of the climatology work at the Voeikov Geophysical Observatory, and with very complete references at the end of each chapter it is important simply as a reference guide to this work in the Soviet Union

Apart from this, it is a book which will be of real value to the serious student of climatology, although it is certainly not always easy to read Starting from solar radiation and heat balance at the Earth, the study of climate and its impact on life is considered within a unified framework which builds upon the work reported in the earlier (1956) summary of research at Voeikov Observatory

I found the sections on climatic change particularly interesting and useful, I would have preferred to find less emphasis on the effects of volcanic dust, perhaps—or at least comparable emphasis on other factors—and I would take issue with the statement that "over a duration of several centuries, noticeable fluctuations of climate can occur only in high latitudes" But these are relatively minor points and in a book covering so much it is no surprise if the author fails to please all of the readers all of the time

JOHN GRIBBIN

Earth science

Geology, Resources and Society An Introduction to Earth Science By H W Menard Pp xi+621 (A Series of Books in Geology) (Freeman San Francisco and Reading, May 1974) £6 10

FROM the days of Lyell to those of Arthur Holmes and Jim Gilluly students of geology have been fortunate in the number of outstanding geologists who have taken on the task of preparing textbooks on their subject To a remarkable degree a few textbooks of the first rank have contributed to the way geology has evolved, setting a pattern of thought which was to persist for several decades

Menard states in his preface that he is aiming this book at students who are not majoring in the earth sciences In other words this is a professional's textbook aimed at a wider audience and one which, in my opinion, may well become a guideline for those who are attempting to integrate various branches of the earth sciences using the term in its widest sense

Menard's approach is to provide readable syntheses on four or five fundamental divisions of each science, giving himself enough elbow room to treat the essentials but not so much as to become involved in detail In succession he takes up the subjects of the planet Earth, its deformation, the atmosphere and hydrosphere, and the manner in which these react with the solid rock, first to render it unstable and to weather it and then to produce the sediments Along the way he includes a brief section on volcanism and concludes with some 80 pages on water, fuels and mineral resources He follows Holmes rather than Lyell in treating the Earth as a machine and making this, not the stratigraphical record, the link-pin of his arguments I think he is particularly successful in conveying a sense of proportion and of the relative importance of phenomena When discussing the circulation of water, for example, he points out what a minute fraction is to be found at any one time in rivers and in the atmosphere, only 0 001% of all the Earth's water is in the air Menard describes the circulation of solid rock, of sediments, air and water as we understand these matters today His text would provide an excellent basis for any course dealing with the physical environment

The title indicates Menard's wider interests These emerge repeatedly through the book, but apart from the chapter on resources amounting to less than 10% of the whole, and the section on engineering problems caused by unstable ground, no extended portion of the text is devoted to them, though Menard does his best to emphasise their importance in the approach he adopts throughout the volume It is difficult to see how he could have done more He has been remarkably successful in his syntheses which in my mind constitute the main virtue of this book

obituary

Alfred E. Mirsky

PROFESSOR ALFRED E MIRSKY, who first isolated and characterised genetic material from mammalian cells, died on June 19, 1974 He was 73

Born in New York, he gained his PhD from the University of Cambridge in 1926 and returned to the Rockefeller University in 1927 He became a professor there in 1954 and retired in 1971

Sir Frederick Brundrett

SIR FREDERICK BRUNDRETT, KCB, KBE, former Scientific Adviser to the Minister of Defence, died on August 1, 1974 He was 79

After attending the University of Cambridge, he joined the wireless branch of the Royal Naval Volunteer Reserve in 1916 He became Chief of the Royal Naval Scientific Service in 1946, and was appointed Deputy Scientific Adviser to the Minister of Defence in 1950 In 1954 he became Scientific Adviser and Chairman of the Defence Research Policy Committee

Gertrude E. Perlmann

PROFESSOR GERTRUDE E PERLMANN, an authority on protein chemistry, died on September 9, 1974 She was 62

After receiving her DSc, from the German University of Prague, she joined the Biological Institute of the Carlsberg Foundation She undertook research at the Harvard Medical School from 1939 to 1946, becoming a full professor in 1973 She was noted for her research on the structure of pepsin

Sir Francis Knowles

PROFESSOR SIR FRANCIS KNOWLES, Bt, FRS, the neuroendocrinologist, died on July 13, 1974 He was 59

Educated at the University of Oxford, he carried out pioneering work into the structure of neurosecretory systems In 1958, he went to the Department of Anatomy of the University of Birmingham, becoming Reader in 1963 and Professor of Comparative Endocrinology in 1967 Later that year he was appointed Professor of Anatomy at the University of London and Head of Anatomy at King's College, London

Announcements

Award

The **A T Shousha Foundation Medal and Prize for 1974** has been awarded posthumously to **Mohamed Taieb Hachicha**

Appointment

Piero Sensi has been elected president of the **Societa Italiana Scienze Farmaceutiche.**

Miscellaneous

The Harkness Fellowships for study and travel in the United States—1975 Candidacy is open to men and women (between 21 and 30 years of age on September 1, 1975) in any profession or field of study provided both their secondary and further education (or equivalent professional experience in lieu of further education) have been wholly or mainly in the United Kingdom For application forms or further information write to The Harkness Fellowships (UK), Harkness House, 38 Upper Brook Street, London W1Y 1PE

Gottlieb-Duttweiler Prize for the promotion of nutritional sciences Applications are invited from scientists with outstanding achievements in the field of nutrition research Applications should be sent by December 31, 1974 to Green Meadow Foundation, c/o Institute for Nutrition Research, Seestrasse 72, CH-8803 Ruschlikon, Switzerland

International meetings

October 24–26, **26th International Congress of Physiological Sciences,** New Delhi (Secretariat, 26th International Congress of Physiological Sciences, Department of Physiology, All India Institute of Medical Sciences, Ansari Nagar, New Delhi 110016, India)

October 29–31, **5th International Symposium on Olfaction and Taste,** Parkville (Dr J P Coghlan, ISOT V Secretary, Howard Florey Institute of Experimental Physiology and Medicine, University of Melbourne, Parkville, Victoria 3052, Australia)

November 4–7, **9th International Symposium on Advances in Chromatography,** Houston (Albert Zlatkis, Chemistry Department, University of Houston, Houston, Texas 77004, USA)

November 6–8, **International Symposium on Pharmacokinetics and Drug Effects, Stockholm** (Hans H Linden, Director, Aputekarsocieten, Box 1136, S-111 81 Stockholm, Sweden)

November 7, **The Control of Cell Growth Regulation by Tumour-inducing Viruses,** The Royal Society (Executive Secretary, The Royal Society, 6 Carlton House Terrace, London SW1Y 5AG)

November 10–14, **17th National Meeting, Academy of Pharmaceutical Sciences,** New Orleans (Academy of Pharmaceutical Sciences, A Ph A , 2215 Constitution Avenue, N W , Washington, DC 20037, USA)

November 23, **British Academy of Psychopharmacology Open Meeting,** London (Professor Max Hamilton, President, British Academy of Psychopharmacology, University of Leeds, Department of Psychiatry, 15 Hyde Terrace, Leeds LS2 9LT, UK)

Errata

In the article "Energy problems facing India" by N K Sehgal (*Nature,* **249,** 710, 1974) there were serious misplacings of the textual matter

(i) The last two paragraphs under "Genesis of problems" (page 711, starting with "A 'gobar-gas' ") should go at the end of "Meeting the challenge" (page 712)

(ii) The entire portion under "Fifth plan and beyond" starting with the fifth paragraph ("Petroleum products ") onwards, must come under "Genesis of problems" in place of the two paragraphs mentioned in (i) above

The corrected version is being published in *Scientific Opinion,* of which Dr Sehgal is the editor, in Vol 3, No 2

In the article "Antibody cell daughters can produce antibody of different specificities" by A J Cunningham and S A Fordham (*Nature,* **250,** 669, 1974) the first sentence of the legend to Fig 1 should read, "Photographs (a–c) and diagrammatic representation (d–f) of clear (c,f) sombrero (b,e) and partial (a,d) plaques "

On goes the missile race

Whatever the international contortions of the last few years—the problems of the monetary system, the uncertainties about commodities, the disappearance of growth, the increased vulnerability of governments to non-democratic action—the business of defence has pursued its own self-effacing and growthful way. It is only the annual reviews provided by SIPRI and the International Institute for Strategic Studies (IISS) which remind us that those decisions taken 'with regret' a few years ago are now converted to expensive hardware for which there has been little public accountability.

The most recent occasion for us to consider defence expenditure and policy is the appearance of the annual report, *The Military Balance*, of the IISS. It arrives at a most appropriate time, for the failure of the Moscow visit of Mr Nixon to put any more significant teeth in arms control agreements between the superpowers can be assessed in terms of the now likely strategic development of the next few years.

The United States now spends 6.2% and the Soviet Union 5.4% of their Gross National Product on defence. Both percentages have been gently declining in recent years. In the American case, of course, the disengagement from Vietnam has at least checked the rise in military expenditure. In neither case does the strategic weapons programme seem to have been seriously hurt by falling budgets.

- In the United States, the contents of the thousand *Minuteman* silos permitted under SALT are changing rapidly, whilst the silos themselves are being increasingly hardened. Within a year all the 550 planned MIRV launchers will be installed, providing three independently targetable 200-kiloton warheads per launcher. The vast majority of the remainder of the sites already contain *Minuteman 2* vehicles which carry three warheads not independently targeted; there is nothing in SALT to stop the upgrading of all of these to MIRV capability.
- The Soviet Union is constrained to 1,618 silos and is now within 43 of that number. She can have 313 'heavy' missiles (with yields up to 25 megatons) and is close to that total. The remainder are at present mostly megaton SS-9 missiles, but MIRVing is on the way for these too.
- At sea, the United States is permitted 41 nuclear submarines with 710 missiles. At present half of the fleet is MIRVed (each missile containing at least ten 50-kiloton vehicles) but not all the rest will go this way, as ten Polaris boats will be pulled out of action in the late seventies and beyond, to be replaced by 24-tube *Tridents*. The warheads in *Trident* are MARVs—manoeuvrable re-entry vehicles, capable of manoeuvre after re-entry to avoid defences.
- The Soviet Navy is restricted to 62 'modern' submarines and is still 20 short of that figure, but building fast. As yet the 660 warheads carried are not multiple vehicles, but tests are under way.

The message is thus from all fronts that the qualitative revolution is now well advanced. Admittedly the Soviet Union seems to lag two or three years, but for both sides it is becoming plain that accuracy and sophistication is replacing numerical growth in the strategic game. Unfortunately since neither side is able, in its monitoring, to do much more than count devices, the prospects for verified arms limitations (and verifications is probably a *sine qua non*) diminish with time.

A case could be made that these qualitative improvements should be allowed to run their course. After all, if it will be possible to deliver nuclear warheads with an accuracy of a metre by 1990, as some believe, the payload could be reduced and the tradition that the military fights the military and does not draw in the general public might be re-established. There must always be the hope that war could be restricted to surgical strikes.

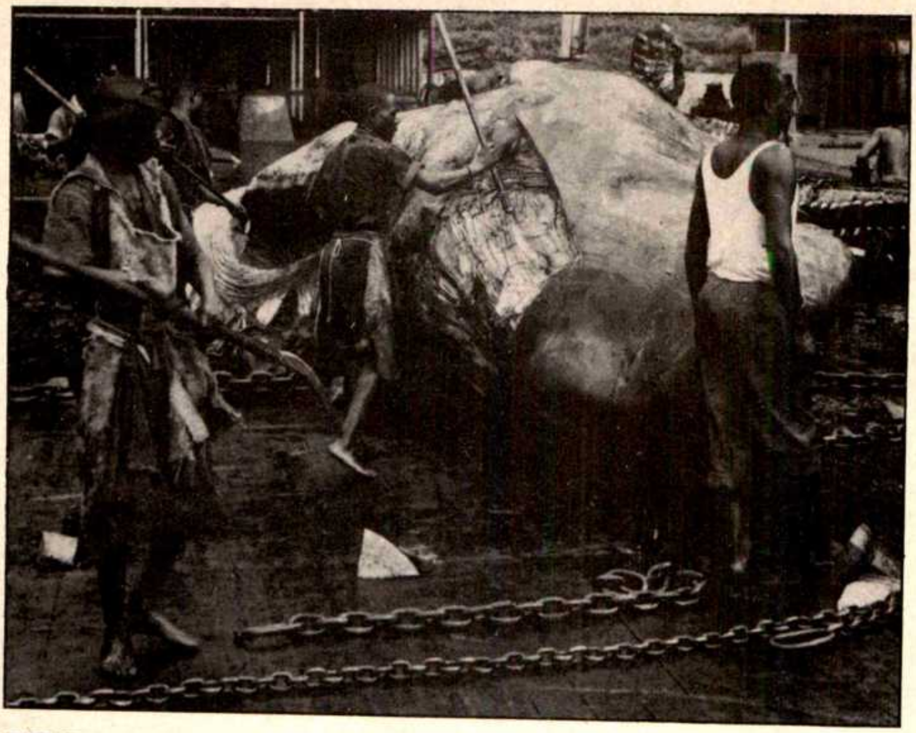
There are several reasons, however, why we cannot expect to have neat wars fought for us entirely by technology. An obvious one is that there are bound to be more than two participants in any future major war, and since the superpowers, in their pursuit of technological sophistication, have actively, if inadvertently, encouraged other countries to go nuclear but at a less sophisticated level, the multiplicity of nuclear-armed participants will inevitably confuse any bilateral game plan. But there is a more subtle reason why we should not believe that wars of opposing and highly sophisticated technologies will be more bearable for the civilian.

No nation would be satisfied that its future be decided entirely by surrogates. It is unlikely that the idea of a football match, say, between the superpowers—once the shape of the ball had been decided—would be deemed an acceptable way of settling political disputes. There has to be some personal involvement and sacrifice in war, and the growing trend away from this that we see in present and future strategic hardware poses an interesting question. If the early nuclear age has been marked by an uneasy truce between the superpowers because the consequences of major war were unspeakable, maybe the coming nuclear age will see further detente because a technologist's war between machines having reduced the unspeakable is politically unacceptable.

A hundred years ago

We referred some little time ago to the fact that a sum of about 30,000*l.* had been left to the " London Academy of Sciences." We hear that already several societies and institutions have sent in, or are thinking of sending in, claims. It is stated, however, that the Royal Society, which certainly is the nearest approach to the institution in Signor Ponti's mind, has not applied. The Royal Society is of course a mere private body, and might well be held to be justified in refusing to incur the responsibility of distributing a large sum for the furtherance of science; but the miserable chaos in our scientific arrangements is none the less strongly brought out by the present juncture. In England, truly, Science is a body without a head !

From *Nature*, **10**, 470, October 8, 1874.



Whales: conserving a resource

In spite of an expression of 'cautious optimism' after this year's meeting of the International Whaling Commission, and a recent Nature article which was optimistic about whale populations, there are still fears that all is not well in the whaling industry. Dr Sidney Holt, Director of the International Ocean Institute in Malta highlights some of the problems still confronting whale conservation and management.

AT the end of the meeting of the International Whaling Commission last June, a number of interested non-governmental organisations put out a statement expressing "cautious optimism" regarding the results achieved there. Dr Ray Gambell has been commendably prompt in bringing these results to the attention of readers of *Nature* (August 9, 1974). We who participated in the IWC meeting must agree that the adoption of what Dr Gambell calls the "amended moratorium proposal" was a significant advance towards rational management of whaling. This is, however, no time for complacency by scientists, governments or the interested public, and Dr Gambell's article is not, I think, sufficiently critical of the present state of whale population assessments. It is not insignificant that Dr Gambell illustrated his article with hypothetical diagrams rather than with an example. "The exact forms of the relationships . . . are not known for certain . . ." is far too mild an expression of real doubts. A number of weaknesses in present calculations are well known to members of the IWC's Scientific Committee, although there seems to be less divergence of opinion within the Committee than in the past. I have drawn the Committee's attention to other deficiencies identified by a special working party of the FAO Advisory Committee on Marine Resources Research with which Dr Gambell is also associated. I will not reiterate these but merely observe that although they do not all point in the same direction, their general sense is that the IWC's Scientific Advisers may still be erring on the side of optimism. Here, however, I wish to draw attention to some specific points raised by Dr Gambell's article. There is a slip in his exposition of the simple theory of density-dependent rates. The natural mortality rate might "fall as whales are caught", but not because they "are caught before they have a chance to die naturally". In all models used the mortality rates, both "natural" and "due to whaling" are, by definition, independent exponential coefficients, not absolute quantities.

Then there are two significant errors in the table of present sustainable yields (SY) given. SY for female sperm whales in the Southern hemisphere is 1,800, not 4,500. The latter figure is the calculated maximum sustainable yield of females which could be obtained if their numbers were reduced. This would, however, be, in part at least, at the expense of the catch of males, which are far more important because they are both bigger and more numerous. The high quota of 5,000 is designed to reduce the number of females quite drastically—an act of doubtful wisdom. The SY of 1,700 given in the table for North Pacific female sperm whales is correct (insofar as any of these calculated values are "correct"); the corresponding MSY is 3,400 which is considerably less than the permitted quota of 4,000.

The second error concerns the Minke whale. The stated present SY in the Antarctic of 7,000–12,000 is an estimate of the maximum SY; the Minke is said to be very lightly exploited at present and its present SY is certainly much lower than 7,000. That, however, is not the main point. There are practically no hard facts about the population of this species. As the report says, "The Scientific Committee was unable to reach any conclusion . . . for Minke whales," and it " advised caution in setting catch limits . . ." By analogy with other species, which are rather better known, the Scientific Committee proposed a quota of 5,000, as they did last year. This was not acceptable to Japan and the Soviet Union, who share about equally the present catches, and the 7,000 quota was a compromise; it cannot be described as the outcome of "rational policy". The case of the Minke is important because it has suddenly become, in the last two seasons, an important item in the catches of baleen whales by the pelagic expeditions. From being negligible in the 1968–69 season, it jumped to 12% by weight in 1969–70, and grew to nearly one-third of the total of 190,000 tons taken in the 1973–74 season. The stepping up of the Minke catch is one more step (the last?) in the process of maintaining the profitability of Antarctic whaling by successively exploiting smaller and smaller species of whales—the earlier steps were from blue whales to fin whales to sei whales. That this process is now regulated—but hardly restrained—under a quota system does not mean that it is "rational", that it will ensure survival of a viable population of Minke whales, or that it will necessarily ensure the possibility of high sustained yields from that species in the long term. Judging from past performance, there may be a lapse of up to ten years before the member countries of the IWC are able to agree to act on important advice from its Scientific Committee. Some of the international commissions which regulate the sea fisheries have a similar concept of time and urgency but biologically fishes are more resilient than marine mammals.

It is also a general feature of the history of whaling that by the time there is widespread concern about the survival of one species the industry has already moved to heavy exploitation of another. Thus, while in the past decade or so, "conservation minded" organisations have become aware of what was happening to the blue whale and, lately, the fin whale, the sperm whale has become by far the most important species both in the Antarctic and in world catches. It now accounts for over 40% by weight of the total catch of all species of whales. Its monetary value is not quite so high because, although sperm oil, the main product, fetches higher prices than, and has different uses from, the baleen oil, the sperm whale meat is not suitable for human consumption. (This means that the argument used by the Japan Whaling Association for continued intensive whaling because whale meat is an important ingredient of the diet of school children and poorer people is not applicable to the sperm whaling industry.) Scientific assessment of sperm whale stocks is especially difficult because of particular features of their biology and of the industry based on them. The IWC Scientific Committee believes that the level of catch of males is at about their maximum sustainable yield in numbers. It is said that a convenient aspect of sperm whaling is that the males are bigger than the females, there is much geographical segregation of the sexes, and the social behaviour (including a "harem" structure) are such that a large "surplus" of males can readily be caught. I find it difficult to reconcile this with the decision to reduce the size limit for females "in order to bring the sexes into better balance". Sperm whales are especially important to the Soviet Union, whose whalers now regularly take over half the world total, yet the USSR delegation to the IWC appeared to be having second thoughts about that decision.

But there is a further problem. Whereas males caught twenty years ago averaged 45 tons each in weight, now they average only 28 tons. The size of females has also declined (though not relatively so much because they have, until now, been less intensively exploited). In fact, the average size of all the large species of baleen whales also has declined over the period in which each of them has been intensively exploited. This means that management for maximum sustainable yield in weight (and hence maximum value of product) requires rather different criteria for management than are at present used. This is particularly true for sperm whales, but for all species the desirable level of population is higher than is needed to maximise the yield in numbers. This should please the whaling industry as well as 'conservationists'. The latter group wants survival of species and of stocks to be assured and for the whales to continue to play an important role in marine ecosystems. The former finds that exploiting stocks when they are at high levels of abundance is much more profitable than when the stocks are depleted. This is as true under management for sustained yields as it is for unrestrained whaling. The only trouble is that to maximise the weight yield from an overexploited stock, one has to agree to more stringent immediate conservation measures, and wait longer for their beneficial effects.

Incidentally, the fact that a substantial part of the sperm whale catch is by ships flying flags of non-member countries of the IWC, that it is not unknown for industries to operate under a convenient flag, especially when international regulations become burdensome, and that some countries refrain from joining the IWC for political rather than technical reasons, suggest that it is desirable for the United Nations Environment Programme and other UN Agencies with wide membership to retain their interest in whaling, while continuing to assist and support the IWC.

To maximise the weight yield from an overexploited stock one has to agree to more stringent immediate conservation measures and wait longer for their beneficial effects. . .

Dr Gambell's article gives the impression that defining MSY in terms of weight involves a new concept requiring special study. On the contrary, apart from being practically universal in fishery management, the MSY (weight) criterion was introduced to the IWC over 13 years ago, at the same time as the attainment of sustainable yields in numerical terms was first seriously discussed there. The necessary data are available, as are the mathematical models; it is simply a question of feeding one into the other. The whaling industry has naturally always measured its success by the weight and price of its products, not by the number of whales caught, and it is time the scientific advisers to IWC did the same.

Calculations of recent and expected yields in weight show that if the 1974–75 quotas for pelagic whaling in the Southern hemisphere are reached (as the 1973–74 ones were not) the catch of all species next season may reach 380 thousand tons, 2 or 3% more than in 1973–74. This pelagic industry is still important; in recent years it has accounted for 60% of the world catch of the larger whale species.

Dr Gambell is right in saying that more research is needed—and at practically every level, including critical study of the mathematical models currently used, and investigations of the ecological interactions between the species of whales, and between them and other marine organisms on which they feed or with which they compete. In this connection it should be noted that the suggestion to which Dr Gambell refers in his opening paragraph—and it was no more than a hypothetical suggestion—that catching some species may help the recovery of others, is based solely on the fact that they overlap in the composition of their diet. No quantitative evidence whatever has yet been presented to support it. In fact, a number of important assumptions that are regularly made have not yet been tested; these include the assumptions that each whale population is in a steady state before man starts exploiting it, and that his effect on it is merely reversed if and when his predation is eased.

Meanwhile, the world catch of whales is, despite the depletion of the resource and because of the rising prices of meat and oil, still worth about £80 million annually. It could, if stocks were permitted to recover, be worth many times that at present prices—and even more with the expected relative rise in the prices of animal protein in the coming years. Against this we recognise that Dr Gambell and his few colleagues work with very limited facilities and funds, as do similar groups in other countries. Although no whaling expeditions now fly the British flag, the United Kingdom is stil a considerable importer of some whale products, and presumably retains a long term interest in resources which could once again yield 10% or more of the total value of the world marine harvest, and practically all from the area of ocean which will be beyond national jurisdictions even if the United Nations Conference on the Law of the Sea agrees eventually to an "economic resource zone" 200 miles wide. Now is the time to make substantially greater means available for research on cetaceans and for international management of them. It would be folly, as some seem to wish, for research to be cut back because of the decline of an important industry, which is a result of our past failure to protect the resource base. At the same time it must be hoped that research on the use of the other living resources of the open ocean, such as the Antarctic krill and the deep water cephalopods, will not be left entirely to the two nations remaining in the business of pelagic whaling. If this is too big an enterprise for other maritime countries, should we not be thinking of a substantial international programme of research and development? •

US plans for solar energy

by Colin Norman, Washington

THE US Congress is now putting the finishing touches to a bill which will greatly expand research and development activities aimed at converting solar energy to practical use. Among the provisions contained in the legislation are the establishment of a Solar Energy Research Institute, coördination of solar energy programmes which are now spread over several agencies of the federal government, and the promise of as much as $1,000 million over the next five years for research and development.

Both the Senate and the House of Representatives have now passed slightly differing versions of the bill, and a House-Senate conference committee was appointed last week to work out a compromise. According to congressional staff members, there should be little trouble reaching agreement, and Congress should be able to send a bill to President Ford to sign before the session ends.

The bill reflects the feeling on Capitol Hill that solar energy has been given too low a priority in the Administration's energy planning, and that present efforts in harnessing sunlight for practical purposes have been too fragmented. It also reflects the fact that a vote for solar energy goes down well back home in election year.

The House and Senate versions of the bill are in complete accord on two major points. First, they would both establish a Solar Energy Coordination and Management Project, consisting of top officials of five governmental agencies and one Presidential appointee, to oversee the federal government's solar energy activities. Such a body "represents a recognition that changes need to be made in the way in which priorities for energy research and development are set and the way in which the Federal Government organises itself to carry them out", according to one of the bill's chief sponsors, Representative Mike McCormack of Washington State. At present, the National Science Foundation has been assigned the leading role in solar energy research and development, but at least a half a dozen agencies have a finger in the pie.

The second chief point of agreement is the need to establish a special Solar Energy Research Institute. Modelled on one of the laboratories of NASA or the Atomic Energy Commission, the institute would be established at either a new or an existing energy laboratory of the federal government. No determination has yet been made on where the laboratory should be established, but Congressional jockeying can be expected from politicians who would like to have it in their home state.

Both bills also define solar energy to include not only direct conversion of sunlight to electrical power and heating, but also ocean thermal power conversion and windpower.

The chief difference in the bills is the amount of money which they recommend should be spent. A preamble to the Senate version states that solar energy research should be funded to the tune of $1,000 million over the next five years, and it also provides $100 million for the remaining half of the 1975 fiscal year. The House version, on the other hand, would provide only $2 million this year to draw up a research and development, and whatever is necessary in following years. McCormack said during hearings on the Senate bill, however, that the $200 million a year estimate is probably "in the right ballpark". Whatever the conference committee finally decides, a large increase from the present level of $50 million a year can be anticipated.□

Research in France: austerity budget

from the Staff of La Recherche

WHEN President Pompidou arrived at the Elysee in 1969, he set out to reorganise the structures of scientific policy. The creation of a Ministry of Industrial and Scientific Development in 1969 actually marked a kind of break with the Gaullist period of scientific policy, even though research, for two years, had no longer been given the priority that it had after 1958. This Ministry, which inherited projects from the former Ministry of Industry and those of the former Ministry of Research also had to oversee the Deligation Genèral à la recherche scientifique et technique (DGRST) which is (or should be) in charge of the coordination of science policy.

It is this hybrid and rather awkwardly functioning ministerial structure that M. Giscard d'Estaing inherited last May. When the new government was set up, Prime Minister J. Chirac decided not to modify the structures of scientific policy fundamentally and entrusted the responsibility of a Ministry of Industry and Research (whose projects are almost identical to those of the ex-Ministry of Industrial and Scientific Development) to M. d'Onano. Hhe first problem which confronted the new minister was the preparation of the budget for 1975. Since it was imperative to fight inflation, drastic cuts in public spending for the following year had to be imposed and thus scientific research will have an austerity budget in 1975. After the Prime Minister's bargaining session, the increase in total funds for research and development included in the 'Enveloppe Recherche' (which comprises the largest part of civil research except for telecommunications and major civil aeronautical programmes) will be about 13% in 1975. This budget raise in funds is approximately as large as that planned for all state expenses, but it may be insufficient to compensate for inflation which is currently increasing at an annual rate of about 15%.

Of course, this budgetary growth conceals serious disparities. First of all, one must realise that basic research will be treated to a relatively lesser degree in 1975 than in 1974 since the increase of programme authorisations for the CNRS will be about 7% next year and this agency will be granted very few newly created budgetary positions for researchers: about 100. Only medical research will continue to have relative priority since funds earmarked for INSERM (Institut National de la Santé et de la Recherche Medicale) for equipping its laboratories will be increased by 28% next year. On the other hand the big projects (the so-called 'grands programmes') which have been the object of much controversy for several years in France will undergo an austerity squeeze to a varying extent. Thus, although the budget increase for the CEA (Atomic Energy) is about 16%, that for CNES (Space Research) investments is practically nothing, as are the funds for the 'Plan Calcul', that is computers.

At any rate, in the fields of space and computer science, budgetary decisions are perhaps only temporary. The choices made reflect a certain agreement to make research in the field of energy a high priority item (funds will be increased by 27%). As far as aid allotted to industrial research is concerned, the 1975 budget will mark a slight acceleration in growth (a 16% increase for the process of aid to development). This research budget, the first of M. Giscard d'Estaing's seven years' term gives some indication of a trend but it does not constitute in itself a scientific policy. The reorientation of research efforts in relation to new priorities implies structural reforms. On this level, major decisions are still being studied. A reorganisation of the Ministry of Industry and Research and of the DGRST could take place in the autumn. The only measure taken in this regard during the summer was to connect the "Delegation à l'informatique" which oversees the 'Plan Calcul' for computers to a new Department of Electronic Industries and Computers within the Ministry. But, at present, the new government's most important innovation is the creation of a Secretary of State to the Universities who is completely autonomous and oversees the universities and the CNRS, thus restricting the power of the Ministry of National Education to elementary and secondary schools. This secretary is expected to outline a policy for university research which the former Ministry of National Education never really concentrated upon. Only during the next few months will one really be able to judge the objectives that the new government intends to pursue in scientific policy. □

Business: problems for Ferranti

from Roger Woodham

ANOTHER British company, the electrical and electronics group Ferranti which makes a wide range of things from naval and aviation electronic equipment to the humble domestic electricity meter, is short of money and has persuaded the government to help out. Looking on the gloomy side and assuming that Ferranti's financial needs continue to grow unabated in the near future, the government has bought the company only a few months of respite with its promise of guarantees to the tune of £5 million so that Ferranti's bank overdraft can be increased yet again. These are the stark facts that make estimates that British industry will be short of perhaps £3,000 million by the end of the year seem plausible.

Ferranti is an interesting case inasfar as much of its work is inextricably linked up with European defence. Sales last year were worth £72 million, £52 million of that in the British market with 40% being accounted for by defence contracts with the British government. Many of its exports go to Europe but the company describes the destinations of its foreign sales as "traditionally erratic", citing a large one-off contract to supply equipment to the Brazilian navy last year as an example. In spite of all this, profits have been hard to come by in recent years, for the company as a whole at least; a profit of £3 million in 1967 turned gradually into a loss of £900,000 in 1971 and the accounts are still in the red after two years of improvement.

The development budget—Ferranti says it does no 'research' in the accepted sense—runs at £15 million a year, about a third of which is for governments. The company declines to say how many of its workforce of 17,000 are involved in development because a correlation of money and heads" could be commercially embarrassing".

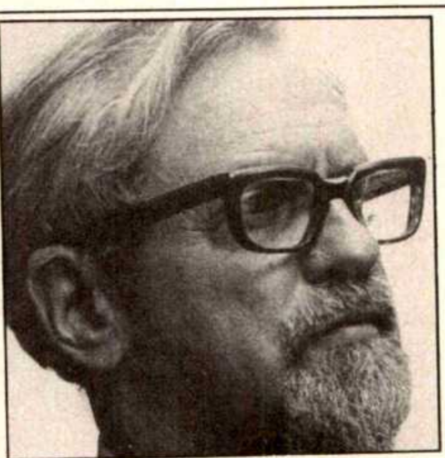
The future for Ferranti in the longer term will depend to some extent on who wins the general election. The present government has several options:

- To buy a stake in the company, thus wresting control from the Ferranti family.
- To bring in an outside organisation to manage the whole concern.
- To provide, as part of a more wide ranging industrial policy, some form of financing for the medium term.
- To persuade the company to sell off parts of itself in order to create a more viable unit. There are several precedents, for example, the sale of Ferranti computer interests to what is now the computer company ICL in the 1960s. □

AMERICA'S first scientifically-based Center for UFO Studies, established by J. Allen Hynek (right) after a wave of UFO reports across the States last year, is planning to ask the National Science Foundation and NASA for funds in the near future. The Center, a loose affiliation of scientists from a dozen US universities, is currently funded by private donations, but feels that its stock in trade—scientific credibility—stands sufficiently high for approaches to be made to establishment bodies like NSF and NASA.

Hynek, professor of astronomy at Northwestern University, Illinois, and author of the best-selling *The UFO Experience*, has been interested in unidentified flying objects for years, and has developed contacts with what he calls the "invisible college" of qualified scientists who believe the UFO phenomenon to be worthy of investigation. In correspondence they agreed that it was time to set up a Center to provide reliable UFO information and to collect reports of events for investigation.

Hynek rented the services of a toll-free telephone switchboard that is manned round the clock, seven days a week, and distributed its number to police throughout the United States. UFO reports on this hot line average about one a day (or night). Depending on their importance, cases are followed up in person or by a questionnaire.



The scientists of the Center are preparing a report on the 1973 UFO wave in which 1,500 cases are listed. The sightings started in the south-eastern states and, in Hynek's words, "spread along the river valleys". When published next spring, the report will be a valuable study of a major UFO event.

Hynek's work has started a steady shift in public and scientific attitudes to UFOs which are documented in a revealing hour-long TV programme being screened coast-to-coast in December by NBC. "I think the programme's impact will be considerable," says Hynek. "When the next wave occurs the Center will be there to serve."

Hynek is impressed by the fact that the nature of the phenomenon itself is the one thing that has not changed. "The typical UFO report today is essentially the same as it was 10 years ago," he says. Yet he carefully points out that he does not support the idea that UFOs are nuts-and-bolts spacecraft from other worlds: "There are too many things against it. It seems ridiculous that any intelligence would come from such great distances to do reportedly stupid things like stopping cars and frightening people. And there are far, far too many reports."

For Hynek and the members of his "invisible college" there remains no doubt that the UFO phenomenon is real. But its explanation? He draws a parallel with early attempts at explaining what makes the Sun shine, which faltered through lack of knowledge of physics. Currently, all the UFO Center can do is to define the limits of the problem. Says Hynek: "We're setting down the things that any hypothesis will have to explain." And, returning to the conclusion of *The UFO Experience*, he adds: "When the solution does come, it's going to be one hell of a quantum jump."

IAN RIDPATH

End of MRC's Edinburgh unit

by Peter Newmark

AFTER seventeen years of pre-eminence in a much-vaunted field of science the Medical Research Council (MRC) Molecular Genetics Unit closed at the end of September. Set up in 1957 at the Royal Postgraduate Medical School, Hammersmith Hospital under the directorship of Bill Hayes, the unit was originally known as the Microbial Genetics Research Unit. In the early 1960s a desire to become more closely involved with teaching as well as research led to negotiations with Edinburgh University. This culminated in a package deal whereby Edinburgh set up a department of molecular biology in which the MRC unit was also to be housed. The chair of Molecular Biology was given to Martin Pollock and his department started up in 1965.

The MRC unit moved up to Edinburgh in 1968 but it was not until 1970 that the department as a whole felt itself to be fully settled down. It was taken for granted at the time of the move that the MRC unit would survive at least until 1978 when Professor Hayes would be 65 and therefore obliged to retire as director of the unit. However in 1971 Professor Hayes began to consider an early departure. It was this that finally precipitated the premature closure of the unit this year.

When the unit was founded microbial genetics was a relatively young subject, but it was clear that it was due for rapid expansion. As such it was an ideal candidate for the MRC to support, in that one of their prime justifications for providing long-term support for a subject is when "for reasons of scale, subject specialisation and duration (it) could not as effectively be organised within a university or medical school". Few people, at least in retrospect, doubt the prudence of the MRC in injecting funds into microbial genetics at that time. The unit rapidly became pre-eminent and began to attract visiting researchers from many countries. It consistently produced very high quality research into the bacterial mechanisms of, for example, chromosome and plasmid replication, transmission of drug-resistance, cell division, host restriction and the control of biosynthetic pathways. It also, in time, achieved a fine record of dissemination of its research interests into British universities. Former members of the unit took up chairs at Kent, Leicester, Newcastle and Sussex.

There is no doubt that the high standards of research emanating from the unit have continued up to the present time. A fall-off in the quality of the unit's research was therefore not the reason for premature closure. It is, however, hard to define exactly what the reasons were, since it is not MRC policy to divulge them except in very general terms.

The general MRC policy on units of this type is quite straightforward. A unit is set up to encourage a chosen subject on the initiative of an individual who then becomes its director. The planned tenure of the unit comes to the end with the retirement of the director at which time the future of the unit is reviewed. Usually the result is closure of the unit but, sometimes it is continued under a new director. In retrospect at least, it is now clear that the chances that the Molecular Genetics Unit would survive its director were already very slight in 1970/71. The MRC Annual Report for that year stated that "since genetics has now been developed considerably within the universities, the Council no longer feels that there is any general need to renew or establish units (in this field)." As a blanket statement this is not unreasonable. However it is not sufficient as a reason for closing the Molecular Genetics Unit, considering for example that the MRC saw fit to set up the Mammalian Genome Unit in 1973, also at Edinburgh University.

Two main interrelated factors must have been considered by the MRC in coming to their decision. The first was whether there had been a loss of momentum in the research being carried out by the unit. The second was the world-wide shift in emphasis in molecular genetics research from investigating the processes in prokaryotic organisms, especially bacteria, to eukaryotic organisms. The members of the unit dispute that there was a loss of momentum, though they admit that some degree of cohesion had been lost as their individual research interests diversified. They do not dispute that eukaryotic research has become very important, or that it is a suitable field for MRC support, but they are adamant that it would be a great mistake to think that bacterial systems have little left to offer to the advance of molecular genetics.

Although the unit's members are by now prepared to admit that its closure was not unreasonable they remain dissatisfied about the way in which this came about. When Professor Hayes in 1971 first considered retiring from the unit prematurely he immediately enquired of the MRC how this might affect the survival of the unit, at least until 1978. The initial MRC response appeared to be reassuring in hinting that the unit could continue. There was even talk of the likely candidates for taking over the directorship. Professor Hayes therefore settled on his move. Shortly after this and without any consultation with the members of the unit, came the news that a provisional MRC decision had been made to close the unit when the director departed.

As Professor Pollock, who acted as director of the unit after Professor Hayes' departure at the end of 1973, put it: "everyone was dumbfounded". He emphasises that everyone assumed the move to Edinburgh to imply continued long-term support from the MRC. And that had it occurred that this might not extend beyond five years many people, including himself, might not have been persuaded to make the move.

However, at least on paper, the 1971 decision was not specifically directed towards the unit, and, indeed, it heralded two years of discussions before being confirmed in mid 1973. Professor Pollock feels that (at least in the final stages) the handling of these discussions by the MRC was impeccable. Some members of the unit, whose futures were unclear for many months, are less complimentary, although nearly all are happy with the ultimate outcome. The discussions mainly revolved around the fate of the unit's staff. Three of its scientific members already had tenure with the MRC and were therefore at least assured of a job, although in principal they could have been requested to move to any MRC laboratory in the country. However, five senior scientific staff were left with an uncertain future. Professor Hayes decided to put these five up for tenure. The MRC may not have liked this at first but on consideration they encouraged it. Four of the five candidates were successful but again this assured only a salary, not a specified place to work.

The MRC at this stage hoped to disperse the tenured staff throughout the country, with the rationale that dissemination of expertise has a beneficial effect on its recipients. However, this proposal was met with great resistance on the grounds that the collective research capacities of the unit should not be disrupted and that too many personal hardships would be incurred by moving. It is possible that this resistance paid off. In the end, after complex negotiations, many of which involved discussions with the trade unions to which the unit's staff belonged, a solution was achieved. A solution which was unbelievably better than seemed possible in the early stages and which in many ways has the appearance of a face-saving operation by the MRC. All six tenured scientific staff members who wish to stay in the department are to be allowed indefinitely to remain there and do the same research as at present. They are to become members of the University Department of Molecular Biology, with their salaries paid for by the MRC.

In addition the MRC is providing reasonable technical assistance for

Letter from Italy (but only just)

By now everybody is aware that the Italian postal services are out of order The damage to the Italian economy must be enormous, if at all calculable· a typical "transforming" economy which is based on export-import and tourist trade cannot exist without communications Science, being deeply international by character, must suffer too

In fact, apart from the usual complaints about the scientific bureaucracy, the most popular topic of conversation among scientists is the abominable state of the postal services Everybody has a favourite story to tell about some postal disservice, which has been worse than anyone else's My worst case is the following an official letter was sent from an organisation to an individual in the same town, in fact the sender and the addressee lives 50 metres apart The letter took exactly 50 days to arrive. that is, one metre per day

Officially there is no strike—for that at least one could prepare better—but only a go-slow, so the results are completely unpredictable and haphazard, the fluctuations from the average delay are very large Apparently all this is caused by the unwillingness of the Ministry to give the men overtime There are delays the scientists cannot do anything about, and others about which they can For example, when ordering and receiving scientific materials, the orders go out with many weeks' delay (on top of the ordinary, "inevitable" administrative ones) and the stuff arrives with even greater delay (this is helped by the occasional wildcat strike of the customs) Not only is thus the experimental work greatly hampered, but in these inflationary times it causes unnecessary financial loss

Scientific journals arrive several months late, if at all (according to newspapers, many tonnes of printed material were simply destroyed by the agents to whom the post office entrusted them for distribution) There is no rational pattern about it In the Frascati science area there are several libraries subscribing to the same journals, however, a particular copy might arrive with several weeks' difference and in a random time-order The March 22 number of *Nature* arrived on the same date (July 12) as that of June 21 in one library, or the August 9 number arrived on the same date (September 2) as the August 23 in the next library, 100 metres across the road

So one is running around the various libraries to find the most up-to-date copy At least now the average delay is only a matter of a few weeks against several months not long ago Also one asks one's scientist friends abroad to photocopy a particularly important item and send it by registered express mail Perhaps it will arrive quicker that way (Not always in the spring more than a million registered letters accumulated in a special sorting office near Rome)

Of course, letters are late too—a request for a reprint posted in January in the States, arrived in July To send out a paper for publication by post is a game of chance So one tries to exploit people who travel abroad for missions, conferences In fact, the international organisations here, like FAO and ESRO, as well as large industries, have organised regular weekly courier services, *à là middle ages* Unfortunately this does not solve the problem of the incoming letters (unless they are addressed to a centre abroad and collected from there)

Particularly vulnerable are scientific meetings in Italy these days At a recent conference on the magnetosphere in Frascati ten scientists came to the conference whose registrations arrived from one week to three months after the event About 10% of the participants cancelled their registration, but their letters arrived when the conference was already over About another 10% did not come probably because of the postal difficulties One author who could not come sent his paper and his slides by post for presentation at the conference, they arrived one month after the conference Some of the main speakers did not receive the letter about the division of topics among them they got to know it for the first time from the printed posters!

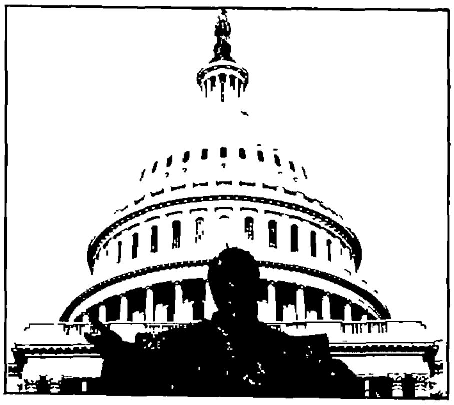
Of course, the main message of all this was that 80% of the scientists came nevertheless, delivered their papers, discussed the magnetosphere and other problems while sipping a glass of good Frascati wine Thus the scientists are not completely downhearted They help themselves as they can They use telex for everything possible—or even impossible, like for instance, writing a common paper with colleagues in Boulder, Colorado, via telex Also, travel arrangements and other urgent matters they conduct over the phone Because of the numerous overseas calls, the telephone bill has gone up a bit Letters would be cheaper—but at least the telephone and telex still work For the moment George Magyar

---

seven years This includes secondment of those members of the unit's technical staff who wish to retain the option of continued employment by the MRC Furthermore like any other research worker, the staff can now apply to the MRC for short-term support of graduate, post-doctorate and visiting research workers This they have already done with some success Ironically they might finish up with more MRC funds that the unit was consuming On the other hand the MRC has more direct control over what research projects they wish to support in the future

Are there any lessons to be learnt from the closing of this particular MRC unit? The final result is satisfactory in many ways but inevitably the interim two years generated a lot of anguish amongst those whose careers were threatened This has certainly confirmed a problem that the MRC were already aware of, namely that they must try and avoid supporting people for so long that it becomes unrealistic for them to find alternative jobs This has led to a continuing shift in MRC support away from long-term commitments

A more specific lesson that has been learnt is that consultation with a unit in future must precede provisional decisions about that unit With luck this may mean that future closures will involve less suffering For there is no doubt that two years of indecision has been detrimental both to the research and to the general morale of the ex-members of the late-lamented MRC Molecular Genetics Unit □



Washington seen

by Colin Norman

THE US Atomic Energy Commission has run into yet another snag with its liquid metal fast breeder reactor (LMFBR) programme The commission has now acknowledged what has been rumoured for some months—the estimated cost of building and operating a demonstration LMFBR has increased by 250% in two years The latest estimate, based on a year-long internal AEC study, is that the demonstration plant now being constructed in Tennessee will cost $1,736 million to build and operate for five years, in 1972, the AEC reckoned it would cost $699 million Furthermore, the AEC now says that the plant will not start operating until late 1982 or early 1983, three years behind the original schedule

These sharply increased estimates, which the commission puts down to inflation and anticipated construction delays, are already causing some government officials to question privately whether the programme should be allowed to proceed at breakneck speed although at present the LMFBR still ranks as top priority in the Administration's drive to make the United States energy self-sufficient The argument which is being increasingly raised against the LMFBR is that it is soaking up a huge proportion of the total expenditure on energy research and development, with virtually no short-term benefits In the last fiscal year, for example, LMFBR research accounted for more than $400 million in government funds, and according to estimates drawn up by the AEC's chairlady late last year, the entire breeder research programme (including the demonstration plant) could cost nearly $3,000 million over the next five years

The issue is likely to come to a head later this year when the AEC finally produces its much-delayed and completely rewritten final environmental impact statement on the LMFBR programme

● The American Association for the Advancement of Science (AAAS) has been forced to curtail a few activities during the summer in an effort to overcome a severe financial problem—the association ran up a deficit of more than $370,000 last year, and was probably heading for an even bigger loss this year Most conspicuous among the belt-tightening moves, which have been imposed by Acting AAAS Executive Officer Philip H Abelson, is a reduction in the number of pages contained in *Science*, and a decrease in the number of AAAS staff

Abelson, who took over as Acting Executive Officer of the Association early this summer when the previous occupant of that post, William Bevan, left to take up an academic appointment at Duke University, described the cut in the size of *Science* as a "painful expedient", but added that the journal "will not be permanently slim" He said that he hopes that it will be possible to wipe the deficit off the books by the end of the year

The chief reason for the financial crisis seems to be that the association expanded its activities during the past few years at a rate greater than its income allowed It has, for example, taken on a number of large programmes—such as an effort to improve the public understanding of science—which, although funded by grants, have resulted in large overhead costs to the AAAS In addition, it cost more than $150,000 to stage the AAAS annual meeting in Mexico City last year, and the whole situation has been exacerbated by a steep rise this year in printing and paper costs for *Science* Abelson said, however, that he does not expect that any major AAAS activities will be cancelled

● These are hard times for people who have a sweet tooth and a weight problem Not long ago they could sate their appetite for sugar with a choice of artificial sweeteners—cyclamates or saccharin—without risk of the sweetener turning straight to fat But cyclamates got banned for possibly causing cancer, saccharin stands accused of the same crime (although the jury is still out on that charge) and there is nothing to take their place

That is why G D Searle's new miracle sweetener Aspartame seemed for a moment to be a perfect answer to at least part of the sugar lover's calorie problem After all, the stuff breaks down into two essential amino acids in the body, it has proved to be safe when fed at moderate doses to rats and dogs and as recently as July it was approved by the Food and Drug Administration (FDA) for a limited number of uses (*Nature*, **250**, 259, 1974) What possible damage could it cause? Brain damage, according to one impassioned medical scientist

Dr John Olney, professor of psychiatry at Washington University School of Medicine in St Louis, has fired off a memorandum to FDA detailing his concern that Aspartame could pose a high risk to children because it may act synergistically with monosodium glutamate (MSG), a food additive which has been found to cause brain damage in mice

He has asked for a public hearing in which to state his case and the FDA has agreed, although no date has yet been set

Olney, who has for years been trying to bring public attention to the dangers posed by MSG, believes that the two additives could produce the same toxic effects, and he has some preliminary research results to bolster his case He argues that the safety margins calculated individually for MSG and Aspartame are both much lower than the FDA claims, and that if the two are taken together, there is no safety margin at all Furthermore, Olney takes issue with the FDA's contention that a person eating between 1 3 and 1 7 grams of Aspartame a day will be receiving only about 1% of the minimum dose found to be toxic to animals He points out that since the calculation is based on an adult body weight of 60 kg, a 15 kg child eating the same amount will not have an adequate margin of safety

Whether or not Olney's claims will be upheld by the public hearing, there is no doubt that the public relations aspects of his charges will seriously tarnish the image of Aspartame

Meanwhile, in a related development, the FDA refused last month to lift its ban on the marketing of cyclamates Abbott Laboratories, the sole manufacturer of the sweetener, had petitioned to get cyclamates back on the market, claiming that it has amassed sufficient data to prove that the chemical is safe and that the FDA's 1969 ban was ill-founded But the agency advised Abbott that its new data is inconclusive and insufficient

● According to the latest compilation of figures by the National Science Foundation, during the 1969–1975 fiscal years (in other words, during Mr Nixon's Presidency), the proportion of the federal science budget devoted to space activities declined dramatically

But the proportion spent on defence science and technology has remained constant At $10,217 million, the military research and development budget still accounts for more than half the total ☐

Blood disease caused by gene deletion

IN normal adult blood the major haemoglobin is a tetramer consisting of two α chains and two β chains In α thalassaemia, a disease prevalent particularly in south-east Asia, a deficiency in α chains results in the production of abnormal globins—before birth the tetramer γ_4 and in adult life the tetramer β_4

The genetics of α thalassaemia are not completely understood but at least two different mutations in allelic genes have been identified, designated α-thal 1 and α-thal 2 α-thal 1 results in a complete absence of α globin synthesis and in the homozygous condition results in Hb Bart's syndrome γ_4 tetramers are characteristic of this disease which results in intrauterine or early neonatal death In the heterozygous state, that is, when one gene has the α-thal 1 mutation and one has the α-thal 2, the disease is less severe so that survival into adult life is possible This condition is known as Hb-H and is characterised by the β_4 tetramer In some populations (including those in south-east Asia) there are two different structural genes for α globin The Hb Bart's syndrome follows the loss of all α loci, whereas in the Hb-H disease one out of four loci is functional, presumably allowing a low concentration of the normal $\alpha_2\beta_2$ tetramer

Weatherall and Clegg (*Br J Haemat*, **18**, 357, 1970) demonstrated that in victims of Hb Bart's syndrome the α chain is completely absent—there being no evidence of abnormal α chains Since then research interest has centred on the transcription of the messenger for α globin and its translation, to determine whether the α-thal 1 and α-thal 2 mutations reside in the α globin structural genes themselves or in other genes controlling the transcription of the structural genes or the translation of the gene product

Translation in a cell-free system of the globin messenger RNA isolated from reticulocytes of patients with Hb-H disease reproduces the protein synthesis pattern in the intact cell in that very little α globin is synthesised relative to β globin, suggesting that α globin mRNA is present in very small amounts of the reticulocytes The possibility that the cells contained normal amounts of a non-functional α globin messenger RNA could not however be excluded until the experiments by Housman and his colleagues (*Proc natn Acad Sci USA*, **70**, 1809, 1973) Using a probe for α mRNA (prepared by transcribing α globin mRNA into complementary (c) DNA with reverse transcriptase), they clearly demonstrated that the concentration of α mRNA was abnormally low in sufferers from Hb-H disease, and therefore most probably completely absent in Bart's syndrome

Having established that no messenger RNA for α globin was to be found in reticulocytes of α-thalassaemic patients, the next step in elucidating the molecular biology of the disease was to differentiate between the α structural genes and the regulatory genes controlling the transcription of the structural genes, as the site of the α-thal 1 mutation This has now been accomplished by two independent groups whose work is reported in this issue of *Nature* Ottolenghi *et al* (page 389) and Taylor *et al* (page 392) Their conclusions are in close agreement In the conclusive duplicated experiment a cDNA transcript of α messenger RNA was used to probe for complementary sequences in DNA isolated from normal human spleen The extent of annealing of the probe with normal DNA was about twice that observed for α thalassaemia DNA The small amount of hybridisation of the α cDNA to the α thalassaemia DNA may be due to contamination of the α mRNA with β mRNA so that the probe contains some β cDNA Another possibility is that the α cDNA is hybridising to the α-type gene zeta which codes for a globin produced at an early stage in foetal development Both groups conclude that in α-thal 1 homozygotes all (or a large part) of the structural genes for α globin are deleted from the genome This is the first time that a gene deletion has been shown to be the cause of a human disease

PAMELA HAMLYN

Lethal mutants and gene numbers

ONE of the most interesting discussions developing over the past few years has concerned the number of genes in the eukaryotic genome The apparent discrepancy between coding potential and probable gene number, about which this question is centred, has been most marked in *Drosophila* That one band might correspond to one gene was first suggested by Bridges[1] because of the apparent equivalence of the cytological and genetic maps of *D melanogaster* There are about 5,000 bands in the polytene chromosomes, yet the DNA content of *D melanogaster* could be divided into 140,000 lengths of 1,000 base pairs (a reasonable estimate for the average length of a gene) Even after restricting the capacity to code for proteins largely to the non-repetitive component of DNA, a concept supported by recent demonstrations that mRNA is derived largely or entirely from this class of sequence, the coding potential of *Drosophila* DNA remains in excess of 100,000 genes

Any estimate for the number of genes in *Drosophila* thus has immediate implications for the organisation of the chromosome At one extreme, if it is of the order of the number suggested by the coding potential of non-repetitive DNA (100,000), all of this component must represent structural genes and there must be many such genes in each band At the other extreme, a number close to that of the bands would support the earlier apparent equivalence but would bring into question the organisation of DNA within the band and the meaning of the 'gene' The experimental approach of the geneticist has been to accept the traditional definition of the gene as a complementation group and thus to attempt to define the number of such groups into which known mutants fall

Mutations in complementation groups must have visible phenotypes to be detected and recessive-lethal mutations are generally used in the genetic analysis of *Drosophila* In an analysis trying to achieve mutational saturation of the 3*A*1–3*C*2 region of the X chromosome of *D melanogaster*, which displays 15 polytene bands, Judd, Shen and Kaufman[2] identified 16 complementation groups, each of which was mapped with deletions to a single band (although with some ambiguity in region 3*B* where the bands are difficult to distinguish) In subsequent experiments to identify any additional classes of mutant that might have been missed originally, Judd and Young[3] isolated mutants that do not alter adult morphology or viability but cause delayed development or female sterility Two new complementation groups were identified by this analysis, both recessive female-steriles located in the 3*B* region The two groups are linked extremely tightly and may comprise a single unit that exhibits intracistronic complementation Another estimate has been made by Hochman[4,5], who has attempted to identify by lethal mutation every gene on the small fourth chromosome of *D melanogaster* This chromosome displays 50 polytene bands and thus corresponds to about 1% of the genome A complementation analysis of 200 mutations resolved 37 loci coding for essential products at which mutations are lethal or cause sterility when homozygous Another six loci had previously been identified through mutations that are recessive-visible, bringing the total to 43 Estimating the number of probable unmutated loci from the distribution of the 200 mutations in complementation groups suggested the presence of a further 17 genes, bring-the total to 60, slightly in excess of the band number The number of lethal complementation groups in the 3*A*1–3*C*2 X region is thus very close to the number of bands

Late lethal mutants of *Drosophila* can be identified by a technique developed by Shearn, Rice, Garen and Gehring[6] for screening third chromosome lethal mutants for those dying after the third larval instar—these mutants are normal in larval functions but defective in functions essential for pupal and adult development In a complementation analysis of three groups of third chromosome late lethal mutations (72 induced by EMS, 35 by nitrosoguanidine, and 35 by an acridine ICR-170), Shearn[7] resolved the first group into 60 loci, 55 represented by one mutant each, five identified by two mutants each, and one giving rise to seven mutants (presumably a mutational hot spot), the second group comprised 29 loci mutated once and three mutated twice, the third group constituting 31 loci mutated once and two mutated twice The Poisson distribution provides a formula which states the relative frequencies of complementation groups not mutated, mutated once, mutated twice, and so on By fitting the experimental data (ignoring the hot spot) to a Poisson distribution for each of the three sets of induced mutants, the total number of third chromosome genes able to give late lethal mutants was estimated as 364, 172 and 273 respectively Since 23% of all lethal mutants on the third chromosome are late lethals, this corresponds to a total of 750–1,600 lethal loci, the number of bands on the third chromosome is about 2.030

If it is true that each complementation group defines a single structural gene (plus any *cis*-dominant regulatory elements), the phenotype of different lethal mutants within each complementation group should be more or less uniform Shannon, Kaufman, Shen and Judd[8] concluded that their non-complementing mutants in the 3*A*1–3*C*2 X-chromosome region do indeed show similarities of phenotype Shearn has also found this to apply to the third chromosome late lethals, using a stringent test of uniformity in which imaginal disk developmental potential was assessed by dissection of disks, injection into metamorphosing hosts, and examination for differentiated structures Disk development is a good criterion since the disks, although superfluous for larval development, give rise to most of the adult structures, many or most late lethals are defective in disk functions (In an analysis of lethal mutants with imaginal disk defects, Shearn and Garen[9] recently identified 52 complementation groups on the third chromosome and concluded from a Poisson distribution analysis that there should be at least 435 such loci *in toto* on this chromosome, about a fifth of all complementation groups) Analysis of the imaginal disks of each pair of Shearn's non-complementing third chromosome late lethals suggested that in each case both mutants caused the same defect This is consistent with the idea that each complementation group represents a single gene function

A critical question which must be resolved before lethal complementation groups can be taken to identify all genes is whether 'null' loci exist—that is, genes whose failure to produce a protein leaves no identifiable mark on the phenotype Two extreme models are to suppose that null loci are atypical so that the small number of lethal loci identifies most genes, or that lethal loci are atypical and the genome largely constitutes a high number of unidentifiable null loci An alternative to these models has been discussed by Bishop[10] 'genes' might be multifunctional, each comprising a transcription unit coding for several proteins, so that although null loci might identify single dispensable protein chains in these units, mutation in other parts of the unit would be lethal

Some apparent null loci have been identified in *Drosophila*[11], but before these can be accepted as such it is necessary to show that mutation at each locus represents a deletion—otherwise it remains formally possible that some gene function remains, although in a form not detectable by simple assays for the protein And assuming that null loci exist, it becomes important to estimate their proportion relative to loci at which deletion is lethal in order to decide whether they represent a major class But for the presence of null loci to repudiate the complementation group–band equivalence by conferring a protein coding function upon most of the DNA in the *Drosophila* genome, it would be necessary for most genes to fall into this class, although it is clearly reasonable that the absence of some gene products might be compensated by alternative metabolic pathways, it is difficult to believe that most genes may be dispensable

It is of obvious interest to obtain estimates of gene numbers in other organisms as well as *Drosophila* and this adds to the importance of a genetic analysis of *Caenorhabditis elegans*, a nematode, reported recently by Brenner[12] *C elegans* is a hermaphrodite (each animal produces both sperm and eggs) and has about 600 somatic cells, half of which are neurones, making it suitable for a planned genetic dissection of the nervous system In an analysis of the DNA of this organism, Sulston and Brenner[13] show that the haploid content is 8×10^7 base pairs (about 20 times that of *Drosophila*) and 83% of the DNA sequences are non-repetitive To achieve a genetic analysis, Brenner has made use of the males which occur in small numbers in a culture and which have the chromosome constitution 5AA+XO instead of the hermaphrodite 5AA+XX

The 285 mutants, most recessive, induced by EMS and identified by morphological and behavioural differences from wild type, fall into six linkage groups and map at 82 genes The limited criteria used to identify mutants mean that only one class of genes is represented, but the large numbers of loci at which more than one mutation occurred suggest that mutational saturation of this class was achieved From the frequency of occurrence of these mutations, Brenner calculates that the average forward mutation rate induced by EMS under his conditions is about 5×10^{-4} per gene Since the non-repetitive DNA component of *C elegans* corresponds to about $6 7\times10^4$ lengths of 1,000 base pairs, if this mutation rate is typical of all genes it would imply that about 34 genes are mutated in each genome If all the DNA represented essential structural genes, each chromosome would thus carry six lethal mutations linked to the visible mutation isolated—clearly impossible since in this case it should not have been possible to isolate the visible mutant Another calculation is possible from the measured frequency of induced lethals per X chromosome, of 0 15 At an average induction rate per gene of 5×10^{-4}, this requires 300 genes This would mean that the six chromosomes constituting the genome contain less than 2,000 genes, representing only 3% of the coding potential Each of these 'genes' could contain 30,000 base pairs, a number similar to the average content of the *Drosophila* band It is interesting to note that the apparent number of lethal loci is of the same order of magnitude as the number of bacterial genes

Estimates of gene number have also been made for man Taking the frequency of deleterious mutation at each locus to be 10^{-5}–10^{-6} as suggested by Muller[14], the human genome of 3×10^6 potential 1,000-base genes should accumulate 3–30 harmful mutations each generation The unacceptability of such a high genetic load has led to suggestions that only a small part of human DNA codes for proteins By reversing the argument, if the actual rate of mutation is known, it becomes possible to calculate the number of genes, Ohno[15] has calculated a number of 4×10^4 and another estimate[16] is about 10^5 But these calculations involve assumptions about parameters such as generation times during evolution and rely upon indirect data for overall mutation rates Although they are therefore clearly not too reliable, the conclusion that only about 5% of human DNA should code for proteins is in line with the estimates for *Drosophila* and *C elegans*, if this number is correct, it does not, of course, prove the validity of the genetic calculations, but if much more human DNA codes for proteins, then the genetic estimates must be incorrect

Each lethal mutation formally identifies an essential site on DNA without making any implication about its function Some mutations may therefore lie in regulator loci rather than structural genes But since mutations within a gene or *cis*-dominant control element should fall into the same complementation group, the number of lethal complementation groups can be taken as the number of structural genes (Of course, any genes coding products which are regulators are included in this number together with genes coding enzymes or structural proteins) Accepting an estimate of 1,000 base pairs for the length of each gene, these low estimates for gene number imply that only a small proportion of eukaryotic DNA codes for proteins This conclusion is consistent with recent hybridisation analyses which show that mRNA is derived largely or entirely from non-repetitive sequences[17–19] and seems to be of comparatively low analytical complexity[20,21]

What can be the function of the non-coding DNA? In addition to all or almost all of the intermediately repetitive DNA component, for which a role in providing recognition elements in control systems can be proposed, this class includes most of the non-repetitive DNA component in which the structural genes are located One extreme model for the structure of the genome is to postulate that each identified lethal complementation group is of a small size, that is of the order of a 1,000 base pair coding sequence and an associated short control element, and that the remaining DNA is without any function identifiable by mutation, if this function is to code for proteins, then most gene products must be dispensable An alternative extreme model is to suppose that the genome is functionally divided into the small number of lethal complementation groups, each comprising some 30,000 base pairs and therefore including a coding sequence as only a minor part of its length, the purpose of the non-coding sequences can be a matter only for speculation The apparent correspondence between genetic loci and bands in *Drosophila,* however, which implies that a large amount of non-coding DNA is associated with the coding sequence in each band, fits well with the second model, and biochemical experiments on the sequences within bands therefore offer one of the most promising opportunities to resolve genetic organisation at the level of DNA

Nature and distance of the sources of Vela gamma rays

THE detection of bursts of cosmic gamma rays by instruments on the Vela satellites (Klebesadel, Strong and Olsen, *Astrophys J Lett*, **182**, L85, 1973) has given a much-needed boost to gamma ray astronomy More than twenty bursts have been observed and they have time scales ranging from one to thirty seconds with evidence of faster pulsations within each burst So far, no optical or radio emissions have been observed to coincide with the bursts

One of the fascinating aspects of a discovery such as this in modern astronomy is the speed at which the subject develops, into a few years is compressed what, in previous eras, would have taken decades or even centuries to accomplish The problem which is occupying the attention of many astronomers at the moment is the question of the distances to the sources of the bursts As always in astronomy this is a crucial question because, until it has been answered, we cannot estimate the scale of the energy release

One of the classic tests of the distances to a class of astronomical objects is the distribution of the objects over the sky This test relies on the fact that our Galaxy is a flattened distribution of stars and gas, thus, provided we can detect a large proportion of any class of objects in the Galaxy, these objects should seem to cluster around the Galactic plane On the other hand the universe outside the Galaxy seems to be isotropic, and extragalactic objects should be distributed isotropically over the sky One limitation of this test is that if the objects do lie in our Galaxy, but we can only detect the nearby ones, they will not seem to cluster around the Galactic plane, the naked eye stars are in a class of this type

An alternative method of gauging the distances to the sources is to measure the distribution in the strengths of the bursts as received at the Earth If the sources are distributed isotropically in space then the number of sources with an apparent strength greater than any value, *S*, will be proportional to $S^{-3/2}$ On the other hand if the sources are confined to the Galactic plane the distribution in the apparent strengths will be proportional to S^{-1}, if the sources are confined to a line as would be the case if they were predominantly in the local spiral arm of the Galaxy, the distribution in the apparent strengths will be proportional to $S^{-1/2}$

Strong and Klebesadel (page 396 of this issue) have applied these tests to the data they have received from the Vela satellites The information on the positions of the sources is poor because the angular response of the detectors on the satellites is isotropic, some information is available because each burst was detected on at least two well separated satellites and approximate positions can be derived from the difference in the arrival times of each burst at the two satellites The distribution in the apparent strengths of the sources seems to be proportional to $S^{-1/2}$ and Strong and Klebesadel claim that this suggests the sources lie in the local spiral arm of the Galaxy But to draw this distribution, they had to extend their observations to include a number of weak bursts and some suspicion must remain that their data on the weak bursts are not complete

Many experimentalists will view the conclusions of this paper with some concern The frequency of the bursts which have been observed by the Vela satellites is small, only ~20 bursts having been recorded in three years But the detectors on the Vela satellites were small and they were able to detect only the stronger bursts, there was hope that larger detectors flown on balloons would be capable of recording a much greater rate of events which would more than compensate for the shorter exposure provided by balloons If the distribution of apparent strengths varies as $S^{-3/2}$ then a large balloon-borne detector would record several events per day, but if the distribution varies as $S^{-1/2}$ the rate would be less than one per week and the experiment would be much less attractive

The lack of reliable distance estimates has not prevented theoreticians from speculating on the nature of the sources The short time scale of the bursts implies that the dimensions of the sources must be small, and most of the theories which have been proposed have assumed a stellar origin for the bursts Colgate (*Can J Phys*, **46**, S476, 1968) had predicted that a burst of X rays and gamma rays would be produced by the relativistic shell of material ejected from a supernova explosion, but, according to this theory, the time scale of the burst would be measured in microseconds and not seconds Moreover no supernova has been observed to coincide with a gamma ray burst Stecker and Frost (*Nature phys Sci*, **245**, 70, 1973) have remarked that the time structure of the bursts is very similar to that of the X rays which have been recorded from solar flares The energy output in a typical gamma ray burst, assuming the source is at a distance of 10 pc, is however ~10^{35} erg which is more than six orders of magnitude greater than that observed in the strongest solar flare Stecker and Strong suggest that the gamma ray bursts are flares on magnetic stars which have magnetic fields three orders of magnitude greater than that on the Sun and might therefore be expected to produce much more energetic flares But it is difficult to see why the time scales should be so similar when the magnetic field strengths are so different

Another theory, by Pacini and Ruderman, is published on page 399 of this issue This theory suggests that a burst is produced on the surface of a neutron star when the neutron star suffers a sudden increase in its angular velocity These sudden increases, or glitches, have been observed in a number of pulsars and it is thought that they are due to sudden decreases in the radii of the stars A change in the radius of a star would be accompanied by a change in the strength of its magnetic field, and there would be a large release of magnetic energy Some of this energy would be converted into relativistic electrons which would then radiate X rays and gamma rays Pacini and Ruderman estimate that there are enough pulsars within a distance of ten parsecs from the earth to explain the observed gamma ray bursts

Two papers in this issue report the measurement of gamma rays from pulsars Kniffen *et al* (page 397) have measured the gamma ray flux from NP 0532 and Albats *et al* (page 400) have observed gamma rays from PSR 0833-45 It is, perhaps, significant that all the well established sources of gamma rays, apart from the disk of the Galaxy, have intensities which show very rapid variations with time Bondi and others have stressed the potential which exists in astronomy in the study of phenomena on very short time scales, and it may be in this field that gamma ray astronomy will make its largest contribution

The stimulus provided in recent years by radio and X-ray astronomy has shown how much the scope of astronomy had been limited when measurements could only be made at optical frequencies, in the future we may see that the long reign of photographic techniques in observational astronomy, and the consequent long integration times of the observations, may have had an equally restricting influence on the development of the subject R R HILLIER

Historic first with community ecology

from Robert M May

A MAJOR purpose served by the First International Congress of Ecology, held in The Hague from 8-14 September was to bring to a focus some of the achievements of the International Biological Program (IBP) The motivating idea of IBP is that communities of plants and animals are productive systems with definable inputs and outputs The hope is that if we accumulate a sufficiently thorough body of measurement and knowledge about these inputs and outputs, we will end up with a better understanding of how ecosystems function, and, in particular, how they respond to the changes wrought by man Judged on their merits (rather than against the overblown aims which were often invoked to justify the early funding of IBP), the accomplishments are substantial

Consider, for example, the total annual production of plant material (primary production) of the earth's land masses Knowledge of quantities of this kind is clearly a *sine qua non* for rational management of the environment One of the earliest estimates of terrestrial primary productivity is due to Leibig around 1850 100×10^9 metric ton per year Ten years ago the widely accepted figure was $40–50 \times 10^9$ ton per year Drawing together many different strands of investigation, essentially all of IBP origin, H Leith of the University of North Carolina gave an estimate which is back near Leibig's guesstimate, namely $110–120 \times 10^9$ ton per year Leith emphasised that there are still uncertainties (another view, put by L E Rodin of the Komarov Botanical Institute, Lenigrad, and N I Bazilevich and N N Rozov of the Dokuchaev Soil Institute, Moscow, would assign a more generous figure of 170×10^9 ton per year), but the 110–120 figure seems now secure to within at worst a factor of two Around 1960 the total marine primary productivity was thought to be about 140×10^9 ton per year, Leith's and the Russian surveys agreed on a current estimate around $50–60 \times 10^9$ ton per year Thus over the past decade IBP studies have led to almost an order of magnitude revision in the terrestrial/marine primary productivity ratio

The major remaining uncertainties as to terrestrial primary productivity are in the tropics These equatorial regions, many of which are under increasing stress from the pressure of human activity, are in need of much further research Leith and others emphasised that temperate zone agricultural systems are unlikely to be best for tropical and subtropical regions

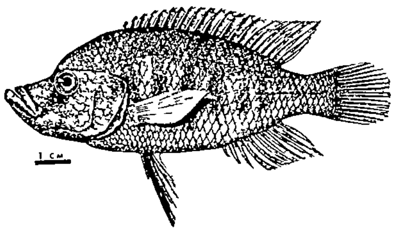
Reviews of current knowledge about secondary production—microbial and faunal production in terrestrial, freshwater and marine ecosystems—were given jointly by O W Heal from Merlewood Research Station, England, and S F MacLean, from the University of Alaska, and also by A Macfadyen, from the New University of Ulster These reviews, which included discussion of the comparative productive efficiencies of different classes of organism and of different levels in the trophic chain, were necessarily painted with a coarse brush, as comprehensive data are rare for most types of ecosystem and much of the IBP research remains to be digested Overall, there emerged estimates of the total secondary productivity in various types of ecosystem which seem secure to within a factor of ten In particular, there was general agreement that we are beginning to understand the limits to the rate at which material can be processed as it passes along the food chain, but there can be major upsets and fluctuations from year to year (as, for example, in pest outbreaks or lemming cycles)

One of the more noteworthy conclusions of the studies of secondary production is that the bulk of it takes place below the ground The birds and bees may engage scientific curiosity, but 90 to 99% of secondary production is by decomposer organisms in the soil and leaf litter MacLean humorously underlined this point by remarking that if humans must consume at the secondary rather than exclusively at the primary level (eat meat instead of only plants), they should at least consider eating earthworms rather than beef

In the plenary session devoted to "diversity, stability and maturity in natural ecosystems", G H Orians of the University of Washington, R H Whittaker of Cornell University and R M May of Princeton University marshalled various lines of empirical and theoretical evidence to suggest that communities with a rich array of species and a complex web of interactions (the tropical rainforest being the paradigm) are likely to be more fragile than relatively simple and robust temperate ecosystems This inverts the conventional wisdom that "complexity begets stability", but seems more in accord with such reported facts as (1) relatively simple arid ecosystems, including human populations with different economies, have persisted for long periods, fluctuating within well-defined limits (I Nor-Meir, Hebrew University, Jerusalem), (2) estuarine ecosystems seem to be disturbed less by, and to recover faster from, indignities imposed by man than do marine ecosystems of higher diversity (D F Boesch, Virginia Institute of Marine Science), (3) the tropical rainforest seems to be a 'nonrenewable source' when it is disturbed over sufficiently large areas (A Gomez-Pompa and C Vázquez-Yanes, Institute of Biology, UNAM, Mexico)

The final two days centred around "diversity, stability and maturity in ecosystems influenced by human activities", and "strategies for management of natural and man-made ecosystems" Here most speakers agreed that many aspects of human activities are now on a scale comparable with natural biogeochemical processes, but that both short and long term impacts are uncertain N Alexander of Cornell University discussed the response of microbial communities to human activities He pointed out that microorganisms are of enormous importance to the functioning of natural communities, that the impact of pesticides, polychlorinated biphenyls, acidic mine wastes and suchlike on various populations of microorganisms cause disturbances which range from "none to catastrophic", and that our ability to predict such outcomes are as yet woeful In a major review paper, J Jacobs of the University of Munich noted the ambiguities and uncertainties associated with the definition of human impact on natural systems, which are typified by a study of bird biomass and diversity in Finland in Helsinki, there were 21 species and a biomass of (in some appropriate units) 1,089, in rural areas near houses, an average of 80 species and a biomass of 371, in areas undisturbed by man, an average of 54 species and a biomass of 297

Indigenous fish



Haplochromis parorthostoma, found only in Lake Victoria, East Africa It is one of more than 100 endemic species of the cichlid genus *Haplochromis* which have evolved in the 750,000 years for which the lake has existed According to P H Greenwood (author of *Cichlid Fishes of Lake Victoria The Biology and Evolution of a Species Flock,* British Museum, London, 1974, £6 00) the explosive speciation was the result of a fortuitous combination of circumstances Lake Victoria (originally a group of lakes) offered many environmental niches, the extent of anatomical specialisation of the ancestral river fish was neither too great nor too small to allow further specialisation in Lake Victoria, and the complexity of the fishes' breeding behaviour allowed barriers to interspecific crosses to evolve

The above account touches upon some of the larger themes of the congress In so doing, it unfortunately has to pass over many interesting individual contributions I particularly enjoyed the account by M Cody, of UCLA, of the parallel and convergent evolution of the avifauna in 'Mediterranian' habitats in California, Chile, and Africa This study was part of the IBP Convergent Ecosystems Project, and it provided detailed illumination of the way species with different evolutionary histories come to have similar roles, to provide striking constancy in the ecological structure of geographically separated communities A diverse array of skills was brought to bear by G H Orians, R G Cates, D F Rhoades and J C Schultz, of the University of Washington, to elucidate some aspects of the cost–benefit accounting of the biochemical defences which plants maintain against the beasts which seek to eat them, and of the biochemical strategies in turn adopted by these consumers

I think the congress would have been improved by widening its scope in two respects

By focusing on the structure and function of whole communities of plants and animals (community ecology) For instance, theoretical notions about domains of stability, or about some numerical characterisation of ecosystem 'resilience', are beginning to be brought into confrontation with the real world in recent studies of low-dimensional systems such as insect host–parasite populations, for complex multispecies communities I think such theoretical speculations are a long way from quantitative testing against nature

Moreover, the congress was largely confined to technical aspects of how ecosystems work Given that the word 'ecology' has come to mean all things to all people, such a narrow construction was probably the wisest course for a professional meeting Even so, I would have liked to see one looser session, in which economists and professional ecologists aired speculations as to whether, for example, the contemporary global patterns of inflation are tied to real diminution in *per capita* supplies of food and energy, or whether these patterns are merely artifacts of present economic systems To have held such a session may have run the risk of vulgarising the congress, but to have done otherwise runs the larger risk of seeming to fiddle while the world burns

●

Is the Martian core solid or liquid?

from Peter J Smith

FROM the mass, radius and moment of inertia of Mars as determined by orbiting and passing spacecraft, it may be reasonably concluded that the planet has a central core. But is the core solid or liquid? The correct answer to this question is not only of interest in its own right, it may also help to resolve a disagreement which is about to arise over whether or not Mars possesses an internal magnetic field. Last year, Dolginov *et al* (*J geophys. Res*, **78**, 4779, 1973) interpreted Mars 2 and Mars 3 magnetometer data in terms of just such a field, but apparently Bogdanov and Vaisberg will shortly argue that the observed magnetic field variations are the result of solar wind–planetary ionosphere interaction instead. Clearly, if it could be shown that the Martian core is solid, an intrinsic magnetic field (at least, produced by dynamo action) would be ruled out, although it must be admitted that proof of a liquid core would fail to resolve the issue either way.

In a situation where the confirmed presence or absence of an internal magnetic field cannot itself be used to infer the state of the core, the obvious approach is to examine the thermal conditions in the Martian interior. Unfortunately, there are no experimental thermal data from Mars. Mariner 9 revealed evidence of extensive volcanism (including a series of prominent shield volcanoes), mildly cratered plains similar to the lunar maria, and circular features such as domes and craters, but although this suggests that at some time in the past Mars must have been hot enough for partial melting to have occurred at depth, it can give no sure indication of present conditions.

In an attempt to deduce whether the Martian core is solid or liquid, Young and Schubert (*Geophys Res Lett*, **1**, 157, 1974) have therefore constructed a thermal model of Mars which involves no experimentally determined thermal boundary conditions but draws on experience and information gained from the application of similar techniques to the Earth. Indeed, as far as structure is concerned the model is a straight 'Earth model' with core, mantle and crust separated by rigid boundaries. The core itself is assumed to contain no heat sources (so there is zero heat flux at the core–mantle boundary), but heat sources are distributed uniformly throughout the rest of the planet (so temperature and thermal gradients are continuous across the crust–mantle boundary). The crust, whose outer boundary is taken to be an isothermal surface, is only able to conduct heat, but the mantle is a region in which solid-state thermal convection is an important mode of heat transfer. It is this last characteristic which particularly distinguishes the Young–Schubert model from most previous thermal model studies of planetary interiors.

In numerical terms, two sets of core parameters are examined: an iron core with a radius 0.4 of the total Martian radius and mass 0.1 of the Martian mass, and a pure FeS core of radius 0.6 and mass 0.26. These core models are the maximum density–minimum size and maximum size–minimum density cores consistent with observed mass, radius and moment of inertia of Mars. The radioactive heat source concentration in the crust–mantle is taken to be the same as that in the terrestrial mantle (2.61×10^{-7} erg cm^{-3} s). The thickness of the conducting crust will be determined by the depth at which the conduction solution for temperature rises to about 1,000° C above the surface temperature of the planet, and is thus highly dependent on the chosen value of heat source concentration. But crustal thickness should be at least 100 km because a thinner crust would probably be subject to plate tectonic activity, whereas no evidence of such activity is available from the Mariner 9 investigations.

The most important point to emerge from the model calculations is that the thermal convection in the mantle is remarkably successful in reducing temperatures (as in the Earth), thus vindicating its inclusion in the model in the first place. For a pure iron core, for example, a temperature difference of 8,000° C between the core–mantle boundary and the planetary surface when there is no convection is reduced to about 2,300° C when convection occurs at a Rayleigh number of 100 times the critical value for the onset of convection. The actual Rayleigh number is, of course, uncertain because viscosities are not known, but one certain point arising from the models is that, for pure conduction, temperatures rise above typical silicate melting temperatures. The implication here, therefore, is that convection in the Martian mantle is actually necessary to prevent large-scale melting there.

And because viscosities are unknown, it is not possible to deduce absolutely whether the Martian core is solid or liquid. But what can be said is that if viscosity is lower than $10^{22}-10^{23}$ cm^2 s^{-1} at temperatures above about 1,500° C, mantle convection will then be efficient enough to cool the core–mantle boundary to temperatures below those at which Fe or Fe–FeS cores would be liquid. As several workers have concluded that Martian viscosity is indeed below this limit, the Young–Schubert model suggests that a dynamo-produced magnetic field in the Martian core is not possible.

Finally, one other important conclusion to be drawn (specifically from the model temperature profiles) is that if partial melting occurs at all in the mantle it will do so at depths of about 300 km. By analogy with the Earth, this suggests that the Martian lithosphere would be several hundred kilometres thick, or intermediate in thickness between those of the Earth and the Moon.

Gravitational waves from collapsing stars

from P C W Davies

ALTHOUGH it is becoming increasingly likely that Professor Joseph Weber's longstanding attempt to detect gravitational waves from a cosmic source has not after all met with the spectacular success originally claimed, the stimulus that his work and propaganda has given to theoretical studies of this phenomenon continues to operate unabated. Gravitational waves are predicted to occur whenever massive objects are disturbed, much as electromagnetic radiation is produced by accelerating charged particles. The main difficulty in the detection of the former rather than the latter is the incredibly low cross section of ordinary matter to these disturbances. Consequently, only very massive and violent cosmic events occurring in relative proximity to the Earth are capable of producing a pulse of gravitational radiation sufficiently energetic to be detectable with current technology.

Attention has traditionally been given to three possible cosmic sources of such radiation: violent agitations occurring in the primaeval fireball of the big bang, objects crashing into black holes and the explosion or collapse of stars. Most books on gravitation contain order of magnitude estimates of the strength of the ensuing radiation, but few explicit numerical calculations seem to have been published. A welcome contribution to the physics of gravitational wave pulses from collapsing stars appears in the August 1 issue of *Astrophysical Journal* (**191**, L105–L107, 1974). Detailed calculations have been performed by Thuan and Ostriker of the Princeton University Observatory for a number of simple scenarios of the collapse of a white dwarf star into a neutron star or black hole.

It is well known that there can be no gravitational radiation from a spherically symmetrical collapsing object. A real star will, however, always possess asymmetries, and these tend to become amplified during the collapse process

The authors therefore consider a uniformly rotating star of uniform density and perform a calculation of the energy radiated away in the form of gravitational waves during the collapse to lowest order approximation in the gravitational potential This sort of collapse is known to occur for a white dwarf star with a mass a little in excess of the mass of the sun Calculations based on Newtonian theory show that a spheroidal shaped object (such as might be the shape of a rotating white dwarf) becomes more oblate as the collapse proceeds, until finally, after a finite period of time, it assumes the unlikely shape of a zero thickness pancake at a minimum radius, say r_{min} The Newtonian approximation will not be valid if r_{min} becomes comparable with the Schwarzschild radius r_{sch}

Thuan and Ostriker first find that a non-rotating spheroid of mass M which starts at rest at infinity with infinitesimal eccentricity, emits a pulse of gravitational radiation of total energy 37×10^{-3} $(r_{sch}/r_{min})^{7/2}Mc^2$ erg This result should be compared with the analogous case of two point masses collapsing in from infinity from an initial state of rest which liberates only $1\,2\times10^{-3}$ $(r_{sch}/r_{min})^{7/2}Mc^2$ erg Evidently spheroidal collapse is extremely efficient for the production of energy in this form

Next the authors include the effects of rotation The highest output would occur in this case if the star was very rapidly rotating with a large ratio of initial to final radius Under these circumstances the energy radiated is boosted further to 109×10^{-3} $(r_{sch}/r_{min})^{7/2}Mc^2$—a gain of 91 6 on the value for two collapsing point masses Moreover, as the authors point out, rapidly rotating stars are unstable to the growth of non-axisymmetrical perturbations, such as might be produced in reality by an oblique magnetic field These additional disturbances would increase the radiation emitted still further Physically, the reason why rapidly rotating collapsing stars radiate so much energy away in gravitational waves is partly due to the way in which the rotation delays the collapse of the equatorial parts of the star in a region of high gravitational potential during which time the poles quickly collapse inwards, so flattening the object still further

Turning their attention to a realistic model of a white dwarf, the authors then estimate the energy emitted during the collapse of a 1 4 $M_\odot$ Maclaurin spheroid with uniform rotation and uniform density of 10^9 g cm^{-3} An upper limit to this energy turns out to be about 10^{52} erg, and a lower limit around 10^{45} erg A single pulse of this sort will have Fourier components nearly constant over a wide frequency range, after which they fall rapidly

In practice a collapsing white dwarf might well emit a whole series of pulses as it 'bounced' back and forth through the pancake configuration, finally settling down into a neutron star However, assuming a Weber-type experiment attempts to detect a single pulse of the type considered, even under the most favourable circumstances the collapsing star would still need to be as close as 100 light years for any hope of success

---

Still no gravitational radiation

by John Gribbin

LEVINE and Garwin report in the latest issue of *Physical Review Letters* (**33**, 794–797, 1974) a new negative result for the detection of gravitational radiation pulses, at a level six times more sensitive than the experiments they reported last year (*Phys Rev Lett*, **31**, 173–176, 1974) They say that they believe "the present results to be in substantial conflict with the detections reported by Weber"

The improved sensitivity over earlier results from the same group has been achieved chiefly through increasing the mass of the aluminium cylinder used as an antenna from 120 kg to 480 kg, the resonance frequency is now 1,637 Hz, close to that of Weber's apparatus, 1,661 Hz During the 27-day period December 3 to December 30, 1973, only one measurement out of $4\,1\times10^7$ values obtained for the mean oscillation energy kT contains a pulse substantially above the noise level

- According to Levine and Garwin, that pulse could be a gravity wave pulse, stress relaxation in the antenna, electrical pickup of "an intense but infrequent laboratory tone", or a signal-processor defect Since no coincident pulse was observed at the University of Rochester detector, the gravitational radiation explanation seems the least tenable

Further analysis of the data—including Weber's observations as far as they are available—seems to rule out both the possibility that gravity waves were detected in May 1973 but the pulses have not been produced since then, and the possibility that "hundreds of gravity waves were incident per day even during December 1973, giving our bar $<0\,3\ kT$" In addition, Levine and Garwin note that an error in the computer program used by Weber's group for some of the analysis would have produced a spuriously high number of pulses, and that Weber has acknowledged the existence of this error All in all, it seems that gravitational radiation has not yet been detected

---

The changing micrometeoroid influx

from David W Hughes

THE disparity between the flux of micrometeorites at 1 AU obtained from lunar microcrater counts and from satellite data has been known for many years A typical example is shown on page 380, the satellite data coming from the work of Alexander (Baylor University, Waco, Texas), the data from the study of microcraters on the surface of lunar rocks and spherules coming from the work of Neukum and Schneider (Max-Planck-Institut fur Kernphysik, Heidelberg) In the 10^{-10}g region the two techniques give results which differ by a factor of 200 and it is of great importance to decide if this difference is due to some physical cause or is just an unresolved systematic error in one or both techniques Fortunately the influx of meteoroids to the lunar surface is the same as that to the Earth's upper atmosphere (most of the satellite observations are made in near-Earth space), the circumterrestrial dust cloud, thought in the late 1960s to exist, now being discounted as a figment of incorrect callibration But satellite-borne detectors do measure the present day influx, whereas lunar microcrater counts measure the mean influx over the last few tens of thousands of years

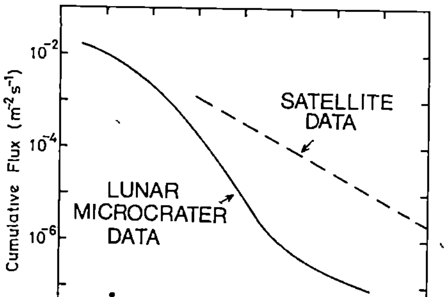
To convert the crater population on a given lunar sample into an interplanetary dust flux the size and form of the craters have to be related to the mass of the causative meteoroid One immediate problem is that crater size also depends on meteoroid velocity, dens ty, and shape Up to now the meteoroid impact velocity has been thought to be about 20 km s^{-1} Two recent results indicate that it is much lower Doppler shift observations of the solar spectral lines scattered by the solar system dust cloud give a geocentric velocity of about 5 km s^{-1} and this observation has recently been backed up by measurements of microcraters found in glass, steel and pyroxene surfaces exposed for 46 days during the Skylab mission Nagel, Fechtig, Schneider and Neukum (Max-Planck-Institut, Heidelberg) reported these observations at the recent COSPAR Meeting (Sao Paulo, 1974) They compared the spall zones, smoothness of the central depression, fracture damage and general shape of the 47 observed craters (diameters >1 μm) with the form of craters produced by simulated micrometeorites, these particles having been accelerated using a Van der Graff accelerator to known velocities in the 1 to 20 km s^{-1} range. In many cases these characteristics indicated the relatively low impact velocity of about 7 km s^{-1}. So both the curves in the figure have to be moved to the right by factors varying with the velocity dependence of microphone response, penetration hole size and crater diameter. As these effects are functions of meteoroid momentum or kinetic energy the use of this new velocity determination is still not sufficient to bring the curves together.

Two other things are assumed when dealing with microcraters, first that the ratio of the diameters of the microcrater pit and the impacting particle η is 2 and second that the density of the particle is 3 g cm^{-3}. Both these assumptions need to be reconsidered, recent laboratory experiments have shown that η decreases with particle density and also that the mean particle density varies with mass. Both these factors make the interpretation of microcraters more difficult. Measurements of crater circularity have led Brownlee (University of Washington) *et al* (4th Lunar Science Conference, Houston, 1973), to the conclusion that the majority of microparticles have equidimensional shapes and that shallow craters are produced by oblique incidence so the direction of the incident flux has also to be taken into account.

The main problem however lies in estimating the time the rocks under consideration have remained exposed on the lunar surface. One way of doing this is to count the tracks in the rock surface produced by retarding solar flare particles. Knowing the present day flare flux and assuming that solar activity has remained constant for about 10^6 years gives the exposure age. This second assumption is the stumbling block, the data of Neukum and Schneider could indicate that either a lower particle flux existed in the past or that the solar flare flux was higher then than now—both would produce the same result.

McDonnell, Ashworth, Flavill, Bateman and Jennison (University of Kent) overcome this problem by considering surfaces with an equilibrium distribution of craters. Laboratory simulation indicates that solar wind sputter erosion (0.043 Å yr^{-1}) is the dominant factor determining crater lifetime. Knowing this erosion rate enables the microparticle influx to be derived from the equilibrium distribution. The authors conclude (COSPAR, Sao Paulo, Brazil) that the microparticle influx has increased by a factor of four in the last 10^5 years.

This would account for the discrepancy shown in the figure but creates the question of why this flux has increased.



Number of micrometeoroids, with mass greater than the given mass, which will impact every second on a square metre of exposed surface one astronomical unit from the Sun

Adaptations of plants to drought

from Peter D Moore

THE C_4 dicarboxyl acid pathway of carbon fixation has now been recognised in a wide variety of plant species from at least six orders of flowering plants. In this process CO_2 combines with phosphoenolpyruvate and is transported to the bundle sheath cells in the form of dicarboxylic acids, where it is released as CO_2 to be fixed by the conventional Calvin (C_3) system. The widespread occurrence of the mechanism suggests that it arose independently in more than one order (Evans in *Photosynthesis and Photorespiration*, edit by Hatch, Osmond and Slatyer, 130, Wiley, New York, 1971). This being so, it has been difficult to study the evolutionary development of the process. Yet the work of Bjorkman *et al* (*Yb Carnegie Instn Wash*, **68**, 620, 1969 and **69**, 640, 1970) indicates that very few genes are involved.

Troughton (in *Photosynthesis and Photorespiration*, 124, 1971) has proposed that a study of the isotopic ratio of ^{13}C to ^{12}C (this is normally expressed in relation to a standard and is termed $\delta^{13}C$) in plant tissue should indicate the relative importance of the two systems of carbon fixation at the time when the plant was alive. This is because C_3 plants discriminate more effectively against ^{13}C in their carbon uptake than do C_4 plants, as a result C_3 plant tissue has an average $\delta^{13}C$ of -29‰ (that is proportionately less ^{13}C than in the air) whereas C_4 plants' average ^{13}C is -14‰.

Troughton, Wells and Mooney (*Science*, **185**, 610, 1974) have now used this technique to study the relative importance of the C_4 pathway over the past 40,000 years in the C_4 desert plant *Atriplex confertifolia*. Two ancient middens of the pack rat *Neotoma* from the Mohave Desert region of Nevada yielded material of this species which dated from >40,000 yr (beyond the scope of radiocarbon determination) and 10,000 yr respectively. The $\delta^{13}C$ of the older sample is -13.4‰ and that of the younger is -16.2‰. A modern sample of *A confertifolia* yielded a $\delta^{13}C$ of -14.8‰. Thus this species has been using the C_4 pathway for more than 40,000 yr.

Troughton *et al* also determined the $\delta^{13}C$ of *Opuntia polyacantha* tissues from the same sites. This species is a desert succulent which also concentrates carbon dioxide before fixing it by the conventional mechanism, but this time by crassulacean acid metabolism in which malic or citric acid concentrations build up during the night and the carbon accumulated in this way is subsequently used in the Calvin cycle. Once again these crassulacean acid (CAM) plants do not discriminate as strongly against ^{13}C as normal Calvin plants, and their $\delta^{13}C$ values resemble those of C_4 plants. In *Opuntia polyacantha* the >40,000-yr-old material gave a $\delta^{13}C$ value of -21.9‰, and the 10,000-yr-old sample gave -13.9‰. This suggests that the degree to which *Opuntia* depended upon the CAM technique of carbon concentration increased over the time interval between the two samples.

It is known that CAM plants become more dependent on night-time accumulation of carbon for their photosynthesis and growth under conditions of water stress. Indeed this mechanism can be regarded as an adaptation to dry habitat conditions in which normal daytime photosynthesis renders a plant liable to desiccation. The change in the $\delta^{13}C$ values of the *Opuntia* tissue analysed may, therefore, reflect the changing contemporary climatic conditions in Nevada. Other plant remains found in the area support this suggestion, since they give evidence of pluvial juniper woodlands, corresponding to the Wisconsin glaciation of the north, giving way to arid desert at about 10,000 yr b p.

There are similar indications from the *Atriplex* material. C_4 plants generally and *Atriplex confertifolia* in particular are frequently associated with rather dry habitats, their cellular resistance to CO_2 exchange is apparently lower than in C_3 plants, which may account indirectly for their capacity to withstand drought. It is significant, therefore, that the remains of *Atriplex* are considerably more abundant in the 10,000-yr-old specimen than in the 40,000-yr-old one. Thus palaeontological and palaeobiochemical evidence provide complementary information concerning the climatic changes during this period.

Proterozoic crustal distribution, mobile belts and apparent polar movements

J. D. A. Piper

Sub-department of Geophysics, Oliver Lodge Laboratory, Oxford Street, PO Box 147, Liverpool L69 3BX, UK

The geological significance of a Precambrian supercontinent deduced from palaeomagnetic results is evaluated. A major transition in global tectonics took place during Upper Proterozoic and Lower Palaeozoic times. Older mobile belts developed along reactivated zones with slight movements of cratonic forelands but were related in time to apparent polar movements. The 1,150±200 Myr mobile belts formed along a single broad arc characterised by anorthositic and silicic intrusion over a long period of Proterozoic time.

PALAEOMAGNETIC studies of Precambrian and Palaeozoic rocks are yielding at present considerable quantitative information on the distribution and movements of the continental regions, and on their relationship to contemporary orogenic belts during these times. Formation of the supercontinent Pangaea involved the welding of several crustal units in Palaeozoic times[1] and the Caledonian orogenic belt developed along the line of closure of a restricted ocean basin[2]. These are two examples of the operation of plate tectonics during an interval for which seafloor spreading data are not available.

There is now substantial evidence that these examples are amongst the earliest expressions of this phenomenon of plate tectonics. The Upper Proterozoic to Lower Palaeozoic was characterised by a transition in global tectonics from a phase of localised internal deformation of large continental bodies to a phase of fracture, translation and collision of essentially rigid plates[3]. Palaeomagnetic results have demonstrated that Lower Palaeozoic and older mobile belts in Africa formed between essentially contiguous cratons[4]. A suggestion that Africa and North America have closely similar apparent polar wander (APW) paths before 1,000 Myr (refs 4 and 5) has been substantiated by detailed assessment of the data[6], and the paths can be closely superimposed over their whole lengths from 1,000 Myr to 2,200 Myr and possibly 2,700 Myr. When this is done the Afro-Arabian and North American regions form a continuous continental body (Fig 1). Palaeomagnetic results from Gondwanic continents other than Africa, although sparse, are consistent with them occupying their Pangean configuration with respect to Africa in Precambrian times[6]. Australia, however, seems to have changed its orientation sometime between 1,800 Myr and 750 Myr ago. This conclusion has been confirmed by a revised interpretation of the Late Precambrian–Lower Palaeozoic data[7]. Orientations of the Baltic–Ukrainian and Siberian Shields with respect to this reconstruction are uncertain but Donaldson *et al*[8] have recognised comparable trends in the North American and Baltic Shield APW curves and have superimposed them to place the two regions close to their present positions between 1,950 and 1,200 Myr.

Present interpretations of Precambrian palaeomagnetic results have two important implications. First they imply that orogenesis, and the behaviour of continental tectonism cannot be directly related to subduction at plate margins. Second, they show that the bulk of continental crust was lumped together as a single body through much of Precambrian time, although paucity of data from European and Siberian regions does not clarify whether or not they were continuously part of such a supercontinent. Here, I examine other evidence for these contentions and examine their implications.

Genesis of mobile belts

The finding that the major Precambrian mobile belts did not form by subduction at destructive plate margins prompts a search for alternative mechanisms. Granites are an important component of these belts and their upward migration through the crust as mobile bodies[9,10] could cause orogenic folding with zero crustal shortening[11]. This rise of relatively less dense material through a more dense sedimentary–volcanic cover is a mechanism amenable to

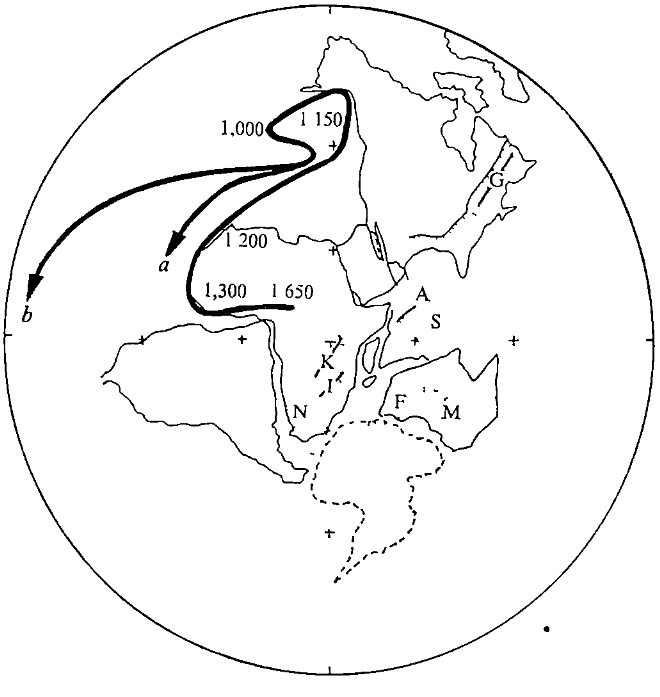

Fig 1 Stereographic reconstruction of the Gondwana continents and North America before about 1,000 Myr BP derived from palaeomagnetic data[6]. Orogenic belts belonging to the 1,150±200 Myr episodes N, Namaqualand, I, Irumide, K, Kibaran, A, Aravalli, S, Satpura, F, Frazer, M, Musgrave, G, Grenville. The apparent polar wander path spanning their formation is shown *a*, North America, *b*, Africa. Ages in Myr.

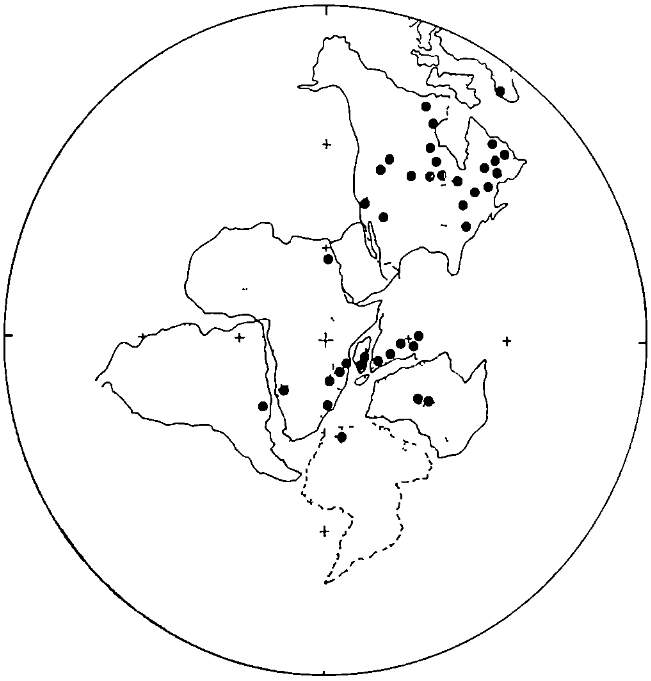

Fig 2 Distribution (stereographic projection) of Precambrian anorthosites (●, refs 37, 39) and granulites (stippled)[24,42] within the Proterozoic supercontinent The granulites in part represent relict rocks which have not been reconstituted by later events[19] and may thus indicate a paucity of fluids rather than the absence of any later thermal events

quantitative analysis, and Ramberg[12] has shown it to be a physically realistic process in mobile belts with a time span in the range 10–100 Myr Shackleton[13] has reached a comparable conclusion by regarding the granite magmas as, in part, a differentiate from rising mantle currents, and has argued[14] that progressive addition of granite magmas to the crust occurred during Precambrian time

This is an obvious mechanism but it is important to clarify the conditions which confine granite intrusion to the narrow zones of basement reactivation along which the Proterozoic belts formed[3 13 15] The absence of high pressure–low temperature metamorphic assemblages, and the widespread occurrence of granulites in Precambrian terrains have been rationalised by assuming a higher thermal gradient Two implications follow from this First, the crust may have been thinner and second, partial melting must have taken place at shallow depths, presumably leaving a granulate residuum The migration of fluids from the surrounding rocks may be necessary if significant upward movement of granites is to occur[16] and the crustal levels which they finally reach will then either reflect the point at which the magma chilled beyond its solidus, or the point at which further upward movement was prevented because sufficient fluid could not be abstracted[16 17] The concept of fluids is important base metal mineralisation is practically confined to the Proterozoic mobile belts in Africa, with the cratons barren except for the gold–silver associations of the greenstone belts[18] Paucity of fluids may also explain why large areas of Archaean granulites were not amphibolitised in later times[19] It is unlikely that Proterozoic belts have experienced much differential erosion with respect to the Archaean cratons, because platform sediments on the cratons can be correlated with those in the mobile belts[20] and their depositional history suggests that the cratons underwent intermittent uplift during Proterozoic times[21] A possible explanation is that the cratons were added to by underplating with andesitic or granitic material[14] whereas the appropriate fluids concentrated to permit upward migration of granite diapirs only in zones later defined by the orogenic belts and metallogenic provinces

Given that mobile zones define accessions of heat and/or fluids at the base of the lithosphere, their distribution must be related in some way to properties of the Proterozoic asthenosphere The distribution of mobile belts and related features on the Proterozoic continental reconstruction is consistent with such a conclusion

Precambrian continental distribution

The Proterozoic continental reconstruction (Fig 1) is applicable from at least 2,200 Myr to shortly after 1,000 Myr BP It is not possible to match the segments of the APW curves for North America and the Gondwana continents[6] between approximately 950 and 650 Myr ago Australia seems to have changed its orientation during Proterozoic times[22–24] to its Phanerozoic configuration[25,26] Before 1,000 Myr sialic crust was distributed as a broad girdle across about 140°, or 15,500 km, of arc and with the inferred placing of the Baltic Shield[8] this is extended to about 190° or 21,000 km The agreement of palaeomagnetic results with a single APW curve across this supercontinent[6] demonstrates that it was disposed on a globe of comparable radius to the present The reconstruction is based on palaeomagnetic data, with uncertainties which accommodate the limited intercontinental movements necessary to explain the intrusion and deformation of basic dyke swarms, the infolding of sediments and the small relative motions of forelands of mobile belts Indeed, it is entirely compatible with internal deformation and metamorphism taking place within a coherent entity, as proposed by Sutton and Watson[3] Whether or not this is to be regarded as a crustal plate[11] in the modern context is academic

The belts of the 1,150±200 Myr mobility, now isolated by later drift, were an essentially unified feature lying on a broad arc close to a great circle spanning the Proterozoic supercontinent These belts had a protracted history In Africa the Kibaran belt experienced major tectonism about 1,300 Myr BP with post orogenic granites intruded approximately 1,250 Myr ago and with the subparallel Irumide belt undergoing synorogenic events about 1,100 Myr ago The

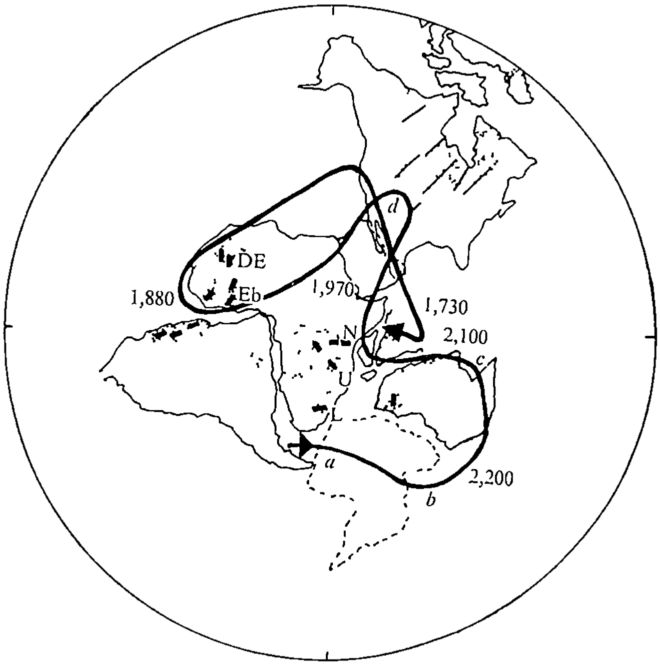

Fig 3 The relationship of recognisable pre-1,150±200 Myr orogenic belts with cratonic regions[24,40], and the apparent polar wander paths executed during their formation The belts are L, Limpopo, N, Nyanzian, U, Ubendian, Eb, Eburnean, DE, Dorsal Eglabs The ages of the belts are not precisely defined but the youngest (DE) was folded about 2,100 Myr ago The straight lines in North America and Greenland are straight belts of late Archaean–early Proterozoic age[19] The generalised APW curve is a composite one which reconciles differences between published APW curves for North America[8 44] by incorporating a 2,000–1,700 Myr loop identified from African data[4] *a–d*, See text, dotted areas, crust unaffected by thermal/tectonic events after about 2,000 Myr BP

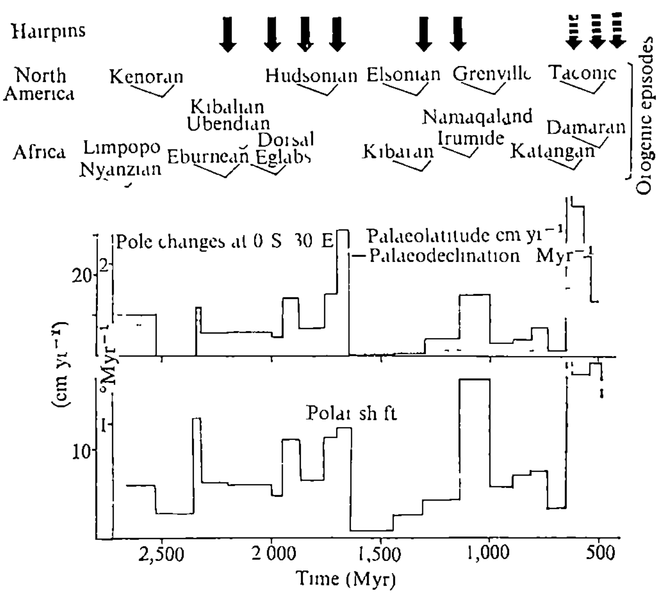

Fig 4 North American and African orogenic episodes shown in relation to hairpin bends (dashed arrows, the Gondwanic continents) and the rate of apparent polar wandering The lower histogram shows rates of angular change in the palaeomagnetic pole and the palaeolatitude of a point in central Africa at 30°E, 0°S Where both of these are large it is probable that the APW reflects crustal drift

Namaqualand (Orange River) belt of south-western Africa, which experienced a widespread thermal event, with remobilisation of a granite gneiss basement at about the same time, seems to be a linear continuation of these belts, although it has been isolated by the development of the pan-African belts (750–450 Myr) The 1,400–1,050 Myr Frazer–Musgrave belt of Australia[27], which, before Phanerozoic drift, connected with rocks of comparable age in the Davis Sea region of Antarctica[24], is brought into parallelism with belts of a similar age elsewhere using the Carey–Hurley Rand reconstruction The Musgrave is regarded by Rutland[28] as a narrow zone of basement reactivation with a high geothermal gradient, and it underwent a main phase of metamorphism 1,330 Myr ago

The continuity of the 1,150±200 Myr orogenic belts is emphasised by identification of rocks about 1,000 Myr old within the pan-African domain of north-eastern Africa (ref 29 and A M Chater personal communication), by the presence of 1,100 Myr old anorogenic rocks in the Arabian Shield[30], and by the parallelism of the contemporary Aravalli belt of north-western India (ref 21 and Fig 1) Stockwell[31] and Hurley and Rand[24] have distinguished a wide zone affected by a thermal (?) episode about 1,300 Myr ago in the North American Shield, bordering the Grenville Belt, and extensive anorogenic igneous activity of similar age[32] has been recognised in southern Greenland, north of the extrapolated continuation of the Greenville belt In common with the later pan-African episode, restricted zones of linear orogenesis were apparently bordered by wider zones of reheating and igneous intrusion

If the reconstruction of Donaldson *et al*[8] is correct then the 1,150±200 Myr mobile belt may have been even longer than indicated in Fig 1 Those authors place the Baltic Shield with the Gothide Belt on a great circle continuation of the Grenville Belt Evidence for a sialic connection is however, lacking There is substanial palaeomagnetic evidence[33,34] that the Grenville Province became attached to the remainder of the North American Shield by predominantly dextral strike-slip plate motion about 1,150 Myr ago and there has been a suggestion[8] that a similar motion may apply to the juncture of the Gothide Belt with the Baltic Shield Alternative interpretations are possible, however, and palaeomagnetic data[4] are not consistent with comparable movement along the contemporaneous African belts Along this whole belt there is close spatial relationship between the orogenic belts, postorogenic intrusion and subsequent sedimentation During and immediately before tectonism the belts were subject to extensive graben faulting and deposition of clastic rocks Keweenawan sediments formed in tensional rifts along the Grenville Front[35] as did Gardar sediments in Greenland and Jotnian sediments in Scandinavia[36] Extensive and lithologically similar Upper Proterozoic sequences which outcrop across central Africa include the Bukoban and Kundelungu Groups, developed in a comparable setting to the Kibaran, Irumide and Namaqualand belts[20,21,29]

Unlike the later supercontinent Pangaea, which was essentially a transient feature[1] evolved and dismembered by plate tectonic mechanisms, the Proterozoic supercontinent (Fig 1) existed for a very long period of time (at least 1,200 and possibly 1,700 Myr), and geological events before the 1,150±200 Myr orogenies may be expected to show a simple distribution on the reconstruction This is indeed the case, and the two broad NE–SW belts of granulites and Archaean cratons which have been recognised on the Pangean reconstruction[24] are brought on to a single line (Fig 2) Also, regions of massive Proterozoic anorthosites, previously regarded as two separate belts ranging from western North America to the Urals and South America to India[37], are in fact seen to be one continuous broad belt These massive anorthosites (Fig 2) contrast with the anorthosites intimately involved with Archaean granite gneisses[38] and their intrusion possibly spanned an interval from 2,200 Myr to 1,000 Myr BP They represent one facet of magmatism[36] that also includes a Rapakivi granite phase, occurring along what is now seen to be a single zone of high thermal activity and block faulting which developed after 2,200–1,750 Myr mobile episodes

The massive anorthosites are widely regarded as having an upper mantle origin, and it is believed that they required both high temperatures and pressures for their formation[39] According to Buddington[39] they were intruded during an

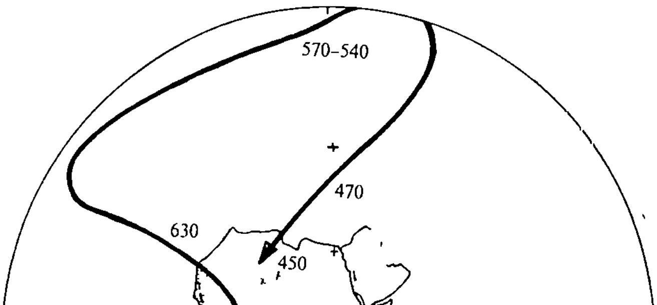

Fig 5 The pan-African belts (750–450 Myr), showing generalised structural trends and the APW path executed during the interval of their formation Based on the interpretation of McElhinny *et al*[8] The Gondwanaland reconstruction is based on refs 25 and 26, a more southerly position for Madagascar as proposed by Tarling[43] would place all continental units to the right of East Africa approximately 10° further south For simplicity present continental outlines are used in these figures although they include crust accreted in later times

interval of high temperature gradients such as have not been attained in later times It is notable that their intrusion ceased at the same time (about 1,000 Myr) as large differential movements of discrete plates first occurred

The broad belt of magmatism and later tectonic activity is not clearly recognisable as a crustal lineament earlier than about 1,700 Myr, and older Proterozoic belts (>1,750 Myr) have a distribution apparently unrelated to it The older belts cannot be followed as linear features for distances of more than 100 km Although that could be a consequence of overprinting by later episodes, where the belt are widely exposed they lie along small circles (Fig 3 and refs 13, 20 and 40), in contrast to the arc close to a great circle of the 1,150±200 Myr belts Correlation of Proterozoic mobile belts with lines of upwelling[13] or downgoing[40] mantle convection currents could explain this in terms of a change in the convective systems

Mobile belts and apparent polar wandering

The parallelism of the Kibaran–Grenville trend and the large contemporary polar shift is a striking feature of Fig 1 The relationship implies that the continental body executed a large lateral movement along an arc close to a great circle during the interval of deformation and metamorphism That this and a later apparent polar shift (Fig 5) represent real translation of the continent, rather than pure polar wandering, is suggested by considerable palaeoclimatic evidence[6,7] But it is not possible to equate directly rates of crustal drift and polar wandering, because these will only be equal when the Euler pole is equidistant from the source and palaeomagnetic pole[1] A minimum estimate of crustal drift can be obtained, however, from the change in palaeomagnetic latitude and the amount of local rotation inferred from changes in declination I have computed these two parameters for a point 30°E, 0°S in central Africa to show that high crustal rates of drift coincide with both the 1,150±200 Myr and the pan-African episodes, with low drift rates characterising the quiescent period between the >1,750 Myr and 1,150±200 Myr episodes (Fig 4) The large lateral shifts are terminated by 'hairpins'[8] in the APW curve, which seem to correlate closely with tectonic episodes This relationship is particularly clear for the 1,150±200 Myr events In these cases the 1,300–1,200 Myr hairpin corresponds to the climax of the Kibaran–Elsonian episode, and the 1,150 Myr hairpin corresponds to tectonic events in the Namaqualand, Irumide and Grenville Belts In addition, two principal events of the later pan-African episode, the Katangan (680–580 Myr) and Damaran (550–500 Myr) (ref 38) are both broadly coincident with hairpins (Fig 5) and the major structural trends of this episode in eastern and western Africa They could be correlated with the major polar shifts which occurred between 650 and 500 Myr ago although this has yet to be clarified

Are hairpins and large polar shifts related to earlier orogenic episodes? In most cases age control does not provide adequate information to permit any decision about which part of the APW curve corresponds to particular episodes There is one possible exception in the southern part of the West African craton, and in comparable parts of the Guyana craton, the Eburnean tectonism took place along ENE lines about 2,200 Myr ago Pre- and syntectonic palaeomagnetic poles from the region lie on segment *a–b* of the APW curve (Fig 3) whereas post-tectonic poles lie on section *b–c* with hairpin *b* occurring synchronously with the tectonic event Further north in West Africa, in the Dorsal Eglabs, north–south tectonic trends at least 1,970 Myr old are sub-parallel to a segment of the curve defined by syn- and post-tectonic poles from the region (Fig 3, *c* and *d*) These correlations go a long way towards establishing a relationship between Proterozoic linear mobile belts and mantle processes Given that they are produced by zones of asthenosphere which are hotter, and/or contain more volatiles, than surrounding regions, migration of the lithosphere with respect to a mantle source, as evidenced by the polar shifts, would be capable of producing linear belts Such mantle sources may be comparable to the thermal highs to which recent magmatism is widely related (for example ref 4)

Model for the regulation of mRNA translation applied to haemoglobin synthesis

Harvey F. Lodish
Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

A kinetic analysis of protein synthesis on ribosomes predicts that certain treatments which reduce the overall rate of polypeptide chain initiation will inhibit translation preferentially of mRNAs with lower rate constants for polypeptide chain initiation The effects of several inhibitors on α and β-globin synthesis by reticulocyte extracts agree with these predictions

SEVERAL factors determine the rate of initiation of translation of an mRNA molecule First, different mRNAs seem to differ in the rate of attachment to ribosomes and/or in other stages of initiation of protein synthesis For example, in the reticulocyte each molecule of α-globin mRNA initiates protein synthesis only 60% as frequently as does each β-globin mRNA[1,2] Similarly, the frequencies of initiation of translation of the ten monogenic reovirus mRNAs differ at least tenfold[3] and the rates of initiation of translation of the three cistrons of bacteriophage RNA differ more than twentyfold[4-8] In this latter case, it has been proposed that the primary nucleotide sequence about the initiation codon and/or the tertiary structure of the mRNA near this codon determine the rate of ribosome attachment[5,7]

Second, under certain conditions there are alterations in the overall rate of polypeptide chain initiation in a cell For instance, during mitosis the rate of chain initiation is only one third of that during other phases of the cell cycle, although the rate of polypeptide chain elongation is unaltered[9] In reticulocytes, the absence of haemin results in formation of an inhibitor of binding of the initiator Met-tRNA$_f$ to 40S ribosomes[10-12], initiation of synthesis of all reticulocyte proteins is restricted[13-15]

In this communication I derive a simple kinetic rate equation for initiation and elongation of polypeptide chains in eukaryotic cells A principal result of these calculations is that any reduction in the rates of polypeptide chain initiation steps at or before binding of mRNA will result in preferential inhibition of translation of mRNAs with lower initiation rate constants (the poorer mRNAs) I present several new results on translation of α and β-globin mRNA in the rabbit reticulocyte which are predicted by, and consistent with, this conclusion I will show, further, that changes in the levels or rate-limiting components required for initiation of synthesis of all proteins (for example, initiation factors, Met-tRNA$_f$, 40S subunits, and so on) could explain many results previously ascribed to mRNA specific factors

The model

Polypeptide synthesis on ribosomes can be described by the following scheme

$$m + R^* \xrightarrow{K_1} P_1 \xrightarrow{K_2} P_2 \xrightarrow{K_3} P_3 \xrightarrow{K_4} \qquad \xrightarrow{K_S} P_S \xrightarrow{K_R} P_R$$

The binding of Met-tRNA$_f$ to the 40S subunit is the first step in protein synthesis in eukaryotic cells[16-19], R^* is the concentration of the Met-tRNA$_f$-40S ribosome complex able to bind an mRNA, m is the concentration of the mRNA, and K_1 is the rate constant for ribosome binding and formation of the 80S initiation complex P_1 Although there are several factors and several steps involved in this process, the use of an overall rate constant K_1, possibly different for different mRNAs, is sufficient and does not affect the nature of the final rate equation It is assumed that mRNA-specific factors are not involved in mRNA binding The polypeptide contains S amino acids and the message S codons, P_i (i=1, 2, , S) represents a nascent chain of i amino acids P_R is the released polypeptide chain K_i (i=2, 3, , S) is the rate constant for addition of the i th amino acid, and K_R is the rate constant for release of the completed polypeptide chain Ribosomes are known to cover many more codons on a message than those being decoded at any instant, the value L is the number of codons covered by one ribosome

MacDonald and Gibbs[20,21] have derived rate equations for polypeptide synthesis in a very general context, and my derivation follows closely their analysis It is necessary to make several simplifying assumptions in order to yield a relatively simple analytical expression which can readily be compared with experimental data First, we must assume that rate constant for addition of any amino acid is the same, that is $K_i(i=2 \quad s)=K_e$ the single elongation rate constant Following ref 20 I define n_i as the probability that an mRNA contains a ribosome with a nascent chain i amino acids long I make the crucial assumption here that under all conditions ribosomes are uniformly distributed along an mRNA (see below), that is that $n_i = n$ for all $i=1, \quad , s$ It is also assumed that $K_R \leqslant K_e$ that is that release of the completed chain does not limit the overall rate of protein synthesis Given these assumptions, the flux of ribosomes, q_e across any given codon in an mRNA is given by equation (10) of ref 20

$$q_e = K_e n (1 - nL) [1 - n(L - 1)]^{-1} \qquad (1)$$

In the steady state this value represents the net amount of protein synthesised per mRNA, hence the total amount of protein produced per unit time, Q_e, is given by

$$Q_e = mq_e = mK_e n (1 - nL) [1 - n(L - 1)]^{-1} \qquad (2)$$

The number of new polypeptide chains initiated per unit time, Q_i is given by the following equation

$$Q_i = mR^* K_1 (1 - nL) \qquad (3)$$

where the term in brackets is the probability that the initiation codon is not covered by a ribosome and, hence, available for polypeptide chain initiation This equation follows from the definitions of K_1 and R^* (ref 21)

Since, in the steady state, the number of new chains initiated is balanced by the number elongated or completed, we can set $Q_i = Q_e$ and solve for n

$$n = [L - 1 + K_e(K_1R^*)^{-1}]^{-1} \qquad (4)$$

and combining equations (3) and (4), $Q = Q_i = Q_e$ is given by

$$Q = mR^*K_1 \left[1 - \frac{L}{\frac{K_e}{K_1R^*} + L - 1}\right] \qquad (5)$$

The average number of ribosomes per mRNA is equal to nS, and the fraction of codons on a message covered by a ribosome is given by nL In comparing the translation of two different types of mRNA in the same cell, I assume that K_e (and R*) are the same for all mRNAs In the case of greatest interest here, the rabbit reticulocyte, we have snown directly that the rate of elongation of the α and β polypeptides is the same[2] K_1 (and hence n) will, in general, be different for different mRNAs

R*, the concentration of Met-tRNA$_f$-40S complex capable of binding mRNA, is a key element in this equation, it can be taken as a measure of the overall rate of polypeptide chain initiation in the cell Reductions in the rate of formation of 40S subunits, or of binding of Met-tRNA$_f$ to them, will result in a lowered value of R*, likewise, addition of an inhibitor of mRNA binding, such as poly(I) on aurintricarboxylic acid, will also result in a reduction of R*

The crucial assumption in the derivation of equation (5) is that ribosomes are on the average distributed uniformly along an mRNA, that is $n_i = n$ for all i This is the case for the α and β-globin mRNA in the normal rabbit reticulocyte[22,23] In the specific experimental situations considered below—inhibition of polypeptide chain initiation in the reticulocyte—it can safely be assumed that in the steady state ribosomes will continue to be distributed uniformly on the average (but at a lower density) However, in cases where initiation is increased from the normal, relative to chain elongation (high values of R*) the assumption of uniform distribution may no longer be valid These cases have been considered theoretically by MacDonald *et al*[20,21]

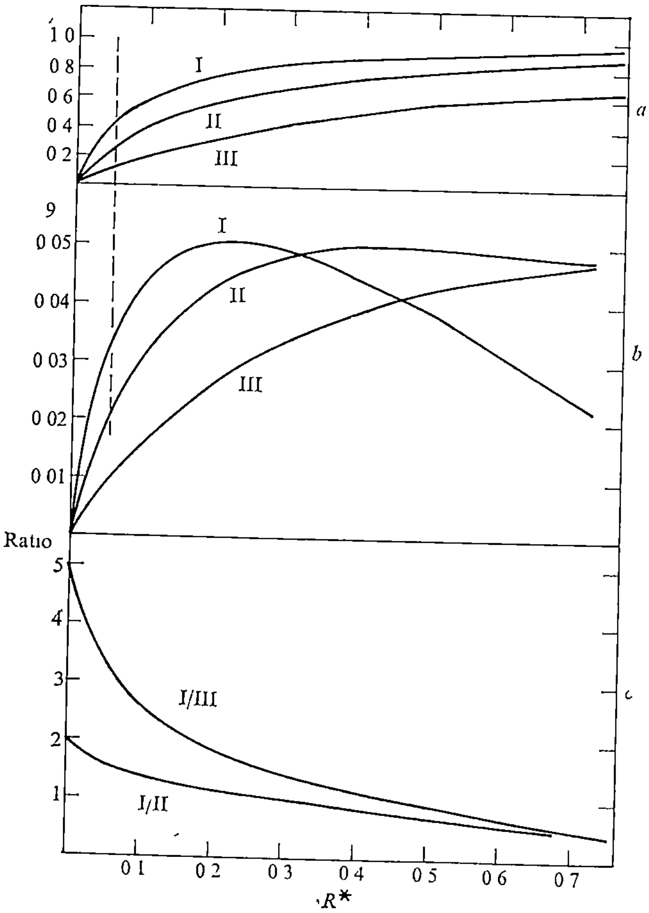

Fig. 1 Theoretical calculation of parameters of protein synthesis as a function of R* A value of 1 is assumed for K_e (rate constant for elongation) and 12 is taken for L, the number of codons covered by one ribosome Rate constants for chain initiation, K_1, are taken as 1 0 (curve I), 0 48 (curve II) and 0 20 (curve III) *a*, The fraction of codons occupied by a ribosome, nL, plotted as a function of R*, using equation (4) *b*, Amount of protein synthesised per mRNA, $q = Qm^{-1}$ plotted as a function of R*, using equation (5) *c*, Ratio of amount of protein synthesised by the different mRNAs, plotted as a function of R* As detailed in the text translation of β and α-globin mRNAs can be approximated by curves I and II, respectively The dashed line represents the conditions obtaining in the normal reticulocyte, where n^{β} (curve I) = 0 0340 and n^{α} (curve II) = 0 0211

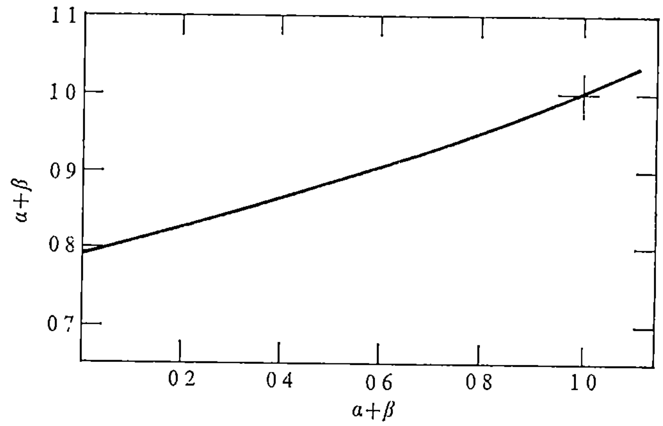

Fig 2 Theoretical calculation of the effect on relative synthesis of α and β-globin chains by inhibiting polypeptide chain initiation a stages at or before binding of mRNA The values, $K^{\alpha}_1 - K^{\beta}_1 = 0\ 48$ and $m^{\alpha} - m^{\beta} = 1\ 57$ were calculated, as detailed in the text, using only the result that, under normal conditions obtaining in the reticulocyte, each α mRNA contains, on the average, three ribosomes while each β contains five These values and equation (5) were used to calculate the ratio of α to β chains produced as a function of total globin synthesis, for the latter a value of 1 0 corresponds to synthesis in the uninhibited reticulocyte

In Fig 1*b* the relative translation of three mRNAs is plotted as a function of R* with values for K_1 set at 1 (curve I), 0 48 (curve II) and 0 2 (curve III) The value of K_e is set arbitrarily at 1, and a value of 12 for L is used Since a molecule of β-globin mRNA (147 codons) can apparently contain a maximum of 12 ribosomes[24] a value of 12 (=144−12) appears reasonable, it is consistent with the size of mRNA protected from nuclease digestion by a ribosome[8] (The relative positions of the three curves in this panel is unaffected if $L=7$ or $L=20$ is used)

Note that, with increasing R*, the rate of protein synthesis increases to a maximum, and then declines This means that above a certain density of ribosomes on the mRNA ribosomes interfere significantly with movement of each other along the mRNA (The optimum value of n can be calculated from equation (2) by setting $dq/dn=0$, it is given by equation (7) of ref 21) It should be stressed that, because of the assumption $n_i = n$ used in deriving equation (5), the curves in Fig 1 may not be correct at high values of R*

The crucial point to emerge from Fig 1 is that the relative translation of two mRNAs with different values of K_1 changes monotonically with R* (Fig 1*c*) At very low values of R* the amount of protein synthesised by a species of mRNA is given by

$$Q_{lim} = mK_1R^* \qquad (6)$$

Increasing the value of R* results in proportionally greater stimulation of translation of the mRNA with a lower value of K_1 Conversely, reducing R* (inhibiting chain initiation nonspecifically) results in a proportionally greater inhibition of translation of the mRNA with lower K_1

Application to synthesis of α and ß globin

Cell-free extracts of rabbit reticulocytes synthesise globin for about 1 h at rates comparable to that of the intact cell These extracts, as do the intact cells, synthesise equal amounts of α and β-globin chains[1,21] Each message for α globin contains on the average five ribosomes ($n^{\beta} = 5/147 = 0\ 0340$) while each α-globin mRNA contains three ($n^{\alpha} = 3/142 = 0\ 0211$)[1,26] Since the rate of elongation of the two chains is the same[2], I conclude that under conditions obtaining in the cell each α mRNA

Table 1 Inhibition of synthesis of α and β globins

Reaction	Time of labelling	% Total globin synthesis	Ratio α β globins synthesised
Control (plus haemin)	0–10	100	1 02

2×10^{-7} M	0–20	17	1 29

Reticulocyte cell-free protein synthesis reactions (0 06 ml) have been described in detail[2,53] They contained 2×10^{-6}M nonradioactive tyrosine, and ^{14}C-tyrosine (5 µCi ml^{-1}, 480 mCi mmol^{-1}, New England Nuclear Corp) was added during the indicated labelling period Unless otherwise noted, reactions also contained 20 µg ml^{-1} haemin Aliquots of the reaction were taken to measure total incorporation of radioactive tyrosine into protein After incubation, about 600,000 c p m ^{3}H-tyrosine-labelled rabbit haemoglobin was added Globin was isolated and digested with trypsin, the tyrosine-containing peptides were resolved by paper electrophoresis and detected by autoradiography (ref 2) The measure of α-chain synthesis was the average of the ratios of ^{14}C to ^{3}H radioactivity in peptides αT4 and αT6, β-chain synthesis was the ratio of ^{14}C to ^{3}H radioactivity in peptide βT4 These three relatively N-terminal peptides were utilised so that peptide labelling represents predominantly (over 98% in the control reaction) polypeptide chains initiated during the course of the cell-free reaction

initiates protein synthesis only 60% as frequently as does each β mRNA and that there must be 1 7 (=1 –0 6) times as much α mRNA as β mRNA[1,2] Further studies showed that any putative α-mRNA-specific or β-mRNA-specific initiation factors or specific ribosomes do not limit the rate of α or β-globin synthesis (unpublished results of G Temple and myself)

Since at the value of R* which obtains in the riboculocyte $n^{\beta}-n^{\alpha}=1\ 6$, I calculate from equation (4) that $K_1{}^{\alpha}=K_1{}^{\beta}=0\ 48$ Since $Q^{\alpha}=Q^{\beta}$, from equation (3) I calculate that $m^{\alpha}-m^{\beta}=1\ 57$, in agreement with a previous estimate (ref 1) The probability that an mRNA will have no ribosomes translating it is given by $(1-n)^{s}$ For α mRNA in the reticulocyte lysate ($n^{\alpha}=0\ 0211$, $s=142$), this value is 0 049 while for β mRNA ($n^{\beta}=0\ 0340$, $s=147$) it is 0 0062 Recent evidence showed that there is indeed 10 times more α mRNA unattached to ribosomes than β mRNA[27 28]

The relative translation of α and β mRNAs, as a function of R*, are thus given by curves II and I, respectively, of Fig 1*b* In Fig 2 are plotted the same data but in a form which eliminates R* — the ratio α β as a function of the total rate of polypeptide chain initiation (the sum of α and β chains synthesised) Figures 1*b* and 2 make one crucial prediction any treatment which (nonspecifically) inhibits the rate of polypeptide chain initiation at stages at or before mRNA binding will preferentially inhibit translation of α-globin mRNA

Table 1 shows the results of experiments involving six different treatments, all of which do not affect polypeptide chain elongation or termination, and all of which block initiation at steps at or before binding of mRNA All preferentially inhibit translation of α mRNA The data in this table follows very closely the theoretical curve of Fig 2

When a reticulocyte lysate is incubated in the absence of haemin, protein synthesis is normal for about 8 min (at 30° C) Synthesis continues at a decreasing rate, and ceases by 15–30 min, concomitantly there is buildup of an inhibitor which blocks binding of Met-tRNA$_f$ to the 40S subunit[10-15] Table 1 shows that there is equal synthesis of α and β globin during the first 10 min in reactions with or without haemin, and also from 10 to 30 min in the presence of haemin By contrast, in a lysate incubated in the absence of haemin there is a marked reduction in the ratio α β synthesised from 10 to 30 min, during the time inhibition is manifest In a second experiment, a lysate was incubated for 1 h in the absence of haemin, to build up the initiation inhibitor, and then a small amount was added to a fresh lysate Again, the amount of α chain made in the second reaction was only 70% that of β (Table 1)

Globin synthesis in the presence of 10^{-2} µg ml^{-1} double-stranded RNA (in the presence of haemin) is similar to that of a reaction in the absence of haemin[13,29,30] There is also produced in this case an inhibitor which blocks binding of Met-tRNA$_f$ to the 40S subunit[31] Table 1 shows that double-stranded RNA has no effect on the amount of α or β chains made during the first 10 min of incubation By contrast, during the next 20 min, when inhibition of initiation is manifest, there is preferential inhibition of synthesis of α globin

Aurintricarboxylic acid, at low concentrations, is a specific inhibitor of chain initiation[32,33] It blocks the binding of mRNA to the Met-tRNA$_f$-40S complex (ref 34 and unpublished data) In kinetic terms ATA can be viewed as lowering the concentration (R*) of Met-tRNA$_f$-40S complexes which can bind mRNA Table 1 also shows that ATA preferentially inhibits initiation of synthesis of α chains

A large number of synthetic polyribonucleotides and polydeoxyribonucleotides are also specific inhibitors of chain initiation and also block binding of mRNA to the Met-tRNA$_f$-40S complex (ref 34 and unpublished data) Like ATA, these can be viewed as reducing the concentration of R* We have shown that all 11 polynucleotides tested preferentially block α-chain synthesis[35] Table 1 shows recent results for two of those, poly(dT) and poly(dI)

It is interesting that the initiation inhibitor pactamycin which acts at a stage after binding of mRNA to the Met-tRNA$_f$-40S complex[36,37] does not preferentially inhibit α-chain synthesis This result is not in disagreement with the theory, which only pertains to steps at or before mRNA binding These results give confidence that my theory is correct at least as pertains to synthesis in rabbit reticulocyte lysates

Application to other systems

That one can alter in a predictable manner the relative translation of different mRNAs by nonspecific changes in polypeptide chain initiation components has implications for other systems In cases where the rate of cellular protein synthesis is either increasing rapidly with time—such as after fertilisation of the quiescent sea urchin embryo (reviewed in ref 38)—or decreasing—such as after infection of cultured cells by poliovirus[39]—one might reasonably expect that different mRNAs would be affected to different extents

Although the above calculations assume that mRNA-specific factors do not regulate polypeptide chain initiation, they could easily accommodate them, in this case K_1 for any mRNA would be a function of the concentration of such factors Whether mRNA specific factors do, in fact, exist is at present controversial In this context it is useful to point out the three eukaryotic systems available which can translate exogenous mRNA at very high efficiency (greater than 10 molecules of protein produced per mRNA added) The rabbit reticulocyte lysate[40,41], the mixed cell-free system of Schrier *et al*[42] and the *Xenopus* oocyte (into which the mRNA is microinjected)[43] In each of these systems a wide variety of exogenous mRNAs have been translated and in no case is there any evidence for mRNA specificity Palmiter has shown for instance, that a molecule of ovalbumin mRNA is translated in a crude reticulocyte lysate with nearly the same rate of chain initiation and elongation as obtains in the intact hen oviduct[41]

In contrast, RNA-specific factors have been observed in cell-free systems, such as preincubated extracts from mouse ascites cells[44-50], in which there is synthesis of, at best, one molecule of protein per molecule of mRNA added[49] It is clear that in such extracts some component or components required for polypeptide chain initiation (and elongation) are limiting (ref 51 and reviewed in ref 52) The present theory shows that addition to such extracts of a component required for initiation for all mRNAs can stimulate preferentially translation of certain mRNAs It is at present difficult to prove or disprove the notion that mRNA-specific factors, are, in fact, nonspecific components which are required for translation of all mRNAs, particularly since the K_1 constant of a mRNA could be changed considerably by reagents used in its isolation, such as organic solvents and detergents Addition of unfractionated rabbit globin mRNA to an extract of ascites cells generally results in synthesis of about twice as much β globin as α globin Nudel *et al*[44] reported a factor preparation from reticulocyte ribosomes which will preferentially stimulate translation of α mRNA in the ascites extract At least in the intact reticulocyte α mRNA has a lower K_1 than β mRNA, the present theory predicts that addition of whatever initiation factor limits synthesis in the ascites extracts would preferentially stimulate α-globin synthesis Whether this factor, and the others[45-49] supposedly specific for translation of β-globin mRNA or myosin mRNA are real entities, artefacts of cell-free synthesis, or, as postulated here, nonspecific components required for all chain initiation, remains for future work

Finally, the theory developed here is applicable to transcription of DNA by RNA polymerase, under conditions of limitation of some factor required for transcription initiation, the theory predicts a selective inhibition of transcription of those operons with a lower rate constant for polymerase attachment and RNA synthesis initiation.

Gene deletion as the cause of *α* thalassaemia

Two independent groups show that the absence of all or part of the globin α-chain gene is the origin of the homozygous α thalassaemia

The severe form of α thalassaemia is caused by a haemoglobin gene deletion

THE thalassaemias are a group of common genetic disorders characterised by a reduced rate of synthesis of either the α or β chains of human adult haemoglobin (Hb A, $\alpha_2\beta_2$), resulting in associated clinical disorders[1,2,3] α Thalassaemia results from a deficiency of α chains, which causes an apparent excess in production of γ chains of foetal haemoglobin (Hb F, $\alpha_2\gamma_2$) in foetal life and an excess of β chains of haemoglobin A in adult life The excess γ and β chains produce the abnormal tetramer haemoglobins Bart's (γ_4) and H (β_4) respectively Although the genetics of α thalassaemia are still not fully understood, three important clinical varieties of α thalassaemia result from the interactions of three different mutations in allelic genes α thalassaemia 1 (α-thal 1), α thalassaemia 2 (α-thal 2), and haemoglobin Constant Spring (CS)[1,4,5] The homozygous state for the α-thal 1 mutation (Hb Bart's hydrops fetalis syndrome) results in intrauterine or early neonatal death with a clinical picture of hydrops fetalis and a haemoglobin pattern consisting entirely of Hbs Bart's, H, and Portland ($\zeta_2\gamma_2$), with complete absence of α-globin chain synthesis[6] The doubly heterozygous states for either α-thal 1 and α-thal 2 mutations, or α-thal 1 and CS mutations, result in Hb-H disease, a moderately severe haemolytic anaemia consistent with survival into adult life[1]

There is evidence that in some populations (including those in south-east Asia), the human α-chain locus is duplicated and there are at least two α-chain loci per chromosome[1] The Hb Bart's hydrops syndrome might result from inactivity of all the α loci whereas in Hb-H disease might be loss of function at one out of the four[7-14] A deletion of all or part of the sequence of the α-globin genes could prevent the synthesis of functional mRNA Alternatively, the α-thalassaemia mutations might affect the control of transcription or translation in such a way as to result in a complete inactivity of α-chain gene The site of mutation could then be remote from the α-globin structural genes

We have tried to distinguish these different models by a study of the hybridisation of the DNA of an α-thal 1 homozygote to purified probes prepared from globin messenger RNAs with viral reverse transcriptase We conclude that the α-thal 1 mutation is a gene deletion affecting at least a substantial proportion of all of the α-globin cistrons

Human globin messenger RNA was prepared[15,16] from adult reticulocyte-rich blood from a non-thalassaemic haemolytic anaemia ($\text{mRNA}_{\alpha,\beta}{}^{r}$), umbilical-cord blood from newborn infants obtained at exchange transfusion ($\text{mRNA}_{\alpha,\gamma,\beta}{}^{r}$), normal foetal liver ($\text{mRNA}_{\alpha\ \gamma\ \beta}{}^{f}$), and foetal liver from an infant homozygous for α-thal 1 The infant died 20 min after delivery, haemoglobin electrophoresis showed only Hb Bart's and the minor components typical of the Hb Bart's hydrops syndrome[6]

Both normal and thalassaemic foetal livers were highly erythropoietic The mRNAs were usually isolated by affinity chromatography using poly(U)—sepharose[17,18] from total polysomal RNA prepared under conditions minimising RNA breakdown[19] Wherever possible the translational capacity of the mRNAs was tested in a heterologous protein synthesis system, either by microinjection into *Xenopus* oocytes[20] or using a cell-free system from Krebs ascites tumour cells[21] or wheat germ[22] The samples were also examined by polyacrylamide gel electrophoresis where possible to evaluate the purity of the mRNAs, but sometimes the small amounts obtained precluded such an analysis

A complementary DNA copy (cDNA) was prepared to various human globin mRNAs with avian myeloblastosis virus reverse transcriptase[23] using labelled ^{3}H-dCTP only cDNA was centrifuged on an alkaline sucrose gradient and the material larger than approximately 5S (300 nucleotides) was pooled and used for further hybridisation cDNAs were prepared using mRNA from adult ($\text{cDNA}_{\alpha\ \beta}{}^{r}$) or newborn ($\text{cDNA}_{\alpha,\gamma,\beta}{}^{r}$) reticulocytes as templates, in these cases, unlike that of foetal liver, kinetic analysis demonstrates that only very low amounts of cDNAs are homologous to mRNAs for proteins other than globin[24] The newborn reticulocytes synthesise approximately equal amounts of haemoglobins A and F

Hybridisations of $\text{cDNA}_{\alpha,\beta}{}^{r}$ and $\text{cDNA}_{\alpha\ \gamma,\beta}{}^{r}$ to their template mRNAs show that each cDNA preparation contains approximately 5–10% labelled material which behaved as double stranded even in the absence of hybridisation, and a further 10–15% which did not hybridise to its template even at very high mRNA/cDNA ratios, and which may consist of very short oligonucleotides None of the data presented here have been normalised (the hybridisation values have not been corrected to allow for the apparently double-stranded or the apparently non-hybridisable cDNA and to equate the observed hybridisation to 100%) since this would obscure the extent of errors which might arise in the experiments Both $\text{cDNA}_{\alpha,\beta}{}^{r}$ (from adult reticulocyte mRNA) and $\text{cDNA}_{\alpha,\gamma,\beta}{}^{r}$ (from newborn exchange-transfusion reticulocyte mRNA) hybridised back to their templates to the extent expected[24]

The same result was obtained when $\text{cDNA}_{\alpha,\beta}{}^{r}$ or $\text{cDNA}_{\alpha,\gamma,\beta}{}^{r}$ are hybridised to total mRNA prepared from normal human foetal liver (Fig 1) But when hybridisation was attempted to total mRNA isolated from liver homozygous for α-thal 1 homozygote, the result was different, with each cDNA hybridising at normal mRNA/cDNA ratios only to approximately 55% of that possible Since the complexity of these cDNAs is approximately 800 nucleotides (data not shown, see ref 24), indicating that most of the cDNA is complementary to only two to three mRNAs of the size of globin mRNA, we can interpret the hybridisation observed as due to only β (or β and γ) cDNA components Any major contamination with cDNAs derived from other mRNAs would have been detected in the kinetic analysis of the hybridisation of cDNA to templates We conclude that the $\text{cDNA}_{\alpha}{}^{r}$ did not hybridise due to the absence of mRNA for α globin from the α-thal 1 liver This is consistent with the complete absence of α-globin chain synthesis in the thalassaemic foetal material[6]

Nuclear DNA was prepared from normal human spleen and from liver and spleen of the Hb Bart's hydrops infant The DNA was purified on hydroxylapatite and sonicated in alkali to an average molecular weight of 100,000 (ref 25)

The sonicated normal and thalassaemic human DNA were then mixed individually with globin $\text{cDNA}_{\alpha,\gamma,\beta}{}^{r}$ and allowed to reanneal (Fig 2) The reannealing of the total nuclear DNA was followed optically by measuring directly the proportion of the A_{260} bound (reannealed) and unbound (single stranded) to hydroxylapatite Under our conditions about 20% reanneals rapidly, indicating its presence in many copies This value is slightly lower than previously published[26], a discrepancy explicable by the differences in size of DNA fragments and method of hybrid analysis The remainder of the reannealing curve represents sequences present in one or only a few copies[27]

The hybridisation of the human foetal globin $\text{cDNA}_{\alpha,\gamma\ \beta}{}^{r}$ to excess normal human DNA, as measured by binding to hydroxylapatite, demonstrates that the genes for α, γ and β globin all reanneal with the kinetics of the non-repeated portion of the genome The hybridisation to normal DNA gives a $C_0t_{1/2}$ of approximately 700, slightly more rapid than the $C_0t_{1/2}$ of the total DNA which is 1,000 This might be predicted from

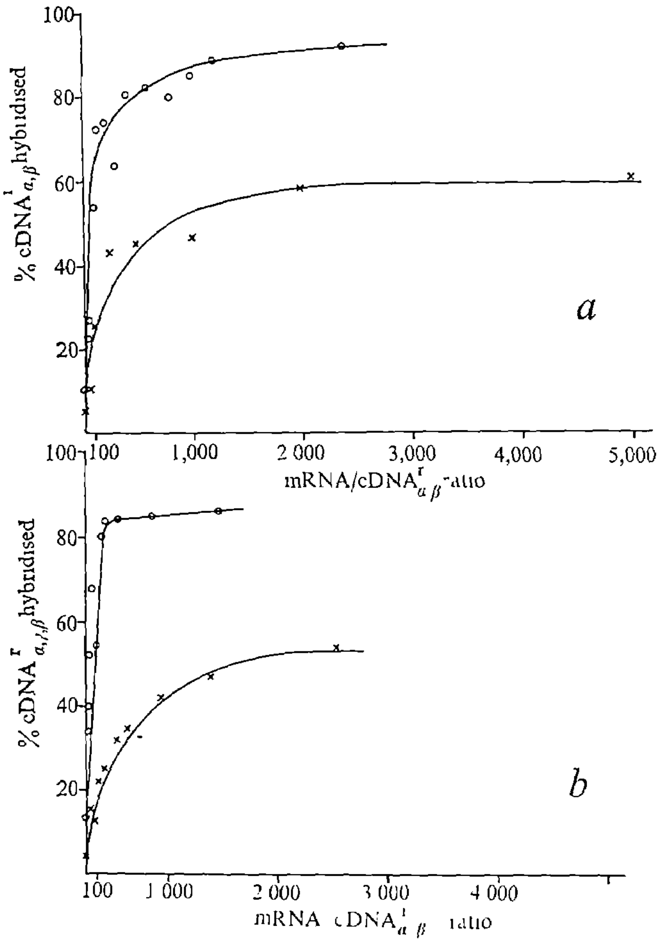

Fig 1 Hybridisation of liver mRNA from normal and α thalassaemic foetuses to cDNA$_{\alpha,\beta}^r$ and cDNA$_{\alpha,\gamma,\beta}^r$ Human globin mRNA was prepared from ribosome pellets of reticulocyte lysates from adult non-thalassaemic anaemic patients (mRNA$_{\alpha,\beta}^r$) and from newborn infants exchange transfused due to Rh incompatibility (mRNA$_{\alpha,\gamma,\beta}^r$) The pellets were extracted by a phenol–chloroform method[33], and the RNA precipitated by the addition of two volumes of ethanol The precipitate was dissolved in NETS buffer (100 mM NaCl, 1 mM EDTA, 10 mM Tris, pH 7 4, 0 2% SLS) and poly(A) containing mRNA purified by a cycle of poly(U)-sepharose chromatography[18] Each mRNA was tested in the wheat germ cell-free system[22] for biological activity mRNA from adult reticulocytes directed the synthesis of 57% α and 43% β-globin chain, mRNA from foetal reticulocytes of 55% α, 32% γ and 13% β-globin chain Counts under globin peaks accounted for at least 80% of the total radioactivity incorporated over the background endogenous synthesis A single-stranded DNA copy (cDNA) of each mRNA was prepared as described previously[23,30], using AMV reverse transcriptase, and with ^{3}H-dCTP (13 3 Ci mmol^{-1} Amersham) as the only labelled deoxynucleotide, upon centrifugation in alkaline sucrose gradients, both cDNAs, prepared with adult or foetal mRNA had a peak molecular weight of approximately 1 1 × 10^5, material larger than 0 9 × 10^5 was pooled and used for subsequent experiments Thalassaemic foetal liver was obtained from an infant with the Hb Bart's hydrops fetalis syndrome immediately after death Normal foetal liver was obtained from *post-mortem* material within minutes of death Livers were homogenised in 3–5 volumes of a solution containing 50 mM NaCl, 1 5 mM MgCl$_2$, 100 mM Tris, pH 7 6, 100 mM sucrose, 0 1% diethylpyrocarbonate, and nuclei were removed by centrifuging twice at 2,000g for 10 min The supernatant was diluted with 5–10 volumes of NETS buffer, and directly extracted with phenol–chloroform RNA was ethanol precipitated and mRNA was isolated by poly(U)-sepharose chromatography 120 pg (specific activity 7 5 × 10^6 c p m μg^{-1} cDNA calculated assuming dCTP to be 25% of the incorporated deoxynucleotide) of each cDNA were incubated in sealed sterile silicone-treated capillaries with increasing amounts of their template RNAs in 4 μl of a hybridisation solution containing 0 5 M NaCl, 25 mM Hepes, 10 mM EDTA pH 6 8, 50% formamide, 500 μg ml^{-1} *Escherichia coli* RNA[23] After 6 d at 43° C, the percentage of cDNA which had hybridised was determined by assay with the single-strand specific nuclease S$_1$ followed by perchloric acid precipitation of the undigested material The indicated RNA/cDNA ratio has been determined from the amount of added 9S RNA (as calculated by polyacrylamide gel electrophoresis analysis of poly (U)-bound RNA) The material which bound to the poly(U)-sepharose column (poly(A)-containing RNA) was hybridised to cDNA$_{\alpha,\beta}^r$ (*a*) and cDNA$_{\alpha,\gamma,\beta}^r$ (*b*) The unbound material did not contain any appreciable amount of globin sequences as determined by hybridisation to cDNA The indicated amount of RNA refers to the total poly (U)-bound material Hybridisation of *a*, cDNA$_{\alpha,\beta}^r$ and *b*, cDNA$_{\alpha,\gamma,\beta}^r$ to normal (○) and α-thal 1 (×) foetal liver mRNA

the fact that there are at least two genes for γ globin and probably two genes for α globin[1] Seventy-five per cent of the cDNA hybridises at a DNA cDNA ratio of 2 × 10^7 The hybridisation of cDNA$_{\alpha,\gamma,\beta}^r$ to the thalassaemic DNA gives a $C_0t_{1/2}$ of approximately 400 but the final amount of cDNA hybridising is only 60% a deficit of approximately one-quarter compared with normal DNA

This non-hybridisation of a portion of the cDNA$_{\alpha,\gamma,\beta}^r$ to the thalassaemia DNA suggests that the genes for α-globin have been deleted To confirm this cDNA enriched in sequences complementary to α-globin mRNA was prepared by two methods In the first, it was assumed that the foetal liver mRNA from the Hb Bart's hydrops fetalis infant contains no mRNA$_\alpha$ cDNA$_{\alpha,\beta}^r$ from adult reticulocytes was hybridised to the mRNA prepared from liver of the Hb Bart's hydrops fetalis infant at an mRNA/cDNA ratio sufficient to give 50% hybridisation of the cDNA The hybridised sequences (putative cDNA$_\beta^r$) were then bound to hydroxylapatite and the non-hybridised cDNA$_\alpha^r$ (α-enriched cDNA) which did not bind was collected At the usual RNA/cDNA ratios the cDNA$_\alpha$ hybridises to α thal 1 liver mRNA to a small extent, approximately 20%, as compared to mRNA$_{\alpha,\beta}^r$ or normal foetal liver mRNA, for which hybridisation is to 70% At very high ratios of approximately 3,000 1 mRNA/cDNA somewhat greater hybridisation (to approximately 30%) occurs between the cDNA$_\alpha$ and the mRNA from the α-thal 1 homozygote We estimate the α-enriched cDNA contains approximately 75% cDNA$_\alpha^r$

The second method for preparing α-enriched cDNA used mRNA prepared from reticulocytes from a patient with homozygous β-thalassaemia as a template for reverse transcriptase From the ratio of cell-free α β+γ chain synthesis the cDNA was estimated to be 80–90% cDNA$_\alpha^r$

The reannealing experiments at vast DNA excess with normal and α thalassaemic DNA were repeated using cDNA$_\alpha^r$ as a probe (Fig 3) The two cDNA$_\alpha^r$ probes gave indistinguishable annealing profiles with normal and thalassaemic DNAs The total DNA reanneals with a $C_0t_{1/2}$ of approximately 1,000 as in the previous experiments and the cDNA$_\alpha^r$ reanneals with the normal human DNA to give a curve very similar to that for cDNA$_{\alpha,\gamma,\beta}^r$ with a $C_0t_{1/2}$ of 700 The cDNA hybridises to 70% In the case of the homozygous α-thal 1 DNA, a quite different picture is seen Hybridisation occurs only very slowly and a final value of 40% cDNA$_\alpha$ hybridised is obtained at a C_0t of greater than 3×10^4, thirty times greater than the $C_0t_{1/2}$ of non-reiterated DNA sequences, as estimated from the ratios of the C_0ts of the low hybridisation values measured

The results obtained with normal globin cDNA$_{\alpha,\gamma,\beta}^r$ and cDNA$_{\alpha,\beta}^r$ demonstrate that, as in the case of duck[28,29] and mouse[30], human globin genes reanneal with the non-reiterated component of the DNA, or slightly faster, and are present as only single or a few copies This is consistent with the current genetic evidence indicating 2–4 human γ and α globin loci[1]

The very different rate of hybridisation for the normal and α-thalassaemic DNAs with both purified cDNA$_\alpha^r$ and cDNA$_{\alpha,\gamma,\beta}^r$ cannot be explained by a single nucleotide mutation which affects transcription or translation The extent of hybridisation of the thalassaemic DNA never exceeds 30% of that of the normal DNA, even at very high C_0ts, demonstrating the deletion of all, or at least a substantial part, of the genes for α-globin mRNA Since there are almost certainly two α-chain genes in this population, this suggests that they are closely linked The cDNA$_\alpha$ hybridisation to 70% with normal total DNA demonstrates that α-globin genes are present in large excess relative to cDNA in these experiments

A deletion of more than half of the α-globin gene at all loci would give the annealing profiles seen in Figs 2 and 3 As the cDNA is transcribed from the poly(A) sequence on the 3′-end of the mRNA, it is particularly rich in sequences at the 3′-end of the gene, coding for C-terminal sequences of the protein, and therefore the extent of the deletion will be underestimated Moreover, the purified cDNA$_\alpha{}^r$ is still contaminated with approximately 25% sequences complementary to other globin mRNAs

A component of the reannealing seen with the purified cDNA$_\alpha{}^r$ and α-thal DNA might be due to mismatched hybridisation to the genes for the α-type chain zeta (ζ). This early embryonic chain forms tetramers with γ chain in haemoglobin Portland ($\zeta_2\gamma_2$) in early embryonic life, and is known to be present in α-thal 1 homozygotes at approximately 1–5% of the total globin[6] Preliminary studies indicate that it contains some α-chain-like sequences, particularly at the C-terminal end[32] Furthermore, it behaves functionally as an α chain, since the tetramer $\zeta_2\varepsilon_2$ (the probable formula for haemoglobin Gower 1[33]) shows complete cooperative function The slow rise in hybridisation between cDNA$_\alpha{}^r$ and mRNA from α-thal foetal liver at very high mRNA/cDNA ratios may also be due to mismatched mRNA–cDNAα hybrid formation.

We conclude, therefore, that a substantial, and in all probability complete, deletion of the genes for α globin is the molecular mechanism which produces the α-thal 1 disorder and hence, in its homozygous state, the Hb Bart's hydrops syndrome Extrapolating from our results with α-thal 1, it seems likely that in many cases α-thal 2 results from the loss of a single α-gene locus Since there is now strong evidence that the heterozygous state for Hb CS also mimics the clinical picture of α-thal 2, it is possible that some cases of α-thal 2 result from a molecular mechanism other than a deletion

From a practical point of view, it is perhaps discouraging that a disorder such as this severe form of α thalassaemia, which causes a major public health problem in many parts of the world, results from a gene deletion, since this precludes any possibility of correction at the post-transcriptional level

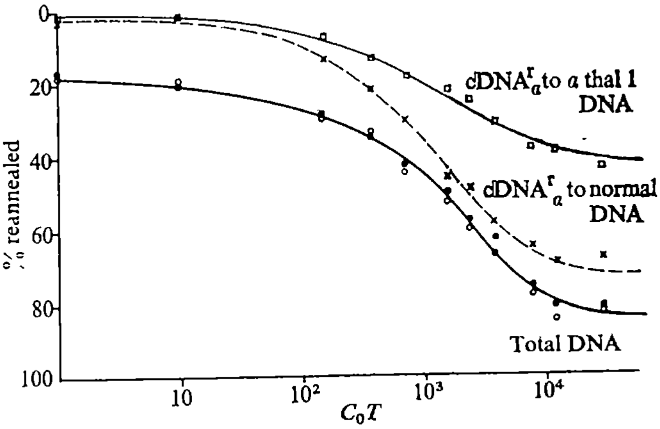

Fig 3 Reassociation of α-enriched cDNA to excess normal or α-thalassaemic total DNA α-Enriched cDNA (0 4 ng) prepared by hydroxylapatite adsorption was mixed with excess (25 × 10^6 l^{-1}) normal or α-thalassaemic DNA at a concentration of 5 mg ml^{-1} in phosphate buffer, and hybridised as in Fig 2 Percentage of radioactivity in single-stranded DNA × (normal DNA) and □ (α-thalassaemic DNA) Percentage of absorbance in single-stranded DNA ○ (normal DNA) and ●, (α-thalassaemic DNA) In a control experiment α-enriched cDNA was hybridised with a 20 × 10^6 excess of *E coli* DNA 3% of the cDNA$_\alpha$ was eluted with the double-stranded fraction at C_0t0, 8% at C_0t 4,500, 9% at C_0t 10,000 The slight increase of cDNA eluted in the 0 4 M phosphate fraction at very high C_0t after hybridisation with *E coli* DNA has been previously reported[23]

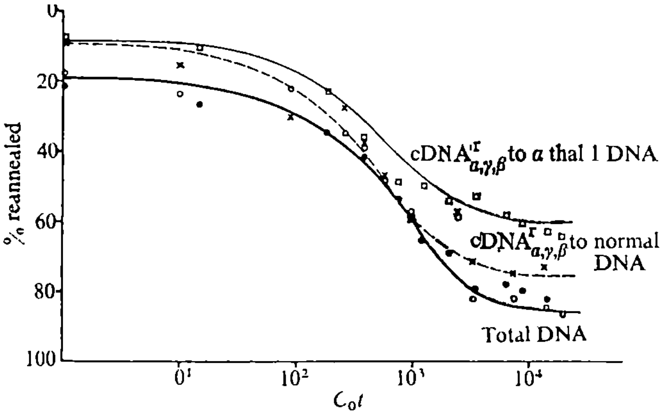

Fig. 2 Reassociation of cDNA$_{\alpha\ \gamma,\beta}{}^r$ to excess normal or α-thalassaemic total DNA DNA was prepared from nuclei of normal human spleen or of hydrops fetalis liver with hydroxylapatite[25], and sonicated in 0 1 NaOH to an average size of approximately 300 nucleotides DNA fragments were neutralised, ethanol precipitated, redissolved in distilled water and dialysed three times against 20 volumes of water cDNA$_{\alpha\ \gamma,\beta}{}^r$ (0 5 ng) was mixed with excess (20 × 10^6 l^{-1}) normal or α-thalassaemic DNA at a concentration of 8 3 mg DNA ml^{-1} in 0 12 M sodium phosphate, *p*H 6 8 120 µl aliquots of the solution were sealed in sterile silicone-treated capillaries, the mixtures were denatured for 10 min at 100° C, then annealed at 60° C At the appropriate times, samples were removed and fractionated on hydroxylapatite columns[30] Reannealing of total DNA was followed by measuring spectrophotometrically the proportion of DNA eluted as single-stranded material (at 0 16 M sodium phosphate, *p*H 6 8) and double-stranded material (at 0 4 M sodium phosphate) Radioactivity of the 0 16 M and 0 4 M phosphate fractions was determined by counting directly in Instagel (Packard) In all cases, at least 95% of the radioactivity, or of the total DNA, was recovered as single-stranded or reannealed DNA by hydroxylapatite The percentage of radioactivity in single-stranded DNA is shown by × (normal DNA) and □ (α-thalassaemic DNA), that of absorbance in single-stranded DNA by ○ (normal DNA) and (α-thalassaemic DNA)

We thank our clinical colleagues in Glasgow and Aberdeen for providing pathological and normal haematological specimens, and for discussions Drs Paul Harrison and George Birnie advised on the use of reverse transcriptase in hybridisation reactions and Dr Bryan Young helped us with the mathematical analysis of our results S O was on leave from the Institute of General Pathology, University of Milan, on a Royal Society exchange fellowship from the Accademia Nazionale dei Lincei when this work was carried out. Genetic lesion in homozygous α thalassaemia (hydrops fetalis)

HOMOZYGOUS α thalassaemia (hydrops fetalis) is invariably fatal to afflicted infants within 30–40 weeks *in utero* or soon after birth[1] In this form of α thalassaemia both the α chain of haemoglobin and the α-globin mRNA are undetectable[2,3] To define the nature of this defect we have examined the DNA from two cases of hydrops to determine whether major alterations in the structural gene for α globin are present

For these studies we prepared complementary DNA (cDNA) to total globin mRNA (α+β) from a non-thalassaemic patient with autoimmune haemolytic anaemia, as well as cDNAs specific for either α or β-globin mRNA sequences The procedures are detailed in the legend to Fig 1 Evidence for the specificity of the cDNAs was obtained by measuring the rates of annealing (expressed as $C_r t$ (mol s^{-1} l^{-1})) to an excess of globin mRNA The two cDNAs annealed at the same rate to globin mRNA from a non-thalassaemic individual (Fig 1*a*) When globin mRNA from an individual with haemoglobin H disease was used, the presumptive α-globin cDNA annealed at a rate about ten times slower than that of the β-globin cDNA (Fig 1*b*) In this disease there is a reduction of α-globin chain relative to production of β-globin chain and a corresponding reduction in the α-globin mRNA[9,10] When an aliquot of the mRNA used in the above experiment was translated with the cell-free system from the Krebs II mouse ascites tumour[5], the ratio of α to β globin synthesised was 1 9 Thus the different rates of annealing observed in Fig 1*b* are consistent with the presumption that the cDNAs used are specific for α and β-globin sequences

We then used these ^{32}P-labelled cDNAs to detect α and β-globin nucleotide sequences in DNA extracted from the livers of two Chinese infants with homozygous α thalassaemia and, as a control, a stillborn infant without thalassaemia Annealing of the ^{32}P-labelled cDNA during the reassociation of the unlabelled cellular DNA was monitored by hydroxylapatite fractionation A large excess of cell DNA was used to ensure that even sequences represented a single time in the human genome would anneal with the cDNA Our results are summarised in Fig 2, with experimental details provided in the legend In each experiment we in-

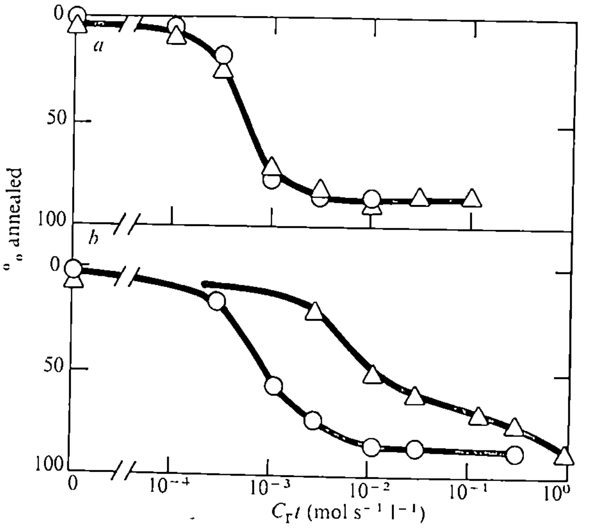

Fig 1 Annealing of globin cDNA to globin mRNA Reticulocytes were obtained from non-thalassaemic individuals or from patients with haemoglobin H disease RNA was extracted with phenol and sodium dodecyl sulphate[4], and analysed by rate zonal sedimentation RNA migrating in the range 7–11S was pooled and used without further purification These RNAs were translated using the cell-free system from Krebs II mouse ascites tumour[5] and the product was analysed by chromatography on CM-cellulose[6] The product translated from non-thalassaemic RNA contained equal amounts of α and β globin and from haemoglobin H RNA the ratio of α to β globin synthesised was 1 9 Both RNAs were transcribed into cDNA using RNA-directed DNA polymerase purified from Prague C strain of Rous sarcoma virus The conditions of synthesis were as follows 0 1 U ml^{-1} polymerase[7], 0 4 μg ml^{-1} RNA template, 0 1 μg ml^{-1} oligo $(dT)_{12-18}$ (Collaborative Research), 100 μg ml^{-1} actinomycin (Calbiochem), 0 1 M Tris (*p*H 8 1), 0 008 M $MgCl_2$, 0 02 M β-mercaptoethanol, 80 μM dATP, 80 μM TTP, 80 μM dGTP, 0 8 μM (α-^{32}P) dCTP (115 Ci $mmol^{-1}$, New England Nuclear Corp) Synthesis was for 2 h at 37° C using a reaction volume of 3 ml After the addition of 50 μg of yeast RNA, the nucleic acids were extracted with sodium dodecyl sulphate and pronase, followed by a single phenol extraction at room temperature The cDNA was precipitated with ethanol and treated with alkali (0 6N NaOH, 37° C, 1 h) to remove RNA The solution was neutralised and again precipitated with ethanol The cDNA was then annealed to an excess of its template (normal or haemoglobin H mRNA) under the following conditions 0 3 M NaCl, 0 001 M EDTA, 0 02 M Tris (*p*H 7 4), at 68° C That cDNA which annealed to RNA was isolated by batch elution from hydroxyapatite[8] and then passed through a column of Sephadex G-50 (40×0 9 cm) The excluded volume was collected, treated with alkali as described above and re-precipitated with ethanol That cDNA transcribed from RNA of the individual with haemoglobin H disease was used as a probe for β-globin sequences without further purification The cDNA transcribed from the normal RNA was subjected to further fractionation in an attempt to obtain probe specific for α-globin sequences First, the unfractionated cDNA was annealed to a limited extent with haemoglobin H RNA After incubation, that cDNA which had not annealed (30%) was isolated by hydroxyapatite fractionation and Sephadex G-50 chromatography, and subsequently treated with alkali and precipitated with ethanol as described above This adsorption process was repeated three more times in an attempt to remove sequences complementary to β-globin mRNA The remaining unadsorbed cDNA was finally annealed to an excess of normal RNA The annealed cDNA was recovered The experiment depicted in the figure shows evidence that this cDNA is specific for α-globin sequences The presumptive α-globin (△) and β-globin (○) probes were examined for their ability to anneal to an excess of RNA either from a normal individual (*a*), or from a patient with haemoglobin H disease (*b*) Hybridisation was assayed by batch elution from hydroxylapatite and results are plotted against the product of RNA concentration and time ($C_r t$)

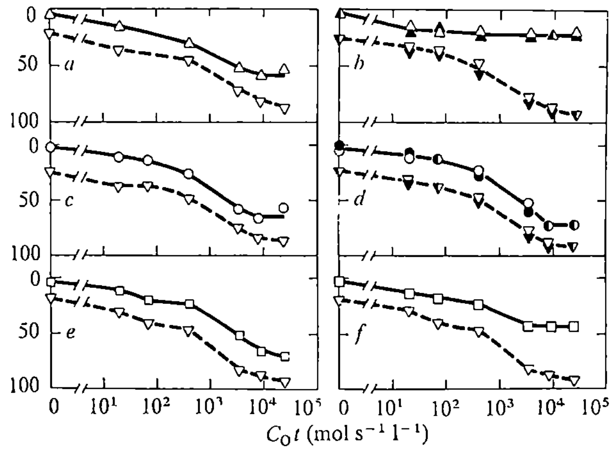

Fig 2 Annealing of labelled globin cDNA to cellular DNA Nucleic acid was extracted from the livers of two patients with hydrops fetalis using sodium dodecyl sulphate and pronase followed by two room temperature phenol extractions After treatment with ribonuclease and further phenol extractions, the DNA was reduced in size to about 2×10^6 daltons either by shearing at 50,000 pounds per square inch[12] or limited depurination[13] (0 3N NaOH, 100° C for 20 min) HeLa cells in suspension culture were labelled with ^{3}H-thymidine for 48 h and the DNA was isolated as described above Single-stranded ^{32}P-cDNA was prepared as described for Fig 1, and annealed under the following conditions 5 mg ml^{-1} cell DNA, 2400 c p m ml^{-1} ^{32}P-globin cDNA, 24,000 c p m ml^{-1} ^{3}H-HeLa DNA, 0 5 M NaCl, 0 002 M EDTA, 0 04 M Tris (*p*H 7 4), at 68° C Incubations were performed in 80 µl reaction volumes, under mineral oil, for from 20 min to 120 h Annealing was assayed using hydroxylapatite[14] and plotted against C_0t values corrected to standard conditions[15] *a* and *b*, α-globin cDNA (△, ▲) was annealed either with normal or hydrops DNA respectively Similarly (*c*) and (*d*) refer to β-globin cDNA (○, ●) annealed with normal or hydrops DNA Unfractionated globin cDNA (□) transcribed from normal mRNA was also annealed to normal (*e*) and hydrops DNA (*f*) In each panel of the figure the ^{3}H-labelled DNA (▽, ▼) acts as an internal control on the observed rate of annealing *b* and *d*, The DNA from two cases of hydrops was tested separately and the results are shown by the open and closed symbols

cluded a small amount of ^{3}H-labelled human DNA from HeLa cells and its annealing was followed to determine the rate of reassociation of the cellular DNA Figs 2*a* and *c* show that α and β-globin cDNAs annealed at about the same rate to DNA from the non-thalassaemic foetus In contrast, α-globin cDNA did not anneal significantly to DNA from the hydrops foetuses (Fig 2*b*) although β-globin cDNA reacted normally (Fig 2*d*) A similar result was obtained when unfractionated globin cDNA (α+β) was used The extent of annealing with non-thalassaemic DNA (Fig 2*e*) was about twice that observed with hydrops DNA (Fig 2*f*) We interpret that data to mean that at least part of the α-globin gene is absent from the DNA in hydrops, the amount of the β-globin genes appears to be normal

This conclusion is subject to several qualifications First, although the cDNA used is specific for α globin, it is not a uniform representation of the structural gene The average size of the cDNA used in the experiment was only 380 nucleotides, when measured by sedimentation in alkaline sucrose The complete α-chain mRNA is composed of about 630 nucleotides[16], about 60 of these are contained in the 3′-terminal poly(A) segment[17], adjacent to which is a segment of at least 93 nucleotides which are not normally translated[18] Since the cDNA used in our experiments was presumably transcribed from the 3′-end of the mRNA, it is likely to represent only a part of the sequence of the α-globin structural gene

Second, the observed rates of annealing of the cDNA to cell DNA depend on the relative excess of sequences in the cell DNA that are complementary to the cDNA The mass ratio of cell DNA/cDNA used was $6\ 7\times10^7$ If we assume the human haploid genome contains 3×10^9 nucleotide pairs and the average length of the cDNA is 380 nucleotides, then the ratio of unlabelled to labelled sequences is 8 5 1 This also assumes that the α-globin gene is represented only one per haploid genome Actually there is evidence that the gene might be duplicated[19] so that our sequence excess might be twice the value calculated above To confirm that these experiments were performed with adequate quantities of cell DNA we have performed annealings with as much as a fivefold greater excess of cell DNA relative to cDNA and have seen no more than a 10% increase in the extent of annealing We therefore deduce from the annealing rates in Fig 2*b* compared with those in Fig 2*d*, that the hydrops DNA contains less than 2% of the α-chain sequences detected in normal DNA Assuming that the DNA of each somatic cell is identical, then part or all of the α-chain gene is actually deleted In addition, if the α-chain gene is normally duplicated then in the hydrops both loci must be affected

In summary, we have shown that for homozygous α thalassaemia in Chinese subjects, the cellular DNA lacks certain sequences normally found in α-globin mRNA

We thank Dr J M Bishop for helpful comments and Ms Janice Holland for assistance This work was supported by grants from the National Institutes of Health and the John A Hartford Foundation, a Senior Dernham Fellowship (J M T) from the American Cancer Society, and Public Health Service research career development awards (Y W K , and H E V) from United States

Highly polarised radio outburst from Cygnus X-3

We report here the results of extensive observations of a new series of outbursts from Cyg X-3 which we commenced following the recent IAU telegram alert from Sir Martin Ryle A high degree of linear polarisation has been discovered in one of the recent outbursts The degree of polarisation changes over a period of 17 d and reaches a maximum of 14% The observations indicate a high degree of order in the source magnetic field and that a thermal plasma coexists with the radiating relativistic electrons In addition, a new upper limit of 0 05″ has been obtained for the angular size of Cyg X-3, together with an improved position for the source

In September 1972 radio emission from Cyg X-3 increased by three orders of magnitude in the course of a few days, reaching a maximum of 22 Jy only to decline again during the following week[1] Since then some 17 outbursts have been recorded by individual observers and by a monitoring program at the Algonquin Radio Observatory[2] The present observations covering the period May 14 to 31 include measurements of flux density, linear and circular polarisation at two frequencies, 2,695 and 8,085 MHz The observations were obtained with the NRAO four element phase-stable interferometer at Green Bank The measured flux densities for Cyg X-3 are shown in Fig 1 with values of the spectral index $\alpha = \log (S_{8085}/S_{2695})/\log (8085/2695)$, where S_{8085} and S_{2695} are the measured flux densities at the two frequencies The flux densities are calibrated in terms of the flux densities of 3C48, 3C147 and 3C286 and have an uncertainty of ≤ 0 1 Jy or 3% whichever is the greater These three sources were also used as linear polarisation calibrators Their adopted flux densities and polarisation parameters are given in Table 1 Observations of these and other secondary flux density calibrators were interlaced with Cyg X-3 observations once every hour A more detailed discussion of the observations and their interpretation will be presented elsewhere

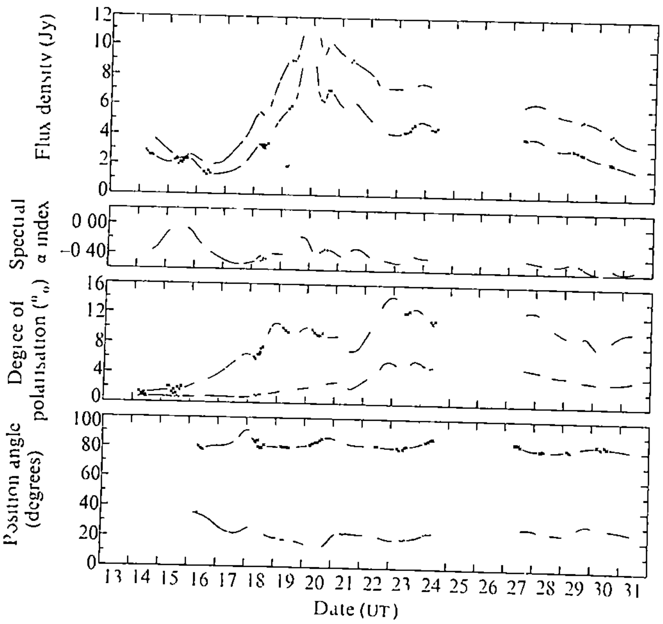

Fig 1 The flux density, spectral index, degree of linear polarisation and position angle of the radio emission plotted as a function of UT date For an unresolved source of linear polarisation P is normally expressed in terms of the degree of linear polarisation m and the position angle χ of the polarised component The measured values of m and χ, corrected for instrumental polarisation, are also shown From an analysis of the measurement uncertainties and from the constancy of the instrumental polarisation during the entire observing period, we are confident that the trends conveyed by the solid curves are real and not produced by noise or variations in the instrumental polarisation ×, 8,085 GM7, ●, 2,695 GM7 Observations cover the period May 14 to 31.

Table 1 Adopted values of flux density and polarisation for the primary calibration sources m is the degree of linear polarisation and χ is the measured position angle of the electric vector

	f=2,695 MHz			f=8,085 MHz		
Source	S (Jy)	m (%)	χ (degrees)	S (Jy)	m (%)	χ (degrees)
3C48	9 00	2 1	60	3 30	5 5	110
3C147	12 60	0 7	44	4 90	0 7	163
3C286	10 10	9 2	30 9	5 20	11 4	34 4

An attempt was made to detect circular polarisation We obtained an upper limit of 0 5% at both frequencies This limit and the theory of synchrotron radiation[3] place a corresponding upper limit of about 0 02 gauss for the magnetic field in the radiating region

The position of Cyg X-3 as measured with the maximum interferometer baseline of 35 km was found to be

$$\left.\begin{array}{l}\alpha = 20\text{ h }30\text{ min }37\ 620\text{ s} \pm 0\ 005\text{ s}\\ \delta = 40^\circ\ 47'\ 12\ 85'' \pm 0\ 05''\end{array}\right\}1950\ 0$$

This position is consistent with previous measurements[4-6] but the quoted errors of the present measurements are significantly lower A new upper limit on the angular size was obtained from simultaneous observations of Cyg X-3 with the 35 km baseline and shorter baselines over a wide range of hour angles The mean fringes visibilities measured at 2,695 and 8,085 MHz were 1 00 ± 0 03 and 1 03 ± 0 11, respectively, and no hour angle dependence was detected The minimum fringe visibility consistent with the 8,085 MHz observations corresponds to an angular size for a circularly symmetric source of uniform brightness of ≤ 0 05″ If we adopt for the distance the lower limit of 10 kpc (ref 7) this corresponds to a linear size of $\leq 8 \times 10^{15}$ cm

The radio emission observed from May 14 to 31 represents a portion of at least two large outbursts which began about May 11, 1974 (P C G , V A Hughes, A Woodsworth and E R S , unpublished) We believe that the decay in the emission between May 14 and 16 constitutes the end of the first outburst The second outburst began about May 17 The spectral index and polarisation of the radio emission together clearly indicate a nonthermal emission process characteristic of synchrotron emission from relativistic electrons If the electrons have a power law energy spectrum ($N(E) \propto E^{\gamma}$) the observed mean spectral index ($\alpha = -0\ 4$) yields $\gamma \approx 1\ 8$ throughout most of the period of the observations In addition, the spectral index profile shows a tendency for α to decline from $-0\ 2$ to $-0\ 6$ during the observations This general behaviour is characteristic of radiation from an optically thin cloud of relativistic electrons in which there are energy losses which occur preferentially at the higher energies With regard to the fact that the source is optically thin the second of these outbursts is similar to the third and fourth outbursts observed in 1972 at similar frequencies[4,8] The first two outbursts in 1972, however, exhibited an optically thick phase at and below 2,695 MHz

One of the principal differences between the May 2 outburst and all of the September 1972 outbursts is the slow rise in flux density from May 17 to May 20, followed by an even slower decline in flux density from May 20 to 31. The September activity was characterised in general by a more rapid rise and decline in the flux density. There is, however, evidence in the fine structure of the May activity that the outburst profile may be decomposed into a series of smaller outbursts, with sharp rise times, occurring so frequently that they are unresolved. The picture suggested is that relativistic particles are repeatedly injected into a region which remains essentially optically thin. On two occasions (May 15.5 and May 19.5) the spectrum flattens significantly and we presume that the associated minor outbursts correspond to particle injection in the form of a new region of emission which is either optically thick at 2,695 MHz or possesses a flatter energy spectrum in the radiating particles.

The most readily observed characteristic of the polarisation is a general increase in the degree of polarisation at both (Fig. 1) frequencies, rising from about 1% to 14% at 8,085 MHz between May 14 and May 23 followed by a slight decline. The position angle of the electric vector is remarkably constant at both frequencies, but there are significant deviations, of the order of 10°, from a mean value. The electric vector position angles at the two frequencies differ by about 60°. The latter observation leads to a mean rotation measure of about −100 rad m^{-2}. This value is consistent in magnitude and sign with the galactic Faraday rotation in the Cygnus direction, although the latter quantity is extemely uncertain. On the other hand, the deviations in rotation measure shown in Fig. 2 indicate that there is some Faraday rotation in the source as well.

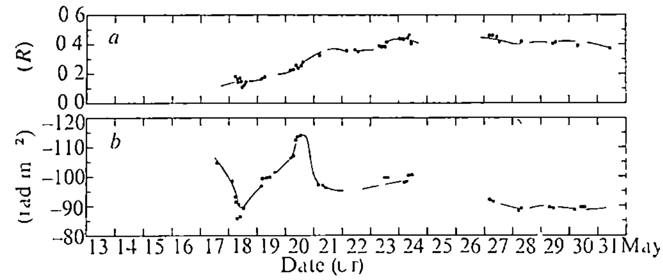

Fig. 2 The derived depolarisation ratio (*a*) and rotation measure (*b*) plotted as a function of UT date.

The degree of polarisation is lower at 2,695 MHz than at 8,085 MHz. The 'depolarisation ratio' R = (degree of polarisation at 2,695 MHz/degree of polarisation at 8,085 MHz) varies from about 0.1 on May 17 to about 0.45 on May 24 and remains roughly constant thereafter. The most direct interpretation of this result is that the radiation at 2,695 MHz is partially depolarised by Faraday dispersion produced by an ionised thermal plasma associated with the source. The polarisation observations therefore make it possible to deduce some of the characteristics of this depolarising medium.

Burn[9] has described the depolarisation behaviour of simple source models with internal and external Faraday dispersion. In particular, he computes the dependence of the observed degree of polarisation and position angle on the amount of depolarisation for varying degrees of order in the magnetic field.

We may have made a qualitative comparison of the Cyg X-3 polarisation behaviour with Burn's model for internal Faraday dispersion in the case of spherical geometry. If the model is applicable the 8,085 MHz radiation is not significantly depolarised by Faraday dispersion but that Faraday effects are partly responsible for depolarisation at 2,695 MHz. The ratio R is then a measure of the amount of depolarisation by Faraday dispersion at 2,695 MHz. So the degree of polarisation at 8,085 MHz is determined entirely by magnetic field disorder, and the position angle is determined by the field orientation. Over the observed range in the depolarisation ratio ($R = 0.1 \rightarrow 0.45$) the position angle of the electric vector at 2,695 MHz would be expected to vary by about 15° or less depending upon the detailed structure of the magnetic field. This expectation is certainly comparable with the observed slight systematic variation in the position angle at 2,695 MHz. The position angle at 8,085 MHz remains essentially fixed. If this interpretation is correct, the observed increase in the degree of polarisation at 8,085 MHz suggests an increase with time in the degree of order of the magnetic field within the source during the course of the outburst.

The observed increase in R suggests a continuous dilution of the depolarising medium with time. With regard to the internal Faraday dispersion model, this suggests either an expansion of the emitting region and depolarising medium together, or a movement of the emitting region relative to the depolarising medium.

If the ordered component of the field is primarily responsible for the depolarisation effects, then when $R = 0.45$, we have, from equations (18) and (19) of Burn[9],

$$nH_{\|}L \approx 4.7 \times 10^{14} \text{ gauss cm}^{-2}$$

where n is the thermal plasma density, $H_{\|}$ is the line of sight component of the uniform magnetic field strength, and L is the size of the emitting region.

If $L \sim 10^{15}$ cm and the field strength is about 0.01 gauss, consistent with the limits on the magnetic field derived for the first outburst[10] in September 1972, we would require an electron density on the order of 100 cm^{-3} to explain the depolarisation observed. The optical depth τ of this plasma would be about 10^{-7} at 2,695 MHz if $T = 10^4$ K, and would therefore be optically thin at the observed frequencies as required.

In a reanalysis[10] of the September 1972 outbursts have shown that a thermal plasma within the emitting region plays the major role in determining the optical depth in the first two outbursts. The high plasma densities $\sim 10^7$ cm^{-3} calculated for the first two September 1972 outbursts would produce a complete depolarisation of the radio emission by Faraday effects. Indeed, most observers (see ref. 11) found only an upper limit to the degree of polarisation. The one previously reported detection of linear polarisation[1] has since been found to be accountable for by an instrumental effect. The high polarisation observed in May is consistent therefore with the fact that the outburst is optically thin.

Distances to the sources of observed gamma-ray bursts

WE suggest that the brief, intense outbursts of hard X rays, or soft γ rays of cosmic origin which have been termed γ-ray bursts[1] are mainly, though not necessarily entirely, of Galactic origin More specifically, the γ-ray bursts reported so far[2] seem to originate in the local (Orion) spiral arm of our Galaxy, at distances of, typically, several hundred parsec If we assume that the sources radiate into 4π sr, the absolute luminosities are ~10^{39} erg per event (It may be significant that this is of the order of the predicted Eddington limit radiation from accretion disks around collapsed stars)

Although observations of the phenomenon of γ-ray bursts are well established—the first report[1] has been substantiated by numerous independent observations[3–7]—the data are by no means extensive In particular, only a couple of dozen events[2] have been confirmed by two or more independent detector systems, and less than half of these have provided useful information on source directions The directions are of critical importance to estimates of source distance, because the more direct methods, such as correlation in time or position with reported cosmic events or stellar objects of known distance, respectively, have so far failed The amount of data is unlikely to increase significantly in the next few years, so we are obliged to squeeze what we can from existing data

At present, directional information exists for 11 events Five of these have alternative positions (see ref 2), with approximately the same Galactic latitudes (because of the fortuitous orientation of the orbital plane of the satellites), but quite different Galactic longitudes The latitude distribution can be examined in order to test the isotropy of the source distributions Figure 1 shows the number of sources above a given latitude as a function of that latitude, for 10 γ-ray bursts and for 10 sources distributed perfectly isotropically (one at a very low latitude is not included, its addition strengthens an argument discussed later) The real sources seem slightly deficient at high latitudes, a result, unfortunately, of no great statistical weight

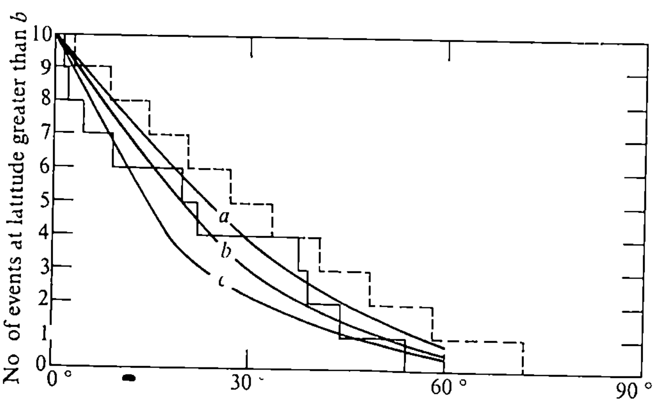

Fig. 1 Actual and isotropic integral latitude distributions compared with calculated distributions for extreme Population I objects Solid line histogram, integral distribution in Galactic latitude of 10 γ-ray burst sources, dashed line histogram, distribution expected for 10 sources distributed uniformly Calculated curves for sources of constant intrinsic luminosity, *a*, detectable out to 200 pc, *b*, 300 pc, *c*, 500 pc

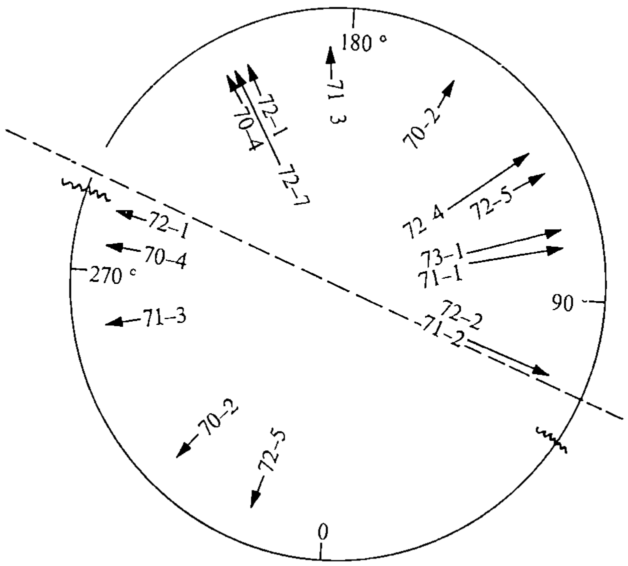

Fig 2 The distribution in Galactic longitude of 11 γ-burst sources Long arrows, unique directions, short arrows (which occur in pairs, one on each side of the dashed line), alternative positions for the source, dashed line, direction of local spiral arm The sources are named according to the system established in ref 2

The longitudinal distribution is shown in Fig 2 Here, there is something statistically more significant The orientation of the local spiral arm of this Galaxy is indicated and all six of the uniquely determined directions lie on the side away from the Galactic centre The Sun is known to lie near the inner edge of the spiral arm If the detected sources lie at distances from the Earth, which are greater than the distance of the Sun from the ill defined inner edge of the arm (a distance of, at most, a few tens of parsec) but less than the distance (around 1 kpc) to the next (Sagittarius) arm in towards the Galactic centre, then they would, if associated with the young Population I stars of the spiral arms, be expected to lie in the longitude range ~70°–~250°

Consider a simple model of source distributions in which the sources have a *z* distribution approximating that of the Galactic gas[8] and intrinsically faint stars[8] This distribution is appropriate because it is close to that of the bright O and B supergiants that have been associated with cosmic X-ray sources[9,10] Initially, we assume all the sources to have the same absolute luminosity and calculate, from the *z* distribution given by Weistrop[8], curves giving the fraction of sources above a given latitude, for any given maximum source distance (Fig 1) It can be seen that a maximum distance of ~300 pc is not a bad fit Assuming that some of the observed range of flux reflects variations in intensive luminosity, the curve can be made to fit even better, including a proportion of extra luminous sources around longitudes of ~70° and ~250°, at distances of up to ~1 kpc

An argument independent of direction can also be adduced for a Galactic origin If the sources were distributed uniformly throughout space then the number detectable above a given flux level would follow the well known '−3/2 power law' If $N(S)$ is the number of sources producing a flux greater than S then $N(S) \propto S^{-\alpha}$, where $\alpha = 3/2$ For sources confined to an infinite, thin sheet, $\alpha = 1$, whereas for sources strung out along an infinite line, $\alpha = 1/2$ This argument does not require the sources to have uniform, intrinsic luminosites

Cline and Desai (unpublished) have examined the IMP-6 data for γ-ray bursts smaller than those detected by the Vela satellites Because of a number of difficulties, the results were

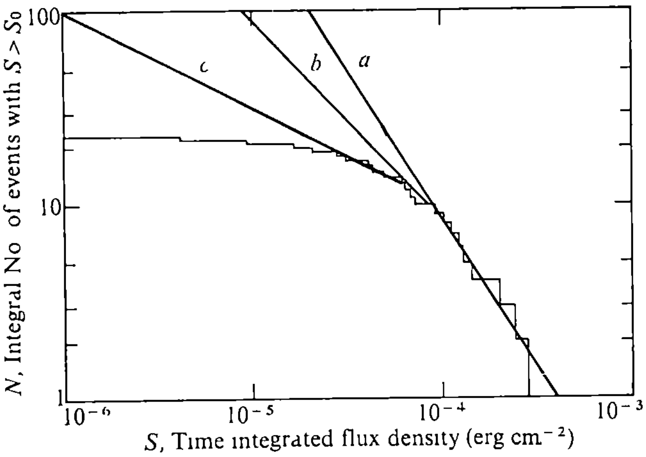

Fig. 3 A plot for 23 γ-ray bursts, detected by the Vela satellites, of the number of sources, $N(S)$, with an energy flux S or greater, against S Vertical and horizontal scales are logarithmic a, Expected curve for sources distributed uniformly throughout a volume (−3/2 law), b, source distributed uniformly over a plane (−1 law), c, sources distributed uniformly along a line (−1/2 law) (All this assumes that the detector is sensitive to infinitely small fluxes, that is, no threshold effects are present)

not conclusive, but they did report that there seemed to be a deficiency of smaller bursts—less than the number predicted by an $\alpha \approx 3/2$ If log $N(S)$ is plotted against log S for the bursts detected by the Vela satellites, the curve of Fig 3 is obtained It was at first assumed that threshold effects in the detector trigger logics could explain the break away from the −3/2 power law below $\sim 10^{-4}$ erg cm^{-2}, but a more careful examination of the problem now suggests that the deviation is mostly real If the sources are Galactic the log $N \sim$ log S curve (less a multiplicative constant) can be predicted from a simple count of, for example, O-associations or H II regions, which would have a similar distribution The resultant curve matches well the observed curve of Fig 3 down to $S \approx 3 \times 10^{-5}$ erg cm^{-2}, where the trigger threshold effects begin to predominate The curve below $\sim 7 \times 10^{-5}$ erg cm^{-2} actually follows a line with α less than 1, but above 1/2 This is partly a result of the narrowness of the spiral arms and partly because of reduced stellar density further from the Galactic centre

Two γ-ray bursts, events 71–2 and 72–2 (see ref 2) each had one of their two possible source directions very close to that of Cygnus X-1 (I B Strong, *et al*, unpublished) If this tentative identification is correct it agrees well with the argument for a Galactic origin The distance, 2 5 kpc, is about a factor of three greater than may have been expected, but if γ-ray bursts do originate in binary systems of the Cygnus X–1 type (a possible black hole?) it may be that Cyg X–1 itself is a particularly luminous member of its class

In conclusion, we warn against the automatic assumption that all the γ-ray bursts have similar origins It may be so, but we are really discussing cosmic X-ray and γ-ray emission processes of brief duration and there may well be more than one such process Also, although we consider the argument for a galactic origin to be sound, there may be a small proportion of extra galactic events included in the data

This research was performed as part of the Vela Satellite Program, which is jointly sponsored by the US Department of Defense, and the US Atomic Energy Commission The program is managed by the US Air Force, and satellite operations are under the jurisdiction of the Air Force Satellite Control Facility, Sunnyvale, California

Gamma radiation from the Crab Nebula above 35 MeV

OBSERVATIONS of electromagnetic radiation from the Crab have been made to at least 1 GeV (ref 1) and possibly as high as 10^{12} eV (refs 2 and 3) The Crab is unique among strong X-ray sources in that the major component in the low energy range (1–10 keV) shows little or no temporal variation A small ($\lesssim$ 10% at 10 keV) pulsed component from NP0532 is observed in the X-ray region, but its strength relative to the constant component increases with increasing X-ray energy Gamma ray observations of the Crab in the 15–100 MeV range have yielded rather uncertain results with reported upper limits[4,5] and fluxes[6-10] in apparent or near conflict As the reported intensities were just marginally detectable above atmospheric background with the balloon experiments which produced the observations, this seems understandable

Here we report observations of the Crab above 35 MeV made with the high energy gamma-ray telescope flown on SAS-2 The detector and technique have been described[11,12]

The data were obtained during the week of December 14–21, 1972 The Crab direction remained about 5° from the experiment axis for the entire exposure The absolute

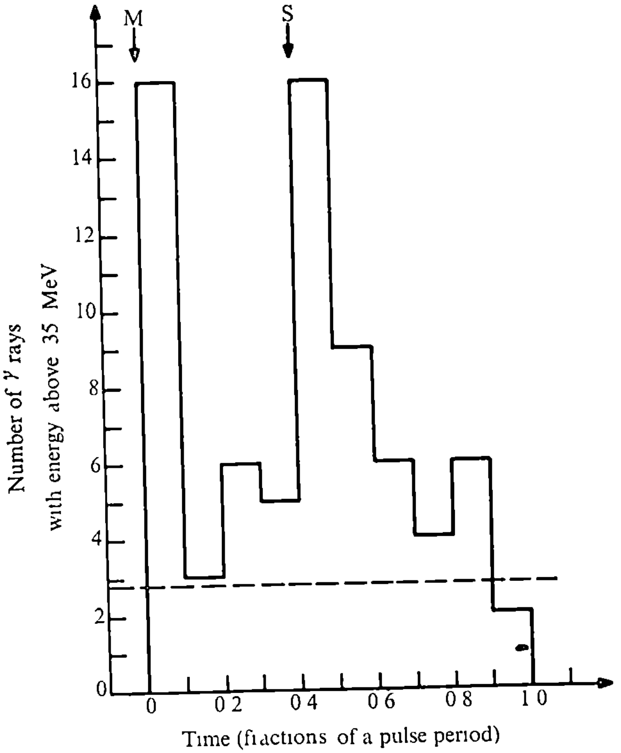

Fig 1 Distribution of γ-ray arrival time in fractions of a pulse period for γ rays above 35 MeV from the direction of NP0532 M and S refer to the predicted main and secondary pulse times as determined from radio observations (J M Rankin, private communication) — — —, background flux

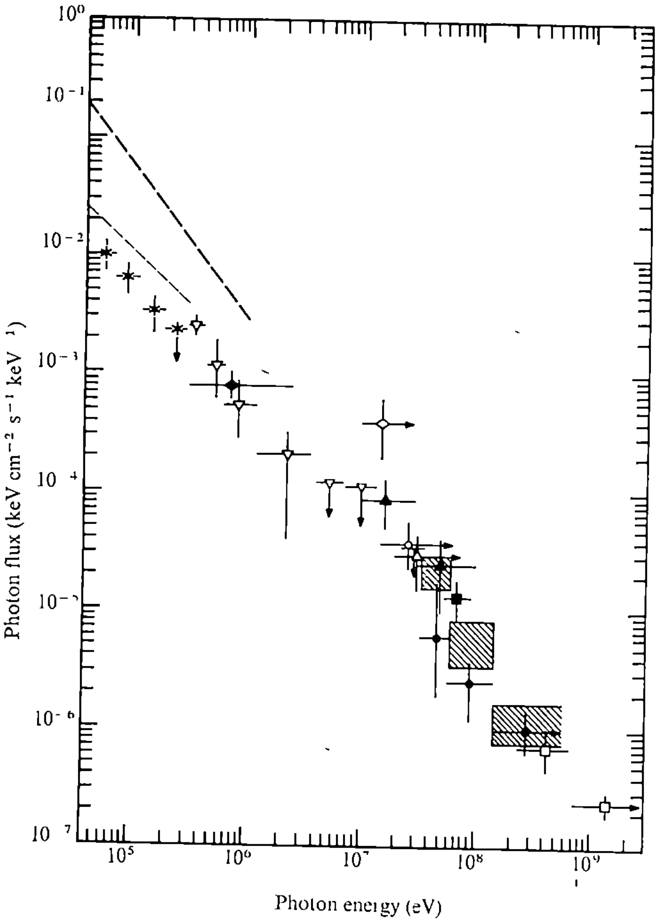

Fig. 2 Spectrum distribution of fluxes observed from the region of the Crab nebula ———, 0 7$E^{-0\ 9}$ pulsed flux[19], — — — 21 8$E^{-1\ 29}$ total X-ray flux[19], hatching, SAS-2 total flux, ●, SAS-2 pulsed flux, △, ref 17, □, ref 1, ○, ref 10, ▲, ref 7, ■, ref 6, open diamond, ref 8, △, ref 9, solid diamond, ref 18, ★, ref 14, vertical arrow, ref 5

timing accuracy of the SAS-2 satellite and the ground station was sufficient to allow separation of the pulsed component Because of the finite angular resolution of the SAS-2 detector, an angular cone of acceptance for γ rays must be included in the final analysis We used a 6° cone for γ rays with measured energies from 35 to 100 MeV and 4° for energies above 100 MeV Appropriate account was taken of the portion of the flux which is calculated on the basis of the known detector angular resolution to fall outside these circles

The arrival time of each γ ray was compared to the radio pulse time using predicted pulse arrival times (J M Rankin, personal communication) and derived as described in ref 13 (Fig 1) An independent timing analysis was made using a program based on a pulse prediction program (D C Backer, personal communication)

Peaks occur at both the positions of the main and secondary radio pulses, and there is a constant component above the general background from the Crab region Although the statistics are limited, the probability of finding by chance 16 γ rays in a bin where a peak was predicted, when the average based on the eight bins where no peak was expected is five, is less than 10^{-4} The probability of finding peaks of the observed size in both bins is then extraordinarily small As the absolute timing uncertainty for SAS-2 was about 1 ms, selecting markedly smaller intervals of time than those shown in Fig 1 does not produce peaks of increased significance

The total flux of γ rays above 35 MeV is estimated to be $(15\ 8\pm4\ 2)\times10^{-6}$ photons cm^{-2} s^{-1}, and that of the pulsed component, using bins 1 and 5 only (Fig 1) is estimated at $(6\ 2\pm2\ 8)\times10^{-6}$ photons cm^{-2} s^{-1} The total flux above 100 MeV is $(3\ 2\pm0\ 9)\times10^{-6}$ photons cm^{-2} s^{-1}, and the pulsed component above 100 MeV is $(2\ 2\pm0\ 7)\times10^{-6}$ cm^{-2} s^{-1} These results are shown in Fig 2, along with data from other experiments The unpulsed component seems to become a progressively smaller fraction of the total flux as the energy increases Above 140 MeV, only a 95% confidence upper limit of $0\ 7\times10^{-6}$ photons cm^{-2} s^{-1} can be set for an unpulsed component, whereas a finite flux of $(1\ 30\pm0\ 46)\times10^{-6}$ photons cm^{-2} s^{-1} was seen for the pulsed component The situation contrasts markedly with the low energy X-ray region, where only 10% of the radiation is pulsed (ref 14)

The most striking feature of the spectral distribution of the electromagnetic radiation from the Crab between 10^{4} and 10^{9} eV, is the shift from a predominantly unpulsed total flux at the lower energy, to one which is predominantly pulsed The spectral shape of the pulsed emission, although only poorly known, can be approximated by a power law with an energy spectral index of $\alpha\sim1$ to about a GeV Qualitatively, this picture is consistent with the Shklovsky[15] model of synchrotron emission from the speed of light cylinder with a steady flux of much lower energy photons from the region of smaller field With a magnetic field in the Nebula between 10^{-4} and 10^{-3} gauss electrons must be accelerated up to 10^{12}–10^{13} eV to produce γ rays in the 100 MeV energy region Such electron energies have been predicted in models of particle acceleration for the Crab pulsar

It is interesting to compare the γ-ray results discussed here with those for the Vela region reported by Thompson *et al*[16] The γ-ray fluxes from the two regions above 100 MeV are nearly equal, the Vela flux is $(5\ 0\pm1\ 2)\times10^{-6}$ photons cm^{-2} s^{-1} But the Crab spectrum in the γ-ray region seems to be a simple extension of the X-ray spectrum, whereas in the case of the Vela source the γ radiation is quite hard and substantially larger than an extension of the X-ray spectrum to that energy region The Vela intensity and spectra are consistent with the γ radiation being the result of about 3×10^{50} erg of cosmic-ray nuclei from the Vela supernova interacting with the local matter

It is not inconsistent with the data, for the Crab supernova also to have released a few times 10^{50} erg of cosmic rays, because as it is about four times further away, the γ radiation from cosmic-ray interactions would be approximately 16 times less intense, assuming the local matter density is not grossly different from 1–2 nuclei cm^{-3} The γ-ray intensity near 100 MeV from supernova nucleonic cosmic rays then, would be more than an order of magnitude less than the pulsed radiation at the present time

So, a consistent picture of the present data ascribes a very different origin to the γ-ray intensity from the Crab to that from Vela, with the Crab γ radiation resulting from the same mechanism responsible for the X-ray emission, and the Vela γ radiation resulting from the nucleonic component of the cosmic rays interacting with the local matter

We thank J M Rankin of the University of Iowa, and Robert Payne of the Arecibo National Astronomy and Ionosphere Center, for providing NP0532 predicted pulse arrival times We also thank D C Backer of GSFC for assistance in the development of timing programs

Gamma-ray bursts from neutron star glitches

THERE is no lack of proposed explanations for gamma-ray bursts A large amount of observational facts and theoretical arguments has been assembled recently[1] The basic facts are

- The occurrence, several times every year, of short bursts of high energy photons These events last ~ seconds and cover the spectral range between keV up to about 1 MeV
- The total flux at the earth is roughly between 3×10^{-6} erg cm^{-2} and 5×10^{-4} erg cm^{-2}
- The bursts consist of distinct components, often two in each event The time interval between components ranges from about 1 s up to about 30 s (a much more rapid intensity variation exists within each component)
- The angular distribution is roughly consistent with isotropy

The sources are either extragalactic or fairly local (say, within a few hundred parsecs) An analysis of the data now available yields a relationship for the 'number of courses as a function of intensity' which has been interpreted as favouring a local origin[2]

Here we propose that the cosmic gamma-ray bursts arise from the very abundant population of old, slowly spinning neutron stars which are no longer observable as pulsars It is supposed that the bursts are emitted because of magnetospheric activity related to glitches

The number density of defunct pulsars in the solar neighbourhood has been estimated to be around 3×10^{-2} pc^{-3} (ref 3) An order of magnitude more of these objects would still be compatible with the Oort limit 0 2 M⊙ pc^{-3} Within 10 pc one can expect 10^2 and possibly 10^3 old neutron stars

A typical burst of order 10^{-4} erg cm^{-2} implies a source power 10^{34} R^2_{pc} erg (R_{pc} is the distance in parsecs) The observed frequency of several events per year and their intensities are compatible with the number of defunct pulsars if each of them emits, say, 10^{35} to 10^{36} erg every 10 to 100 yr

This possibility is suggested by recent observations of period irregularities in old pulsars R Manchester and coworkers have monitored half a dozen pulsars during four years and have definite evidence for two irregularities ('glitches') In the first case (PSR1508 +55) they have found a glitch of relative magnitude $\delta=\Delta\Omega/\Omega\gtrsim2\ 2\times10^{-10}$ (ref 4), in the other case (PSR0329+54) the glitch is of order $\delta\simeq1\ 8\times10^{-10}$ (Manchester, private communication) These observations suggest a rough figure of about one glitch per pulsar every 10 to 20 yr

A considerable fraction of the energy released in a glitch probably causes a sudden change of the magnetospheric fields and leads to the production of fast particles How much energy is actually released is, however, model dependent If a glitch is a sudden change in stellar shape caused by internal relaxation processes the stellar magnetic field (well anchored in the conducting surface) will change by an amount $\Delta B=\delta\, B$ This will give rise to an induced electric field in the conducting magnetosphere, to Alfven waves and to particle acceleration The total energy release is of the order $\delta\,(\mathrm{B}^2{}_0/4\pi)(4\pi/3)R^3$ Typical parameters $R=10$ km $B^2{}_0=10^{26}$ erg cm^{-3}, $\delta=2\times10^{-10}$ correspond to an energy release around 10^{34} erg Note, however, that this is a lower limit because some surface rearrangements can alter B without changing the stellar moment of inertia

In alternative models the glitches are caused by magnetospheric instabilities and the energy release can be much larger

In this type of model the maximum glitch would have a magnitude[5]

$$\delta_{\mathrm{max}}=(\Delta\Omega/\Omega_{\mathrm{max}})\simeq(B^2{}_0\,R/M\Omega^2)$$

A glitch of intensity δ would release an energy of the order

$$(\delta/\delta_{\mathrm{max}})\,B^2{}_0\,R^3\simeq\delta M\,R^2\Omega^2$$

If $\delta=2\times10^{-10}$, $P=6$ s, a typical neutron star would release about 4×10^{35} erg

If the magnetic field is around 3×10^{12} gauss and $\delta=2\times10^{-10}$ the induced electric field is sufficient to impart relativistic energies to the magnetospheric particles Indeed

$$\int E\,\mathrm{d}t=R/c\ \Delta\ B\simeq10\ \mathrm{V\ cm^{-1}\ s}$$

The energies which can be reached are clearly insufficient to radiate high energy photons through the curvature radiation mechanism On the other hand, any amount of energy pumped into motions transverse to the field lines will be radiated away Low energy electrons radiate near the Larmor frequency—field measured in units of 10^{12} gauss) Relativistic electrons they emit photons $\mathrm{k}h\nu\simeq10\,B_{\perp,12}$ eV ($B_{\perp,12}$ is the perpendicular could easily emit gamma rays These high energy photons, however, would not be able to escape from the star surroundings if their energy ε (in MeV) satisfies the relationship $\varepsilon\ B_{\perp,12}\gtrsim4$ (they would instead give rise to electron–positron pairs)

If the bursts arise near the neutron star surface and the emission is not highly collimated with the field lines, our model naturally accounts for the spectral range covered by the bursts and predicts a sharp cutoff around 1 MeV

Pulsars turn off after their periods lengthen to about 3 s, at a typical age $t\simeq10^8$ yr If the torque remains unchanged, then $P\propto$ (age)$^{1/2}$ and the dead pulsars should have periods in the range from 3 to 30 s (most of them will have the slowest rotation) If, however, the braking and the radiation mechanisms are associated, (for instance if both of them result from the current flow through the polar surface) most dead pulsars would have periods not much greater than that at turnoff

These considerations suggest a possible interpretation of the time structure of the bursts If the emission arises in a specific sector of the magnetosphere and the activity lasts longer than one rotation period, then the bursts can be expected to disappear from our view because of rotation and should reappear some time later (say, 1 s up to about 30 s later) If there were no evolutionary effects in the active region there would be an exact periodicity for the repetition of pulse groups within an individual event In real life such an explosive phenomenon is likely to be accompanied by spreading and motions of the active region this would prevent genuine periodicities Rotation could also introduce other horizon effects and possibly explain why some bursts are detected not during their rise but when they already have peak intensity

Finally, we note that the neutron star model for bursts can potentially suggest the presence of two characteristic time scales The first is in the millisecond range and represents the time for an Alfven wave to cross the magnetosphere The other is roughly around 10 s, the time needed by an Alfven wave to cross the star interior

It is easy to see that the lack of gamma-ray bursts in coincidence with the glitches in the Vela and in the Crab pulsar does not pose a serious problem for our model Indeed, because of the very large distance of these sources, a gamma-ray burst would have been detected only if the power was enormously greater than in the other cases It is of obvious interest to monitor the timing of nearby pulsars this could give hope of detecting a coincidence between glitches and gamma bursts

To conclude, we note that there is no reason to exclude the possibility of glitches in neutron stars also occurring when they accrete mass from a nearby companion It is then possible that some X-ray binaries may emit gamma-ray bursts If Cyg X-1 is confirmed to be a source of bursts (I Strong, private communication) our model would require the accreting object to be a neutron star rather than a black hole

Pulsed 10–30 MeV gamma rays from PSR0833-45

Of the more than 100 known pulsars the one in Vela, PSR0833-45 is the most like the Crab pulsar in many of its characteristics It has the second shortest period (89 ms), the second largest d*P*/d*t*, undergoes sudden 'glitches' or decreases in its period[1] and is associated with a known supernova remnant[2] The many optical searches for pulsed radiation have so far been negative[3] In the X-ray region a positive result was reported for 0 5 to 1 5 keV but 29 ms earlier in phase than the radio frequency pulse[4] At 23 to 80 keV evidence was found for pulsed emission with a period 155 ns different from the radio period[5] Later X-ray observations have not detected any pulsed radiation[6–8] Observations from Uhuru show an X-ray source at this position[9], but the time resolution was too long to detect pulsing Grindlay *et al*[10] have reported a possible indication of pulsed emission above 3 × 10^{11} eV

Here we report detection of pulsed emission from PSR0833 at 10–30 MeV A sharp peak is observed coincident with the radio pulse There is also some evidence for precursor emission

The balloon-borne spark chamber detection system is the same as used earlier for the detection of γ rays from NP0532 (ref 11) On flight 571 from Longreach, Queensland, on November 16, 1972, Vela was observed[12] from 1620 to 2320 UT An azimuthal orientation system kept the spark chamber axis pointed south at a zenith angle of 35° The timing system was essentially the same as used previously except for a telemetry transmitter with a narrower passband, which caused a greater uncertainty in absolute time An on-board clock was synchronised with the ground station several hours before launch and read out for each spark chamber event The synchronisation was continuously monitored during the seven hour observation by checking the phase of the on-board clock one pulse per second against the station clock Loran-C sky wave transmission (100 kHz) from the Yap Island station was used to monitor the absolute time of the ground station clock to 0 1 ms VNG broadcasts from Lyndhurst, Australia, gave a check at 1 ms accuracy All the timing signals were recorded on analogue tape Estimated errors in the timing of events are a systematic offset of ±0 7 ms due to the instrumentation involved in comparing the on-board and ground station clocks, and a random error of ±0 3 ms for

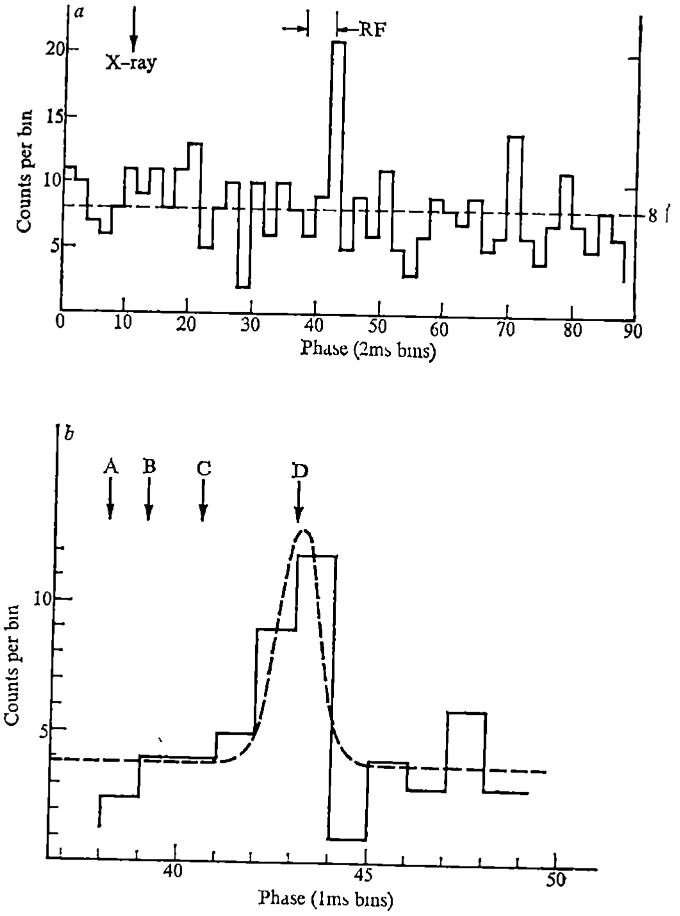

Fig 1 *a*, Phase plot of the 10 to 30 MeV γ rays from within 15° of PSR0833–45 The X-ray phase is the observation of Harnden and Gorenstein[4] *b*, Expanded phase plot of radio frequency and γ emission region showing radio timing markers A, 10% amplitude, leading edge, B, 2,388 MHz peak, C, 8,415 MHz peak, D, 10% amplitude, trailing edge ———, Maximum likelihood Gaussian (1 2 ms FWHM) the time of a given event, due to a combination of the clock 1/8 ms quantisation, uncertainty in balloon position, and variations in the electronics

Figure 1*a* shows the phase plot in 2-ms bins of the 357 events from within 15° of PSR0833 which originated in the bottom five conversion plates of the spark chamber during the 7-h exposure to Vela The Parkes group (unpublished work) monitored the pulsar during the week of the balloon flight and provided period and phase data at intervals of 12 min for the given time and location of the balloon The Parkes' phase refers to the arrival time of the half-power point of the sharp leading edge of the 1,400 MHz pulse extrapolated to infinite frequency using the dispersion measure 2 8658×10^5 s MHz^2 The absolute error on this phase is ±1 ms P Reichley of JPL made similar observations and his period predictions are within several ns of Parkes' periods The JPL phase marks the peak of the 2,388-MHz pulse The 1-ms lag of the JPL phase is consistent with the shape of the radio pulse observed at these frequencies and the reference points on this pulse chosen by the Parkes and JPL groups

At 5,000 MHz the pulse becomes double peaked (M M Komesaroff *et al*, unpublished) with a separation of ~1 8 ms between the peaks For 8,415 MHz, the later peak dominates[13] and the early peak disappears into a slight plateau region in the early part of the pulse Thus, the situation is more complicated than with NP0532 where the main pulse is a single sharp peak in the RF and maintains the same qualitative shape up through the infrared, visible and X-ray regions

Figure 1*b* shows the various timing points in more detail The maximum likelihood fit of the Gaussian shape to our unbinned data gives a peak position at 43 1 ± 0 3 ms and a width (FWHM) of 1 2 ± 0 5 ms In Fig 1*b* this comes at the 10% amplitude point on the trailing edge of the radio pulse The combined absolute timing errors do not preclude the γ-ray peak from being in phase with the 8,415-MHz pulse

The statistical significance of the peak at 42 to 44 ms in Fig 1*a* may be assessed from the following With the mean of 8 1 events per bin the chances of getting 21 or more events per bin from a random distribution during the time of radio emission (~ 6 ms) is 1 in 3,000 The statistical significance of the peak is even greater if one chooses narrower bins as suggested by the 1 2 ms width of the peak from the unbinned maximum likelihood analysis The peak is present only when events with directions near PSR0833 are chosen, and only when analysed with the unique period and change of period of PSR0833, which lends support to the identification of the peak at 43 ms as γ-ray emission from PSR0833

A further test of the reality of the effect and determination of emission against the phase of PSR0833 may be obtained by referring to the directional data The events from the lower five plates show a 2 5σ excess (independent of the phase of the events) at the position of PSR0833 This excess is modulated by the phase of the events If one takes only events with phase 0–44 (time referenced as in Fig 1*a*) the excess is 3 6σ For phase 44–88 there is no excess (101 compared with 99) We note that the Harnden and Gorenstein observation[4] of X-ray emission at ~ 1 keV occurs 29 ms before the radio emission (phase = 11 ms in Fig 1*a*) Although we see no significant narrow pulse at this position, the phase plot of Fig 1*a* has 179 events for phase 0–42 and 150 for the background phase

Thus, the 10 to 30 MeV pulse structure from Vela has similarities to that of the Crab Each shows a sharp spike ~1 ms in width coincident with the radio pulse When the poor statistics γ-ray data for the Crab are combined[15], there is evidence for about 15 ms of enhanced emission following the main pulse when compared to the next 15 ms For PSR0833 our data raise the intriguing possibility that a similar enhancement occurs for the 40 ms before the main peak

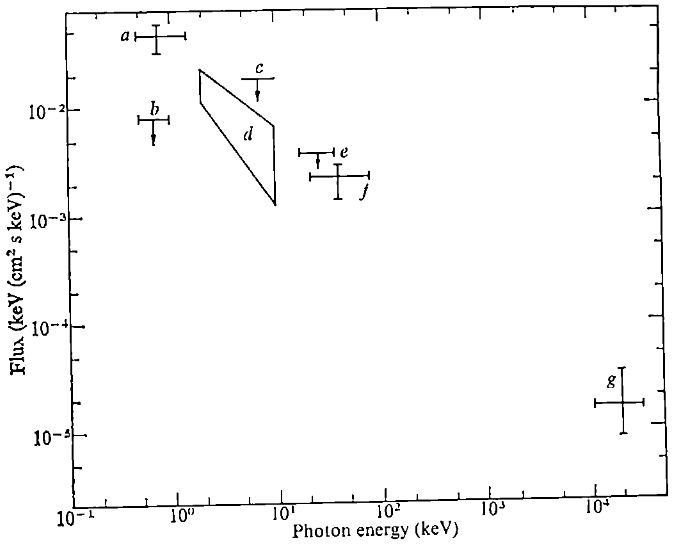

Fig 2 Spectral data on time averaged flux from PSR0833-45 above 0 5 keV All the points and upper limits are pulsed measurements except Uhuru (ref 9) *a*, ref 4, *b*, ref 8, *c*, ref 6, *d*, Uhuru[9], *e*, ref 7, *f*, ref 5, *g*, present work

The flux in the main peak to within a factor of two is 1 5×10^{-5} MeV cm^{-2} s^{-1} MeV^{-1} at 20 MeV compared to our result of (6±3)×10^{-5} MeV cm^{-2} s^{-1} MeV^{-1} for NP0532 Sturrock[14] predicts a $T^{-4\ 25}$ dependence for the γ-ray luminosity of the pulsar on its period, that is L(Crab)/L(Vela)= 68 Taking the Crab[16] and Vela[2] distances as 2 0 and 0 5 kpc our measurement is 64±32 (The intensity ratio is known more accurately than the absolute intensity of either source and its uncertainty arises primarily from the statistics and the threshold setting of the Čerenkov detector) It will be of interest to test further the Sturrock period-luminosity dependence by searching for γ-radiation from other short period pulsars with the COS-B satellite to be launched next year or the larger area balloon detectors now under construction

Figure 2 shows the existing results on the PSR0833 energy spectrum They are consistent with the spectral index of −0 9 observed for the main pulse of the Crab over the same energy range[11], but not with the −0 5 dependence predicted by Sturrock for electron polar zone radiation[14] If the excess in bins 0–42 (Fig 1) represents an actual pulsed component, the total pulsed emission (to within a factor of two) would be 4×10^{-5} MeV cm^{-2} s^{-1} MeV^{-1} at 20 MeV

Collimation of auroral particles by time-varying acceleration

IT is generally accepted that charged particles aligned with the magnetic field, which occur in some forms of auroral precipitation[1-4], are collimated within a few thousand kilometres of the Earth's surface, by an acceleration parallel to the geomagnetic field Static electric fields are thought to provide this acceleration, and various modes of injection of charged particles have been invoked to account for the details of observed energy spectra and angular distributions[1-4] A time-varying acceleration of an incident stream of charged particles, provides an alternative explanation

We assume that the incident stream of charged particles has a Maxwellian energy spectrum Such spectra are commonly observed in the plasma sheet[5]—the probable source of most auroral particles—and the energy distributions of auroral particles often resemble accelerated Maxwellian distributions We also assume that the intensity of the incident particles is isotropic, and that there are no upward-moving particles The intensity at energy E_1 and pitch angle α_1, is then

$$J_1(E_1, \alpha_1)=A(E_1/E_0)\exp[-E_1/E_0] \text{ for } 0\leqslant\alpha_1\leqslant 90^\circ \qquad (1)$$
$$=0 \qquad \text{for} \quad \alpha_1>90^\circ$$

where A is a constant, and E_0 is the energy equivalent to the temperature of the Maxwellian distribution

We shall first consider the energy, Δ, gained by a particle traversing an acceleration region to be constant, positive and independent of energy The energy E_2, and intensity, $J_2(E_2, \alpha_2)$, of the same particles measured at a detector beyond the region, follows from the energy gain and conservation of phase-space density, along a trajectory (ref 6, and E C Ray, unpublished) Thus

$$E_2=E_1+\Delta \qquad (2)$$

and

$$J_2(E_2, \alpha_2)/E_2=J_1(E_1, \alpha_1)/E_1 \qquad (3)$$

The pitch angle, α_2, follows from an assumed conservation of magnetic moment

$$(E_2\sin^2\alpha_2)/B_2=(E_1\sin^2\alpha_1)/B_1 \qquad (4)$$

where B_1 is the magnetic field strength where the particles enter the acceleration region, and B_2 is the magnetic field strength at the detector Combining equations (1)-(4) we have

$$J_2(E_2,\alpha_2)=A(E_2/E_0)\exp[-E_2/E_0]\exp[\Delta/E_0] \text{ for } \alpha_2\leqslant\alpha_c \qquad (5)$$
$$=0 \qquad \text{for } \alpha_2>\alpha_c$$

$$\text{where} \quad \sin^2\alpha_c=(B_2/B_1)(1-\Delta/E_2) \quad \text{for } \Delta\geqslant E_2(1-B_1/B_2) \qquad (6)$$

$$\text{and} \quad \alpha_c=90^\circ \qquad \text{for } \Delta\leqslant E_2(1-B_1/B_2)$$

These results have been discussed in detail by several authors (refs 1–3, and F W Berko, and R A Hoffman, unpublished), and the main features are that accelerated particles have energies of Δ or more, and are confined to pitch angles of α_c or less, the intensity being independent of pitch angle in this range Equation (6) shows that α_c increases with increasing E_2 and B_2/B_1, and that maximum collimation ($\alpha_c=0$) occurs for particles of energy Δ Some particles back-scattered from the atmosphere would be reflected in the acceleration region and contribute to the emerging stream energies and pitch angles 'forbidden' to the particles which have traversed the region[13]

As an alternative to constant acceleration, we postulate that Δ varies with time, with the probability of occurrence, $P(\Delta)$, of a particular value given by the normal distribution

$$P(\Delta)=(1/\sigma\sqrt{2\pi})\exp[-(\Delta-\mu)^2/2\sigma^2] \qquad (7)$$

where μ is the mean value of Δ, and σ the standard deviation We assume that significant changes occur in Δ within the resolving time of our detector (10^{-2} s) so that only an average effect is observed The time scale of changes in Δ must, however, be greater than the local gyroperiod (near the Earth $\sim 10^{-6}$ s for electrons) for the magnetic moment to be conserved Similar considerations apply to the scale size If changes in Δ were accompanied by scattering, phase-space density would not be conserved and a different treatment would be required For this analysis we assume, however, that equations (3) and (4) are valid, so that the observed intensity, $J_2(E_2,\alpha_2)_{obs}$ is the average of $J_2(E_2,\alpha_2)$, given by equation (5), for all values of Δ

$$J_2(E_2,\alpha_2)_{obs}=A(E_2/E_0)\exp[-E_2/E_0] \int_{-\infty}^{\Delta m}\exp[\Delta/E_0](P(\Delta))\mathrm{d}\Delta \qquad (8)$$

where $\Delta_m, =E_2(1-(B_1/B_2)\sin^2\alpha_2)$, is the largest value of Δ making a nonzero contribution to the integral, which follows from equation (6) Substitution for $P(\Delta)$, and integration gives

$$J_2(E_2,\alpha_2)_{obs}=\tfrac{1}{2}A(E_2/E_0)\exp[-E_2/E_0]\exp[\mu/E_0+\sigma^2/2E_0{}^2](1+\operatorname{erf} x) \qquad (9)$$

where

$$x=[(E_2/E_0)(1-(B_1/B_2)\sin^2\alpha_2)-(\mu/E_0+\sigma^2/E_0{}^2)]/2(\sigma/E_0) \qquad (10)$$

When $\mu=0$ and $\sigma=0$ the particle stream is unchanged as equation (9) reverts to equation (1), when μ is nonzero and $\sigma=0$, equation (9) reverts to equation (5), the equation for acceleration by a static electric field On putting $\mu=0$ with σ nonzero, random fluctuations in Δ produce a net change in intensity, but in this case equation (9) does not revert to equation (5) Equation (9) shows on inspection that the intensity increases monotonically towards smaller pitch angles (except when $\sigma=0$) for any value of E_2 A particularly interesting property of equation (9) is that the postulated fluctuations in Δ

can, under some circumstances, collimate both electrons and protons at the same time An increase of the ratio B_2/B_1 will reduce the degree of collimation

Using a sounding rocket flown during the expansion phase of an auroral substorm, we observed electrons collimated towards the direction of the local geomagnetic field Electron energy spectra were measured three times per second over the range 0 5–10 keV, within a pitch angle range 5°–25° scanned in a 12-s period In addition, electron intensities at 6 keV were measured every 10^{-2} s, within a pitch angle range of 20°–70° scanned every 2×10^{-1} s Electron intensities were found consistently to increase monotonically towards small pitch angles at energies both above and below the peak of the energy spectrum

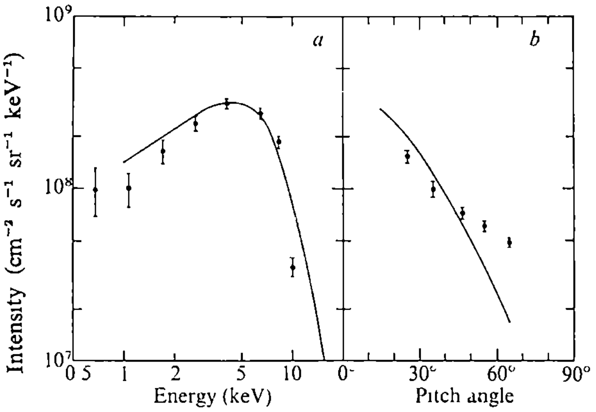

Fig 1 *a*, Energy spectrum at a pitch angle of 20°, *b*, simultaneous pitch angle distribution at 6 keV Measurements taken at 20 11 24 UT, on November 22, 1971, at an altitude of 135 km, using ESRO sounding rocket C78/2, launched from Kiruna, Sweden Curves predicted using equation (9), with parameter values $\mu=0$ keV, $\sigma=4$ keV, $E_0=1$ keV, $A=8\times10^7$ cm^{-2} s^{-1} sr^{-1} keV^{-1}, $B_2/B_1=1$ 33 The ratio B_2/B_1 was chosen assuming that acceleration took place within 700 km of the atmosphere

Figure 1*a* shows an observed energy spectrum, with a peak intensity at 5 keV and Fig 1*b* shows the simultaneously observed angular distribution at 6 keV, typically, the intensity increases monotonically towards small pitch angles Only 10% of the increase between 65° and 25° can be accounted for by atmospheric absorption This was evaluated using an identical payload in a control experiment performed under stable auroral conditions, and is consistent with calculations made by Walt[7] The absence of sharp changes in the slopes of the energy spectrum and angular distribution, together with collimation at energies below the peak of the energy spectrum are not readily accounted for by acceleration in a static electric field Either the 'back-scattered' particles would have to be collimated before reflection, which does not agree with observations[8,9], or charged particles would have to be injected or produced over a range of energies at all altitudes where the electric field was present[4] To account for our data, this injection or production would need to depend on altitude in a manner which has not been observed On the other hand, the angular distribution and energy spectrum predicted using preliminary values of the parameters in equation (9) provide promisingly good fits to the measurements shown in Fig 1*a* and *b* Equation (9) also predicts the observed collimation above and below the peak of the energy spectrum

We are unable to propose a physical mechanism which would result in the postulated distribution of the energy gained by particles A form of stochastic acceleration[10-12], or an acceleration by electric fields maintained by a time-dependent anomalous resistivity could possibly induce the effect This work was carried out as part of the research programme of the Appleton Laboratory

Anomalous lunar plagioclase composition and the composition of coexisting melt

THE anomalous composition of lunar plagioclases may be accounted for by various substitutions, principally the replacement by Fe and Mg, with some Ca and Na, of Al in tetrahedral sites in the lattice[1]

The composition of Apollo 11 and 12 plagioclases with less than 95% anorthite becomes increasingly anomalous as the ratio Ca/(Ca+Na) decreases (Figs 1 and 2 and ref 2)

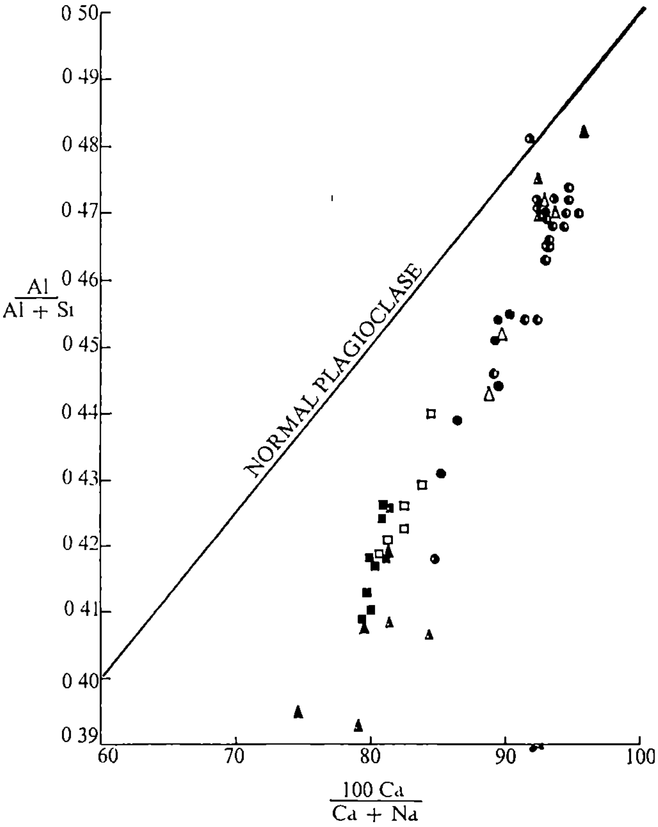

Fig 1 Al(Al + Si) against Ca/(Ca+Na) for Apollo 11 plagioclase ■, 10017 (this work), □, 10017 heated at 1,108° C for 17 h in Mo, f0_2 ≏ 10^{-13} bar (this work), △, 10045 (refs 9 and 10), ▲, 10022 (refs 11 and 12), ● ◑ ⊗, three lithic fragments in 10019*, ◐, lithic fragments in 10021*, ▲, 10062 (this work) *Analyst Mr P G Hill

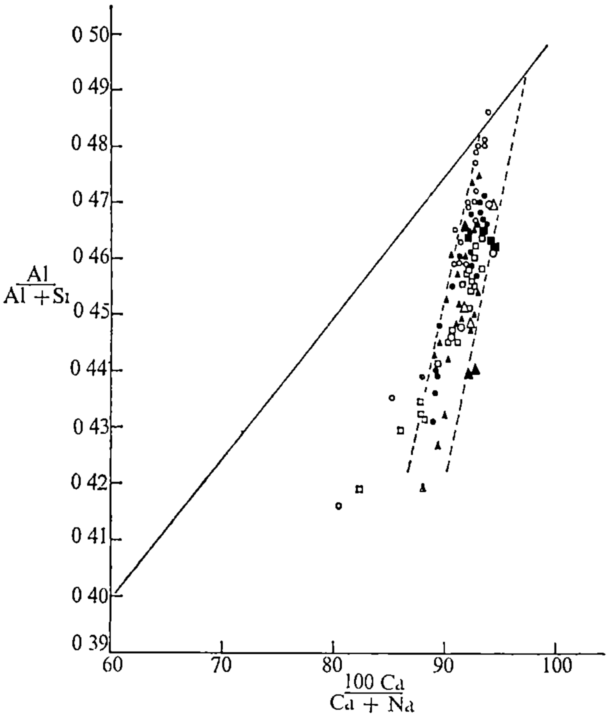

Fig. 2 Al/(Al+Si) against Ca/(Ca+Na) for Apollo 12 plagioclases △, 12040*, ■, 12040 heated at 1,149° C for 5 h in Mo, $fO_2 \simeq 10^{-12.5}$ bar (this work), ○, 12040 (this work), △, 12020 (this work), ○, 12040 (ref 13), □, 12051 (this work), ●, 12051 (ref 13), ▲, 12018 (ref 13) Plagioclases in rocks 12021 and 12004 (ref 13), 12063 (ref 14), and 12039 (ref 15), also plot within the area bounded by the dashed lines
*Analyst Mr P G Hill

Initially, the variation from the ideal composition is almost directly proportional to the albite content Rock 14310, in which all plagioclases, regardless of size or albite content, have nearly ideal compositions, (Fig 3) is exceptional Terrestrial groundmass and phenocryst plagioclases which have a similar Ca/(Ca+Na) ratio to lunar basalts, exhibit no compositional anomalies It is improbable that anomalous plagioclase is produced by the selective subsolidus volatilisation of alkalis in the lunar vacuum Plagioclase from a Reunion basalt showed negligible change in composition after heating for 1 week at 1,000° C *in vacuo* (10^{-7} torr) The relatively high albite content, and the complete exposure of the plagioclase surface to the vacuum in this experiment, would be more favourable to alkali volatilisation than is the case with lunar plagioclase, which has a generally low albite content and in which the surface of the plagioclase in the rock is either partially or totally covered

It has been suggested that one of the main factors influencing the composition of lunar plagioclase is the low viscosity of the melts which, combined with rapid cooling, gives rise to rapid disequilibrium crystal growth[1] Phase equilibria studies designed to re-equilibrate lunar plagioclases with coexisting melts indicate, however, that this is not the case Various lunar samples were heated within their melting intervals, and were then quenched rapidly (the conditions are indicated in the relevant figures) That had no effect on the anomalous nature of the plagioclase composition (Figs 1 and 2) Furthermore, there is no obvious correlation between the degree of compositional abnormality and rock texture[4] (Figs 1–3) which is assumed to reflect the cooling rate and, thus, the degree of supersaturation and rate of crystal growth

There is, however, a stong correlation between the variation from the ideal composition of lunar plagioclase and the compositions of the melts from which they crystallised This is particularly apparent with the Apollo 12 rocks (Fig 2) These show a similarity, regardless of the whole rock chemistry, between the compositions of the plagioclases and those of the coexisting melts (see Figs 3 and 4 and Table 5 of ref 3) Plagioclases with similar albite contents exhibit similar variations from the ideal composition The plagioclases from Apollo 11 rocks have not been as extensively investigated as those from Apollo 12 rocks but in support of my findings, the small number of determinations available in the literature indicates a similar correlation between the composition of the plagioclase and that of the coexisting melt[5] (Fig 1) The plagioclases in the low potassium–high titanium group of Apollo 11 rocks—10045, 10062, 10019/15, 10021/62—(refs 5–7), are similar in composition and in the degree of variation from the ideal composition, to the plagioclases from Apollo 12 rocks So in both cases there are similarities (if titanium is excluded) between the compositions of the melts which coexist with the plagioclases and the plagioclases themselves (Table 2 and analyses 6 and 11–13 of ref 5)

The maximum variation from the ideal composition corresponds to a deficiency of approximately 0.05 per unit formula in the Al+Si content, when the Ca/(Ca+Na) ratio is about 0.82–0.83 That is found in plagioclases of the high potassium–high titanium group of Apollo 11 basalts—10017 and 10022 (refs 6 and 7)—and in the rims of some plagioclases from Apollo 12 rocks—12040, 12051 It seems to be the maximum deficiency acceptable to the plagioclase lattice, because it does not increase further as the Ca/(Ca+Na) ratio continues to decrease The general trend with Apollo 11 and 12 plagioclases is, therefore, towards increasingly anomalous composition, reaching a limit in the Apollo 11 high potassium–high titanium basalts as the alkali content of the coexisting melts increases and the alumina content falls

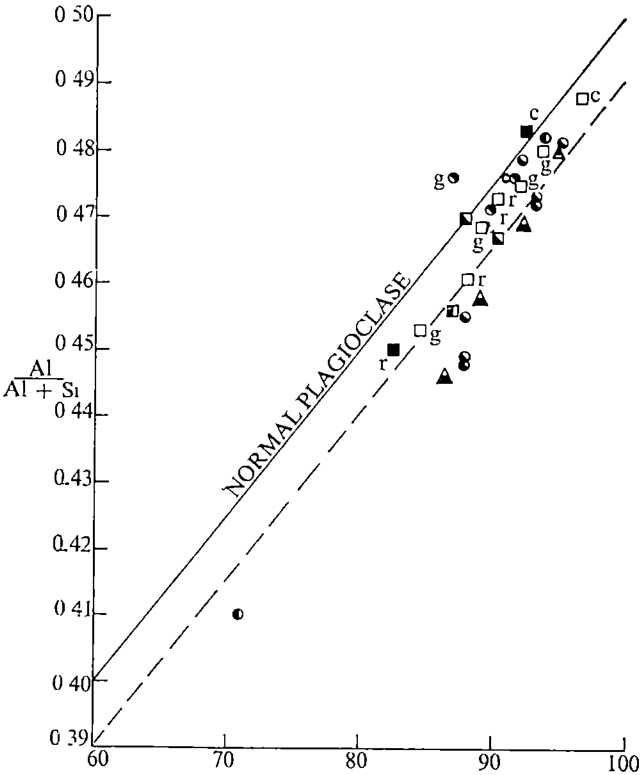

Fig 3 Al/(Al+Si) against Ca/(Ca+Na) for plagioclases in lunar rock 14310 ◐, Experimental[16], ▲, experimental[17], □, ◔, ■, ◩, ◧, ▲, plagioclase analyses from ref 18 c, Core, R, rim, g, groundmass, dashed line, maximum deviation from normal composition in terrestrial plagioclase

The importance of the alumina content relative to the alkali content of the coexisting melt in determining the degree of variation from the ideal composition is illustrated by rock 14310 The alkali contents of the melts which coexisted with the plagioclases in that rock are similar to those in Apollo 11 high potassium–high titanium basalts, but the alumina contents are much higher—30 weight % (ref 16) compared with 10 weight % (ref 5)—and the plagioclases have nearly ideal compositions (Fig 3)

If the composition of the melt is of primary importance in determining the plagioclase composition, then the same relationship should occur in lunar rocks 15555 and 15016, which have the same composition but sharply contrasted textures[8]

I have also considered whether anomalous plagioclase compositions could result because plagioclase hosts have been analysed together with submicroscopic inclusions of olivine, pigeonite, augite and silica, or liquid That would tend to increase Ca/(Ca+Na) ratio relative to the Al/(Al+Si) ratio and so the composition would vary from the ideal The areas of the plagioclase crystals which I have analysed were, however, microscopically free of inclusions If submicroscopic inclusions of olivine, pigeonite, augite or liquid are present then the extent of the compositional variation should be proportional to the Ti content of the plagioclase, which should increase as the composition becomes less ideal This was not observed Inclusions of a silica phase are unlikely to be present

The anomalous composition of lunar plagioclases probably reflects the nature of the structural groups and, therefore, the activities of the ions, particularly Al^{3+}, in the coexisting melts The influence of alkalis and/or water may be critical in this respect, and it is probable that their higher concentration in terrestrial melts is responsible for the ideal composition of terrestrial plagioclases In cases where the plagioclases have grown rapidly from melts, inherent abnormalities in composition may be exaggerated by disequilibrium crystal growth

I thank Professor M J O'Hara, Dr G M Biggar and Mr C E Ford for discussions Mr P G Hill supplied unpublished analyses of plagioclases in lunar sample 12040 and in lithic fragments from lunar samples 10019 and 10021 This work was supported by the Natural Environment Research Council

Earthquake prediction and oriented microcracks in rocks

VARIATIONS in the ratio of compressional wave velocities and shear wave velocities, presage some earthquakes[1] The ratio first decreases, but just before the earthquake it returns to, or rises above, the original value An attractive model has been proposed by Nur[2] Briefly, he suggested that anelastic expansion of the rock (dilatancy) reduced the velocities With the subsequent rise of the pore pressure of water, the velocity increases again The increased pore pressure also weakens the rock, resulting in an earthquake All that effects the velocity of compressional waves more than the velocity of shear waves, giving the apparent variation in their ratio

Aggarwal *et al*[3] have found, however, instances in which there are no observable variations in travel times before earthquakes They have also observed cases in which there was a clear decrease in velocity McEvilly and Johnson[4] found no variations in velocities before earthquakes in central California, although variations have been detected by Robinson *et al*[5]

In earthquake prediction it is important to understand the underlying reason for the contradictory findings Possibly, it is because of a lack of velocity anomalies in certain regions[3] McEvilly and Johnson[4] proposed that either the anomalous source regions for earthquakes on the San Andreas Fault in central California were too small, or the stress in these regions was below the level necessary to cause dilatancy Nur *et al*[6] suggested that the dilatancy hypothesis may not be applicable to strike-slip faults such as the San Andreas Although these suggestions offer useful explanations for particular cases I can suggest a unified explanation based on laboratory studies and theoretical predictions of the elastic properties of rocks containing oriented dilatant microcracks

Gupta[7] has reported experimental results on sound velocities and their ratios in a limestone subjected to anisotropic stresses oriented dilatant microcracks can be generated by clamping a rectangular specimen in one direction and increasing the difference in stress in the other two directions Gupta found little variation in sound velocities and their ratios along directions parallel to the cracks, but he found large variations perpendicular to that direction Anderson *et al*[8] showed theoretically that parallel to the microcracks the pore fluid has little effect on sound velocities and their ratios, but that it significantly affects these properties perpendicular to the microcracks

Nur *et al*[6] suggested that dilatant expansion of the crust occurs only in the direction perpendicular to the Earth's free surface That is because expansion in that direction is opposed only by gravity, whereas expansion in the horizontal directions is resisted by the surrounding rocks Although dilatancy in rock occurs at very high confining pressures, it is reasonable to expect that dilatant cracks in the crust would open predominantly in the direction of least resistance I assume the model of dilatant cracks lying parallel to the free surface of the crust The conflicting observation of the behaviour of the precursor, can then be explained

Figure 1 shows schematically a region of dilated crust with horizontal cracks, parallel to the Earth's surface Five cases are illustrated In case A, seismic waves are generated at a surface source which, together with a nearby seismic station, are located above the dilated region This situation is similar to one of the Blue Mountain Lake experiments[3] in which nearby road blasts were used as seismic sources The ray path for the seismic waves reaching the recording station penetrates the dilated crust at a shallow depth This is partly because of the surface location of the source and partly because of the anisotropy in velocity, that is, waves travelling in the horizontal direction are much faster than those in the vertical direction Therefore, the seismic rays are strongly diffracted upward Thus the waves follow a path nearly parallel to the Earth's surface, that is, parallel to the horizontal cracks So neither the seismic velocities nor their ratios will show much change as cracks open and close or as the pore pressure varies

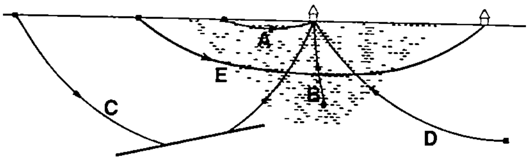

Fig. 1 Seismic rays travelling through a dilated crust Dilatant cracks are shown as broken lines parallel to the Earth's free surface A—E, see text

In case B (Fig 1), seismic waves are generated from small earthquakes in the dilated region beneath the recording station The seismic ray traverses the dilated region at a large angle to the alignment of the dilatant cracks Thus the opening and closing of cracks and changes of pore pressure in the cracks would have significant effects on the seismic velocities and their ratio The situation is similar to the Garm experiments and the Blue Mountain Lake experiments[1] Seismic rays arriving at the recording station may also traverse the cracks at a large angle to their alignment if the station is above the dilated region and if the waves are either refracted from a high velocity layer below the recording station as in case C (Fig 1) or if the waves are generated by small earthquakes outside the dilated region as in case D (Fig 1) The latter case is similar to the situations in the San Fernando earthquake of February 9, 1971 (ref 1) and the Bear Valley earthquake of February 24, 1972 (ref 5) In these cases (C and D) the velocities of seismic waves will be affected by the opening and closing of the dilatant cracks and by changes in the pore pressure in the cracks, but as the ray path in the dilated region is only a portion of the total traverse, the relative change in travel time will probably not be as pronounced as in case B Besides, in case D, the anomalous nature of source region may constitute an additional complication for the detection of the dilatant effect of the region Finally, in case E, both the recording station and the seismic sources are outside the dilated region Even though the seismic ray penetrates the dilated region it may traverse the region in a direction parallel to the alignment of the dilatant cracks Therefore, neither seismic velocities nor their ratio will show much change as cracks open and close, or as pore pressure in the cracks varies This case may be compared with the situation in the study of quarry-blast records in central California[4]

Crystal structure of I-tetragonal boron

THERE are three polymorphs of crystalline boron α-Rhombohedral boron is the simplest form It has only one B_{12} icosahedron, the basic building block in the unit cell of all crystals rich in boron The parameters of the unit cell are $a = 5\ 057$ Å, $\alpha = 58°\ 04'$, $Z = 12$

β-Rhombohedral boron has a more stable configuration, but the crystal structure is complex[2,3] The unit cell parameters are $a = 10\ 145$ Å, $\alpha = 65°\ 17'$, $Z = 105–108$

The crystal structure of the third polymorph, II-tetragonal boron, is not known, but its unit cell parameters are $a = 10\ 12$ Å, $c = 14\ 14$ Å, $Z = 192$

Here, we discuss a non-metal boride known as I-tetragonal boron, which was first prepared in crystal form in 1943 (ref 4), and which was subsequently believed to be a polymorph of elementary boron, we have accumulated results that show unequivocally that this is not the case The crystal structure of

*Standard deviations are given in parentheses

I-tetragonal boron has been discussed by Hoard *et al*[5], it has unit cell parameters $a = 8\ 75$ Å, $c = 5\ 06$ Å, $Z = 50$

We have prepared crystals of the non-metal borides $B_{48}B_2C_2$ and $B_{48}B_2N_2$, and have made precise electron density determinations of them

Quantum mechanical considerations, using the concept of closed shell type boron icosahedra[6], explain why elementary boron cannot be prepared in the I-tetragonal form Each boron atom has four valence orbitals, one 2s and three 2p In the LCAO approach the unhybridised set of 48 atomic orbitals of one B_{12} icosahedron can be combined into twelve equivalent outward pointing sp-hybrid orbitals and a set of 13 bonding and 17 antibonding molecular orbitals, separated by a substantial energy gap The latter set, with the 13 orbitals, lies mainly within the icosahedron, with strong bonding forces to the next borons on the icosahedral surface The 12 sp-hybrid orbitals are approximately perpendicular to the nearly spherical icosahedral surface, thus providing single radial sp-hybrid orbitals, each of which can form a strong σ bond between the icosahedron and the next icosahedron or any external group

To obtain a more stable crystal configuration two conditions have to be fulfilled First, to achieve a closed shell configuration, 38 valence electrons are required for each icosahedron The 12 boron atoms can, however, contribute only 36 electrons and the additional electrons have to come from intericosahedral atoms Second, to form covalent bonds, the 12 sp-hybrid bonds must find atomic orbitals close enough and in the proper directions

It is obvious, that the structure proposed by Hoard *et al*[5] with the composition $B_{50} = (B_{12})_4B_2$, cannot fulfil either of these requirements

We therefore used careful chemical preparative techniques to reproduce the crystals described by Laubengayer *et al*[4] These systematic investigations[7,8], however, yielded no results, and we concluded that it was impossible to prepare the I-tetragonal phase, $B_{48}B_2$, of elementary boron We did succeed however, in developing methods for producing the lattice of the I-tetragonal form, using pyrolysis of BBr_3–CH_4–H_2 mixtures on Ta substrates yielding boron carbides[9] This method is analogous to the method described by Laubengayer *et al* At 1,200° C a boron-rich tetragonal boron carbide of composition $B_{25}C$ (lattice constants $a = 8\ 722$ Å, $c = 5\ 080$ Å, with density $= 2\ 43$ g ml^{-1}) was deposited, and pyrolysis of BBr_3–N_2–H_2 mixtures on BN substrates at 1,400° C yielded a boron-rich tetragonal boron nitride of composition $B_{25}N$ (lattice constants $a = 8\ 646$ Å, $c = 5\ 127$ Å, with density $=$ 2 46 g ml^{-1}) (ref 10)

We have determined subsequently the single crystal structure of both the B–C and B–N phases (ref 10, and Will, G , and Kossobutski, K H , unpublished) With high precision intensity measurements we were able to determine absolute electron densities in the intericosahedral positions of the icosahedral framework using Fourier sections and least-squares techniques, reaching *R* factors of 5 8% and 5 5% for $B_{50}C_2$ and $B_{50}N_2$ respectively It was thus possible to localise and differentiate between carbon or nitrogen atoms and the single boron atoms, and to assign them to well defined sites in the icosahedral framework

The unit cell (Fig 1) contains 50 boron atoms and two carbon or nitrogen atoms Forty-eight boron atoms form four B_{12} icosahedra centred in the position 4(e) ($\frac{1}{4}\frac{1}{4}\frac{1}{4}$, $\frac{1}{4}\frac{3}{4}\frac{3}{4}$, $\frac{3}{4}\frac{1}{4}\frac{3}{4}$, $\frac{3}{4}\frac{3}{4}\frac{1}{4}$), which is in agreement with the crystal structure of Hoard *et al*[5] The remaining boron, carbon and nitrogen atoms take positions between the icosahedra in such a way that the already mentioned conditions for a stable crystal structure are fulfilled as closely as possible The resulting chemical formulae of the crystals are then $B_{48}B_2C_2$ and $B_{48}B_2N_2$

Within the icosahedra we found boron–boron distances of 1 774–1 859 Å in $B_{48}B_2C_2$, and 1 777–1 885 Å in $B_{48}B_2N_2$, with average B–B distances of 1 809 ± 0 004 Å and 1 808 ± 0 004 Å, respectively These are very similar to the values found in elementary boron[1,3], AlB_{10} (ref 11), C_4AlB_{24} (ref 12), and rhombohedral boron carbide, $B_{13}C_2$ (Will, G , and Kossobutzki, K H , unpublished)

Of the 12 icosahedral boron atoms, six form bonds with the next icosahedra, four of which have B–B distances of 1 67 Å ($B_{48}B_2C_2$) and 1 66 Å ($B_{48}B_2N_2$) Of the remaining six, two are bonded to carbon or nitrogen atoms in the position 2(b) ($00\frac{1}{2}$ $\frac{1}{2}\frac{1}{2}0$), respectively, with a B–C distance of 1 63 Å and a B–N distance of 1 59 Å, and four are bonded to two single boron atoms in the statistically occupied positions 8(i) and 8(h) The B–B distances to the atoms in 8(i) and 8(h) are 1 622 Å and 1 728 Å, respectively, for $B_{48}B_2C_2$ and 1 611 Å and 1 702 Å, respectively, for $B_{48}B_2N_2$

The 2(b) positions deserve special attention They form bridges with covalent bonding between four icosahedra These bridges are, however, occupied by carbon or nitrogen and not by boron atoms, as suggested by Hoard *et al*[5] The four icosahedra surrounding the C or N atoms form a flattened bisphenoid because the tetragonal *c*/*a* ratios are 0 58 and 0 59, respectively The boron atoms in the positions 2(a) merely fill interstitial holes They have no bonding functions

The main difference from former proposed structures is found in the two single boron atoms per unit cell—which give rise to the improvement of the electronic properties—and which are statistically distributed in the large tetrahedral holes around the positions 4(c) ($0\frac{1}{2}0$, $\frac{1}{2}00$, $0\frac{1}{2}\frac{1}{2}$, $\frac{1}{2}$) These tetrahedral holes measure about 3 4 Å in diameter and are therefore too large to accept just one bonding boron atom in a fixed position as a link between four icosahedra The borons are therefore displaced towards two of the next icosahedra, which finally yields a statistical distribution over 16 positions—8(i) and 8(h), (see Table 1) The displacement is about 0 6 Å from the centre The spatial situation easily permits such a displacement of atoms from the central position The geometrical bonding conditions in the icosahedral framework in fact force the borons to such displacements These additional atoms do, however, allow the conditions for a stable structure to be fulfilled to a very high degree

The attachment of carbon, nitrogen and boron atoms to the listed intericosahedral sites is unequivocal The quantitative occupations given in Table 1 were derived from least-squares calculations If, for example, carbon in (00½) is replaced by boron, the *R* index increases from 5 8% to 7 5%

Thus, the quantum mechanically unstable B_{48} lattice is stabilised by boron and carbon or nitrogen atoms yielding the compositions $B_{48}B_2C_2$ and $B_{48}B_2N_2$ The extra atoms fill holes in the tetragonal icosahedral framework Apart from electronic reasons the instability of the basic B_{48} lattice also results from geometrical problems which arise from the characteristic packing difficulties in three-dimensional network icosahedral structures

Further phases with the lattice of the hypothetical I-tetragonal boron include BeB_{12} (ref 13) and $AlBe(B_{12})_2$ (ref 14), and the non-metal borides $B_{50}C_2$ and $B_{50}N_2$ All can be prepared in a reproducible manner in which the tetragonal icosahedral framework is stabilised by foreign atoms For BeB_{12} and $AlBe(B_{12})$, however, no absolute electron densities are known in the icosahedral holes and no further comparison is possible

We therefore believe that the I-tetragonal boron, $B_{48}B_2$, is not a polymorph of elementary boron Hoard and Hughes[16] have already expressed doubts about the existence of this phase

Gothenburg magnetic 'flip'

SHORT events are only recorded occasionally in stratigraphical sequences, for example, during periods of rapid sedimentation, or if the record is continuous or samples are very closely spaced If the chronology is not very exact, even these occasional records cannot usually be reliably correlated, making it difficult to distinguish between 'noise' and real events (see ref 1)

A 'Late Weichselian magnetic reversal'[2] has been found in several areas of the world We originally named[3] this reversal "the Gothenburg Reversed Event" This name, however, may not be entirely relevant The word 'event' is generally only applied to dipole reversals of durations of more than 10^3 yr The Gothenburg Reversal is a very short magnetic 'flip', which may need a term of its own, instead of 'event' Magnetic 'excursions' are defined as being caused either by dipole tilting or by dipole intensity decrease with non-dipole activity becoming dominant The Gothenburg 'flip' could be either a very short magnetic event or a magnetic excursion

The Gothenburg 'flip' was first recognised in a core (B873) taken in the Botanical Gardens, Gothenburg[2–4] The upper boundary was fixed very precisely at the boundary between the Fjarås Stadial and the Bolling Interstadial, dated at 12,350 yr BP[4,5] The change from reversed to normal polarity is very rapid (Fig 1), occurring within a couple of years Furthermore, there is no major intensity change related to the polarity change

Since we first recognised the 'flip', we have measured several additional cores and sections (Fig 2) Other workers have undertaken similar investigations elsewhere and the 'flip' has been found in several localities (Fig 2)

In the samples from localities 1–15 (Fig 2) the chronological control indicates that the recorded reversals refer to the same magnetic event or excursion, but in samples from the remaining localities the dating is not sufficiently precise for direct correlation

As yet we do not know the exact duration and form of the 'flip' There are three possibilities first, a long, constant reversal which lasted 1,000–2,000 yr (the records do not, however, show a constantly negative polarity of that duration, second, a long period (1,000–2,000 yr) of unstable geomagnetism, with several flips between normal reversed polarity, third, a short period (≤100 yr) of reversed geomagnetism at around the Fjarås Stadial (12,400–12,350 yr BP[5]) which followed a millenium of irregular (but not fully reversed) magnetism

Consequently, it may not be the proper time to decide whether the 'flip' should be classified as an event of very

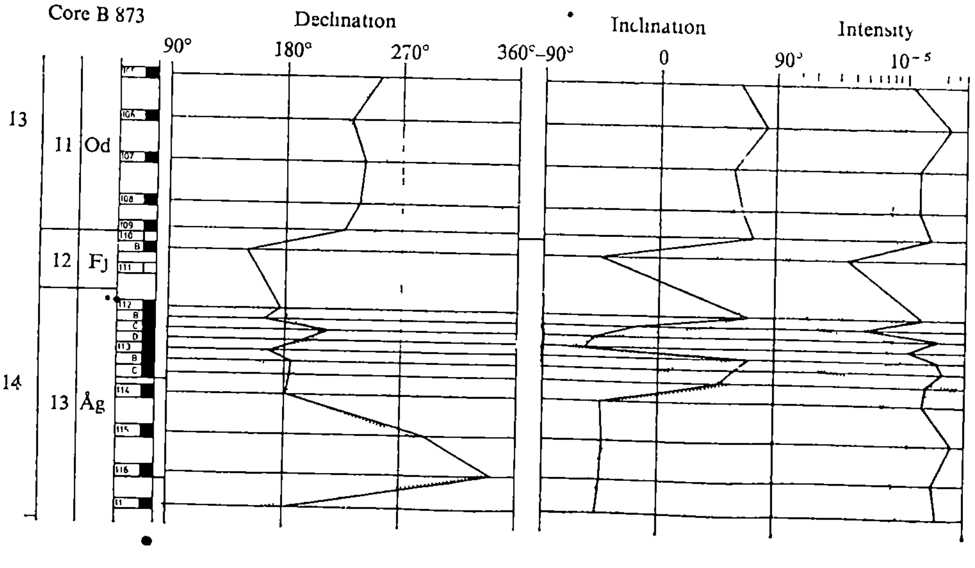

Fig 1 Palaeomagnetic measurements of the base of Core B873 (ref 4) The 'flip' includes layers 12 and 13, that is, the top of the Ågård Interstadial (Åg) and Fjarås Stadial (Fj) Solid lines, natural remanent magnetisation, dotted lines, magnetisation after cleaning in 200 oersted Layers 12 and 13 probably only represent about 100 yr

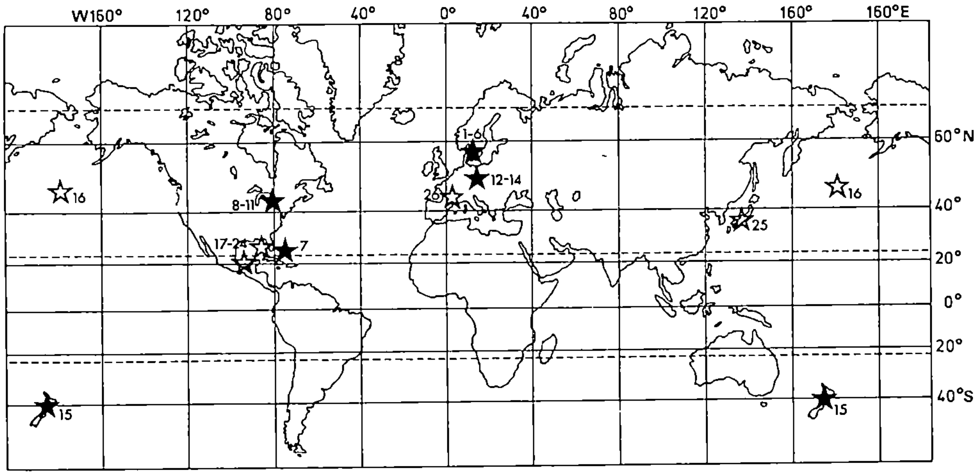

Fig 2 Localities at which the Gothenburg geomagnetic 'flip' has been established and well dated (black stars), and at which it has been tentatively recognised (open stars) 1–6, Gothenburg[2–6] and five other Swedish cores all having a well established chronology and all closely correlated on other grounds than the magnetic results (N -A Morner and J P Lanser, unpublished), 7, deep-sea core A179–15 from the North Atlantic (ref 6, and N -A Morner and J P Lanser, unpublished), 8–11, four Canadian clay sections (refs 6 and 7, and N -A Morner and J P Lanser, unpublished), 12–14, three Czechoslovakian loess sections[8], 15, the Okupata Tephra on North Island, New Zealand (W W Topping, unpublished), dated at 12,450±340 BP[9], 16, deep-sea core V20–108) from the northern Pacific[10], 17–24, eight deep sea cores from the Gulf of Mexico[11], 25, Lake Biwa-Ko, Japan[12], 26, the well known but undated Laschamp 'Event' in France[13,14]

short duration or as an excursion (or as a combination of both) The fact that it seems to be a full reversal not associated with any intensity decrease and that it is found in several different areas of the globe, seem to indicate that it is a real dipole reversal despite its very short duration

So far, the 'flip' has only been looked for carefully in a few areas In spite of that, however, it has been established in several closely dated and mutually correlated stratal sequences Therefore, it must be a real magnetic event or excursion (not just 'noises') that has global validity This means that the 'flip' is a global marker which can be used as a tool for detailed correlations on a global scale[6], and its short duration is an advantage for precise correlations

Geostrophic comparisons using measurements from a moored current and temperature meter

THE vertical shear of horizontal current, calculated from moored current meters, can be compared with the geostrophic shear calculated from moored temperature measurements The results of this comparison show good agreement in sign and magnitude and indicate the validity of the geostrophic balance in the conservation of momentum

The geostrophic balance is used by oceanographers to infer ocean currents from measurements of temperature and salinity[1] Instruments which measure temperature and pressure at very short intervals have also been used[2] The close relationship between temperature and salinity[3] in the MODE region (28°N, 70°W) allows determinations of density from temperature measurements alone, so that moorings with several temperature recorders may serve as continuously operative hydrographic stations Current meters on the same moorings give information about the currents which may then be compared with the temperature field

In theory, ocean currents are usually assumed to be geostrophic and hydrostatic to the lowest order, implying a thermal wind relationship

$$\rho_0 f(\partial V_n/\partial z) = -g(\partial\rho/\partial s')$$

where $\vec{s}$ is the direction of the line joining two moorings, and $\vec{n}$ is the direction normal to $\vec{s}$ Assuming a close relationship between temperature and salinity, so that $\rho = \rho[T,S(T)] = \rho(T)$, the thermal wind equation becomes

$$\rho_0 f(\partial V_n/\partial_z) = g\alpha(\partial T/\partial s)$$

where $\alpha = -(\partial\rho/\partial T)$ An attempt has been made to use the MODE-I current meter and temperature data to examine this balance in its vertically integrated form

$$\rho_0 f\Delta V_n = g\int\alpha(\partial T/\partial s)dz$$

* 28°09′N 70°08′W
† 28°42′N 70°16′W

In the MODE field experiment current meters at depths of approximately 425 m and 725 m on each mooring, measured horizontal velocity and temperature In addition a recorder at 525 m on each mooring measured pressure and temperature In that analysis 4-d averages of both velocity and temperature were used

Current meters on moorings approximately 60 km apart at positions 28°09′N 70°08′W and 28°42′N 70°16′W, were used to calculate the vertical change in the horizontal velocity, normal to the line joining the moorings, over the 300 m depth interval The velocity difference for each mooring and an average velocity difference for the two moorings are given in Table 1

To estimate the horizontal temperature gradient the temperature measurements had to be corrected to standard pressures, chosen at 421, 521, and 721 dbar The corrections were made using the pressure measurements and a spatially averaged CTD station, giving temperature and salinity as a function of pressure (R Milland, and H Bryden, unpublished) It was then assumed that the pressure surfaces were essentially level, so that differences of temperatures between the two moorings at each depth could be used to obtain estimates of horizontal temperature gradients, $\partial T/\partial s$ Values of $\alpha = -(\partial\rho/\partial T)$ were obtained for each depth from the average CTD station, and the quantity

$$(g/\rho_0 f)\int_{-721}^{-421}\alpha(\partial T/\partial s)dz$$

was estimated by assuming $\alpha(\partial T/\partial s)$ to be constant over a depth interval

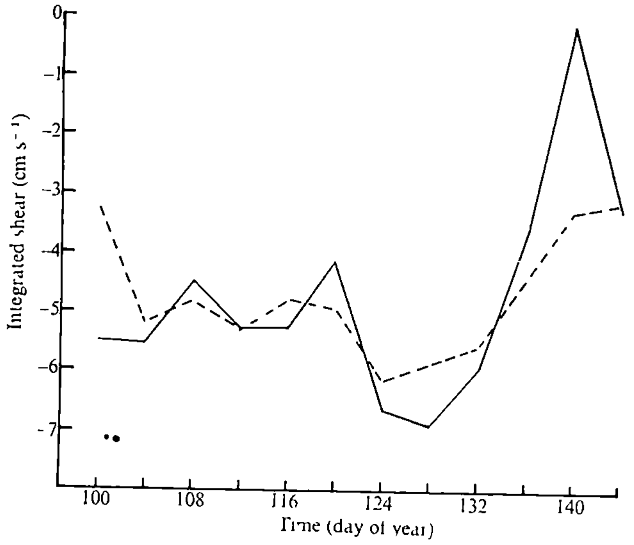

Fig. 1 Horizontal current shear, ΔV_n, from moored current meters (——), and geostrophic shear $(g/\rho f)\int_{-721}^{-421}\alpha(\partial T/\partial s)dz$ from moored temperature measurements (– – –)

Values of average ΔV_n and $(g/\rho_0 f)\int_{-721}^{-421}\alpha(\partial T/\partial s)dz$ shown in Table 1 are plotted in Fig 1 as a function of time The average difference between the observed and calculated shears is 0 01 cm s^{-1}, and the average absolute difference is 0 87 cm $^{-1}$, about 18% of the current shear

Similar comparisons were attempted using other mooring pairs All other MODE pairs with good current meters and pressure–temperature recorders were separated by horizontal distances greater than 60 km These comparisons were not as good but they did on the whole show agreement in sign, with differences in magnitude of the shears of about 3 cm s^{-1} over the 300 m vertical separation

The MODE experiment is supported by the Office of Naval Research and the National Science Foundation, The Office of Naval Research, and the office of the International Decade of Ocean Exploration of the National Science Foundation maintained the equipment and provided data analysis Dr W Schmitz and Professor C Wunsch kindly made released current meter data and pressure–temperature recorder data, respectively This work was supported by the Office of Naval Research I thank Dr N Fofonoff for encouragement

Spatial ability, throwing accuracy and man's hunting heritage

ATTENTION has recently been drawn[1] to the indications that spatial ability—the ability to create, maintain and mentally transform a visual image[1,2]—has an X-linked recessive mode of inheritance in Caucasians[1,3-8], with males having a proportionately greater facility[1,9-12] At first glance, this result seems paradoxical in that such a presumably adaptive trait would not be expected to be transmitted on a recessive allele If past selection pressures were exerted primarily on males, however in whom the spatial allele is co-dominant, the paradox would be resolved satisfactorily

Moreover, this is an interesting focus for anthropological research because the existence of an X-linked behavioural trait in the present would constitute independent evidence for a sexual

division of labour during the 99% of human history that men have been hunters Certainly, directional orientation and memory for visual landmarks must have been required for a man to find his way back to the group If, in addition, spatial ability were positively correlated with judgement of distance and throwing accuracy in males (for example, as regards such weapons as stones and spears), this could presumably have allowed them to hit game at greater distances, thereby making hunting less hazardous and resulting in longer lived hunters as well as more meat

With these ideas in mind, we have collected data on spatial ability and throwing accuracy in 67 white boys, 14–16 yr of age Data for each subject include his age, his raw score on the PMA spatial test[13] and several measurements of his average performance over 20 successive throws of a baseball at a vertical target 30 feet away[14-16] The target was a section of canvas, 9 × 9 feet, on which were inscribed five concentric circles, from 1 to 5 feet in diameter, with the centre circle or bull's eye 3 5 feet from the floor The target area was also divided by very light lines into a grid of 81 1-foot squares Five measures of accuracy were derived for each thrown ball (1) Concentric circle—with point values declining from 5 for a bull's eye to 0 for throws missing the outermost circle, (2) horizontal direction—differentiating right from left, scored 0 5 to 9 5, (3) horizontal deviation—the absolute distance from the central vertical column in either direction, scored 0 to 4 5, (4) vertical direction—differentiating above from below the central row, scored 0 5 to 9 5, (5) vertical deviation—the absolute distance from the central horizontal row in either direction, scored 0 to 4 5 In addition to the accuracy records, the speed of each throw was measured and converted to a velocity in feet per second[15,16] Subjects were allowed to warm up according to their own individual preferences, after which they were instructed to execute 20 overhand throws, in two bouts of 10 each, as fast and as accurately as possible

No significant relationship to age was found for the spatial or accuracy scores For the spatial test, which has a multiple-choice format, only the raw scores were available and we could not correct for guessing Therefore, six subjects scoring at or below chance levels were eliminated from the analysis The descriptive statistics for the remaining 61 subjects are shown in Table 1

A regression analysis was performed to assess the extent to which spatial scores were a predictor of throwing performance The results are the univariate F statistics on 1 and $N-2 = 59$ degrees of freedom in Table 2*a* Clearly spatial ability is significantly related only to the vertical deviation and concentric circle accuracy scores Proceeding a step further, we performed a step-down regression analysis in which dependent variables 1 to n are successively removed as covariates, n going from 1 to 5, with the $n+1$st variable thus being regressed on the preceding n variables and the spatial score Each of the step-down Fs then has 1 and $N-n-1$ degrees of freedom[17] This analysis indicates that when the effect due to vertical deviation accuracy is allowed for, concentric circle scores lose their relationship to spatial ability The converse is not true however When concentric circle accuracy scores are partialled out (Table 2*b*), spatial scores still predict vertical deviation scores at the 3% level of significance Thus, concentric circle scores show a relationship only because of their vertical component

This relationship between spatial ability and vertical accuracy is especially interesting in that vertical deviations on an upright

Table 2 Statistics for regression analysis on PMA spatial test

target would translate into skill and judgement with respect to distance if the target were laid on the ground Therefore, while emphasising that only 14% of the variance is accounted for by the PMA test, we believe we have tentative evidence relating spatial skills to an important component of the hunting enterprise Although caution is warranted in extrapolating from the present data to our hunting heritage, the suggestion of Washburn and Lancaster[18] should be noted

> "The Pleistocene way of life can only be known by inference and speculation As we go farther back in time, there is less evidence and the biological and cultural difference becomes progressively greater Yet it was in those remote times that the human way of life took shape, and it is only through speculation that we may gain some insights into what the life of our ancestors may have been "

Local suppression of alpha activity by pattern in half the visual field

If Lippold's hypothesis[1], that the alpha rhythm of the human electroencephalogram (EEG), (and perhaps other electrical signals that can be recorded from the scalp) are artefacts that result from eye movements, rather than genuine manifestations of neural activity, was found to be correct, it would seriously reduce the value of EEG and evoked potential techniques in research and clinical neurology In the latter area, for example, considerable attention is being given to the validity of accepting an absence of EEG activity as a criterion of cerebral death One of us (C R C) has already discussed[2] earlier experiments that relate to the eye-movement hypothesis We will describe here results that are consistent with a neural explanation for the control of alpha activity, but not with an eye-movement explanation

Briefly, Lippold's hypothesis states that alpha activity is found when the standing potential between the front and rear of the eye is modulated by eye movements (especially movements that are parallel to the optic axis) and by changes in the length, and therefore in the resistance, of the extraocular muscles In addition, electrical activity of the extraocular muscles may contribute directly to the alpha rhythm According to this hypothesis, the act of observing a visual stimulus reduces alpha activity by reducing tremor of the extraocular muscles

If alpha rhythm depends on muscle tremor, visual stimulation should result in an equal reduction of alpha over both hemispheres, irrespective of which part of the visual field is stimulated If alpha is under neural control, however, the amount of suppression of alpha in one hemisphere should depend upon which lateral half of the visual field is stimulated, as, except for a small central region, the primary pathways from the two halves of the visual field project to separate hemispheres We find that visual suppression of alpha activity is related to the location of the visual stimulus

The subject faced a rear-projection screen that subtended a visual angle of approximately 90°×90° The screen could be illuminated uniformly so that very little visual detail was visible, or a pattern could be projected on the left or right half of the screen When a pattern appeared in half the screen, the subject was instructed to fixate in the blank half of the screen, about 1° from the edge of the pattern Thus, when the pattern appeared on the left, only the right visual cortex received direct stimulation from the patterned area, and *vice versa* In a preliminary experiment the pattern was a black-and-white chessboard, but the subject found this so soporific that the pattern was later changed to a series of coloured slides that were rich in visual detail (for example, interior views of the Royal Pavilion in Brighton) In another preliminary experiment, the effect on alpha suppression of varying the luminances of the patterned and blank fields was studied No difference was found as luminance was varied from that luminance at which the pattern was first clearly visible, to the maximum luminance of the projector, nor did the relative luminances of the pattern and blank fields have any measurable effect For simplicity, in the main experiment the patterns were projected at full intensity (about 200 cd m^{-2})

The subjects were four right-handed males who had normal vision and fairly abundant alpha Electrical activity was recorded bipolarly between chlorided silver electrodes in positions O_1–T_5 (above the inion, and left of centre) and O_2–T_6 (above inion, right of centre) In addition to conventional EEG recordings, the outputs of the left and right hemisphere preamplifiers were led to two bandpass filters that had quality factors of 10 The centre frequency of the filters was set at the individual subject's alpha frequency, which was measured from the EEG record while he faced the blank screen with his eyes open The outputs from the filters were rectified and led to integrators that gave the sum of activity at the alpha frequency during 1 min recording periods We used this signal, which includes both the amplitude and abundance of activity at the alpha frequency, as our principal measure of the effectiveness of selective visual stimulation

Less activity was consistently recorded from the scalp over the hemisphere that was contralateral to the visual field in which the patterned stimuli were presented Although the ratio of activity from the blank- and patterned-hemisphere derivations was never large (the maximum ratio, averaged over an experimental session, was approximately 2 1), it was highly significant, as shown by the inter

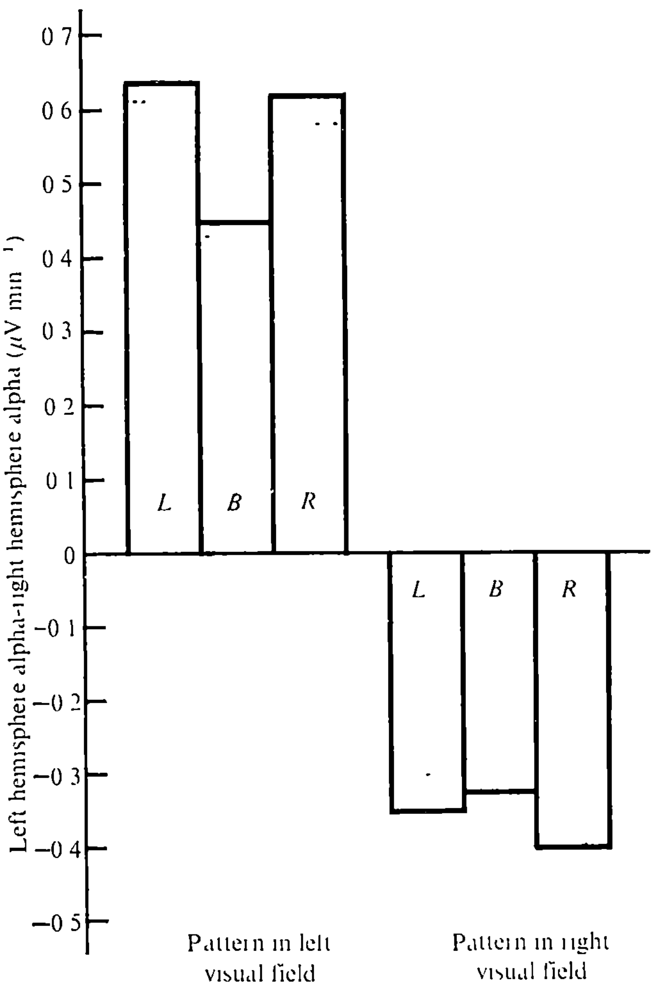

Fig. 1 Effect of left eye (*L*) and right eye (*R*) monocular observation and binocular (*B*) observation on the relative amount of alpha activity over the left and right occipital regions. The distance from the dotted line to the top of each bar = 1 s.e. The interaction between visual field and recording hemisphere was significant at $P < 0.00001$

action between visual field and hemisphere (Table 1). It should be noted that this is a conservative measure of the effect of changing the side of the visual stimulation, as any extraneous electrical activity that fell within the passband of our filters, such as movement and muscle artefacts, would have added randomly to the amplitudes of the signals from both recording sites and would have tended to obscure the difference that was produced by selective visual stimulation. Table 1 also shows that the major source of variance in the recorded alpha occurred among subjects, which is not surprising. In addition, the abundance of alpha was slightly, but consistently, greater over the left hemisphere in all subjects.

Lippold suggests[1] that an important criterion for true alpha is that its frequency remain constant. We therefore monitored the frequency throughout the recording sessions by means of a digital counter that was triggered by zero crossings. Using an average response computer, triggered in the same way, we also cumulated activity from the electrodes that were ipsilateral and contralateral to the side on which the patterned stimulus was presented. Very little change in frequency was observed during periods in which alpha-like activity could be seen in the raw signal from the scalp electrodes, and at no time was there a systematic change in frequency with change in the side on which the stimulus was presented, which leads us to conclude that the activity that we recorded satisfies Lippold's definition of true alpha.

The principal experimental evidence that has been advanced for the eye-movement hypothesis has come from studies in which differential treatment of one eye, such as dark adaptation, or cooling of the orbit, was accompanied by the appearance of asymmetrical alpha activity over the right and left occipital regions. If alpha is controlled primarily by the ipsilateral eye, it should be predicted that asymmetrical alpha will be found when a visual stimulus is presented to one eye only. To test for this, one subject observed the visual fields monocularly as well as binocularly. (During monocular observations the other eye was covered by a flap of black cardboard.) The results in Fig. 1 clearly show that alpha activity depended on the position of the patterned and blank fields, quite irrespective of which eye was stimulated. Monocular viewing with either eye resulted in slightly more suppression than binocular viewing, but we tend to attribute this to the fact that the monocular observations were made near the end of a long recording session, when the subject had more abundant alpha, and hence more alpha to suppress.

Table 1 Results of analysis of variance of alpha blocking by visual stimulation

Source	Mean square	d.f.	*P*
Visual hemifield	0.73	1,144	n.s.
Recording hemisphere	31.38	1,144	$P \ll 0.00001$
Subjects	324.07	3,144	$P \ll 0.00001$
Visual field × hemisphere	31.63	1,144	$P \ll 0.00001$
Visual field × subjects	0.77	3,144	n.s.
Hemisphere × subjects	5.43	3,144	$P < 0.01$

The main findings in this study are consistent with Morrell's observation that, during an operation in which a patient's visual cortex was exposed, highly localised suppression of alpha activity could be effected by stimulating a restricted part of the patient's visual field[3]. All these results are explained if we accept Adrian and Matthew's conclusion that visual stimulation suppresses alpha activity by means of neural activity[4]. We do not believe that they can be satisfactorily accounted for by the eye-movement hypothesis, for in our main experiment both eyes received the same stimulation and presumably would have been induced to engage in the same movements, if indeed there were any.

These findings also strongly suggest that alpha activity is controlled by visual stimulation and not, as has been claimed, by the act of fixing the gaze[5], or by rolling the eyes upward[6].

We thank Professor L. H. van der Tweel for providing facilities and Dr J. D. Mollon for advice on the English translation.

Water in the nutrient cycle of a Papuan rain forest

INTEGRATED ecosystem studies of nutrient cycling on a catchment basis[1] for tropical rain forest areas are few[2–4], but information on the effects of nutrient cycling in these ecosystems on soil development, hydrology, and variations in stream water quality is needed, since rain forested areas in many developing tropical countries are rapidly being cleared to provide agricultural land[5].

I carried out an investigation into the hydrological part of the nutrient cycle in a tropical rain forested catchment of 16.26 km^2 below the Sogeri Plateau in Central Papua, Papua New Guinea (Fig. 1). The stream (Ei Creek) has incised approximately 600 m into the Pliocene andesitic and basaltic volcanic agglomerate capping of the plateau to expose the underlying Cretaceous phyllite, which includes chlorite, mica, and graphite, and comprises approximately 13% of the catchment. The catchment is ringed by cliffs, giving way to steep convex valley sides with a shallow covering of acid red to brown clay soils. Gullying occurs under the forest, and landslips occur after heavy rains. The rain forest of the area is dominated by *Castanopsis* and *Elaeocarpus* species which provide an open high storey, a more dense understorey, and a rich growth of ferns, epiphytes and lianes[6].

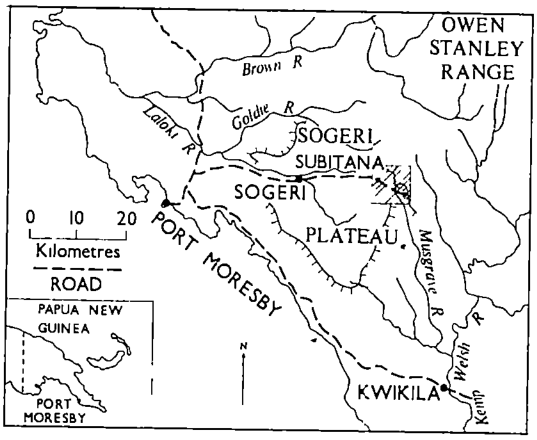

Fig. 1 Location of the study area.

A Hellman type pluviograph and a Bristol gauge recorded rainfall and streamflow for 10 months (July 1972 to May 1973), samples were taken weekly, and more often when heavy storms produced stream rises. Because of human interference throughfall could not be sampled continuously, but samples were taken, through five individual storms and an incidence of dew fall, with four 0.25 m^2 polyurethane coated troughs placed 1 m above ground. This method provides a large sample area equivalent to approximately 75 standard 13 cm diameter polythene funnels, but tends to mask the true throughfall variability. Leaf litter leachate and soil water solutions were simulated by washing with distilled water[7,8].

Water samples were analysed with a Varian Techtron atomic absorption spectrophotometer for Ca, Na, K and Mg. Samples were not buffered for Ca analysis[9], and the absence of Ca in the cation sequence (Table 1) for leaf litter leachate may be due to interference or precipitation out of solution, Ca results may therefore be anomalous.

Table 1 Cation sequences (meq l^{-1})

Rainfall	Na	> Mg	>	K	>	Ca	
Throughfall	Na	> Ca	>	K	>	Mg	
Leaf litter leachate	Mg	> Na	>	K			
Soil water (to 15 cm)	Mg	> Ca	>	Na	>	K	
Soil water (to bedrock)	Mg	> Na	>	K	>	Ca	
Stream water	Mg	> Na	>	Ca	>	K	

The colorimetric heteropoly blue method[10] was used for Si analysis. Dissolved salts and suspended solids in stream water were also measured.

The figures for the annual transfer of nutrients in the hydrological cycle (Table 2) are derived from measured elemental concentrations and measured or estimated volumes of water. Because of insufficient throughfall measurements an approximate value, of 80% rainfall as throughfall and stemflow, was arrived at by reviewing the literature for other tropical rain forests[11–13]. The chemistry of stemflow has been found to be not very dissimilar to throughfall[2,12,14], and, as it constitutes a small percentage of the rainfall reaching the forest floor, its inclusion with throughfall will not lead to large errors in estimates of nutrient return.

In simulating leaf litter leachate and soil water solutions by washing with distilled water there is the problem of accounting for residence time of water in the compartments, and the lateral flow and mixing of water with depth in the soil. McGinnis *et al*[15] calculated a residence time of 0.35 d for water in the litter layer, and 33.06 d for water in the soil of a moist tropical forest. If residence time represents leaching ability, the annual turnover of nutrients in these compartments may be very different from that calculated here. The rate of nutrient turnover in the forest floor is probably dependent upon both the volume of water and the length of time the compartment remains saturated. Not all of the 2,155 mm reaching the soil surface will reach the bedrock, and use of this volume of water in calculating the nutrient flow out of the lower soil compartment may result in an overestimate. Since the soils in this study were shallow and lateral flow on the steep slopes may add to the flow, the overestimate may not be too great. In spite of these problems, the cation sequences in Table 1 are very similar to those found in lysimeter studies under rain forest in Costa Rica[2].

The values for throughfall in the nutrient cycle indicate the rates and relative importance of the movement of individual elements in the hydrological section of the cycle. On a kg ha^{-1} basis, Na provides the greatest return in throughfall, followed by K, Ca and Mg. Neither Nye[12] nor Kenworthy[3] measured Na in throughfall, but both found the above sequence. The relative importance of throughfall in total nutrient return (litter, timber and throughfall) was shown by Nye[12] to be K, 75%, Ca, 9%, and Mg, 25%. Although actual amounts of Mg in throughfall are low, throughfall is of relatively greater importance to Mg than to Ca in their respective cycles. Both Jordan[16], and Sollins and Drewry[14] considered that in tropical rain forests nutrient return in throughfall, and in particular K, is as important as litter fall in the nutrient cycle.

Silicon was not found in rain or throughfall, but the high Si content of the forest floor is considered by Rodin and Bazilevich[17] to be typical of the tropical rain forest. Si represents a different type of cycling from the other elements considered here, it is not washed out in throughfall and depends entirely on litter and timber fall for its return to the ground, whereafter it must be leached from the litter layer in order to be returned to the roots through the soil. The low *p*H and destructive flora and fauna of the forest floor provide an ideal environment for the removal and transfer of Si. The accumulation of Si by forests[18] is of geological significance and many tropical trees have

Table 2 The nutrient cycle

	Depth water (cm yr^{-1})	Si	Ca	Na	K	Mg

No samples *a*, 20, *b*, 49, *c*–*f*, 3, *g*, 99

been found to contain high concentrations[19] Mg dominates the cation sequence for the litter, soils and stream water This was found to be the case in McColl's study[2], and supports Kenworthy's observations[3] that most of the Mg is derived from litter leachate Litter is of great importance under tropical rain forests because of the rapid rate of decay, estimated by Nye[12] to be 1 3% d^{-1}

In stream water, Si, Mg and Na, showed strong tendencies to dilute with increasing discharge, Ca displayed a poor dilution relationship, and K concentrated weakly with increasing discharge Similar relationships with discharge have been found in widely differing study areas[20,21] which suggests that biological rather than geological processes are dominant in the variability of stream water quality The large amounts of nutrients involved in both the solid and dissolved phases of the cycle, compared with the losses in stream water (less than 1 2% of total nutrients measured), demonstrate the fully closed nature of the nutrient cycle The persistence of relatively low concentrations of elements in stream water through a wide range of discharges is due to the efficiency of the root systems in filtering out the nutrients leached through the soil The loss in stream water, however, does not include the elemental composition of suspended sediment and organic debris At peak flows after large storms much sediment and organic debris is washed into the stream from the forest floor, trees are carried downstream and the large bedload is moved In one instance, suspended sediment after a storm rose from 22 8 p p m at 1 11 cumecs to 1,945 7 p p m at 51 cumecs This material is an important form of nutrient loss from the ecosystem

Regulation of larval corpora allata in *Galleria mellonella*

IN insects metamorphosis occurs when the corpora allata stop secreting juvenile hormone, but it is not known how the production of juvenile hormone is regulated Wigglesworth[1] first indicated that the nervous connections from the brain to the corpora allata provide a mechanism for control, this control could be nervous or neurohormonal In many adult insects, the corpora allata seem to be inhibited *via* their nervous connections to the brain, since in most cases severing these nerves activates the glands[2,3] Whether the same is true for larvae has not been demonstrated conclusively Activation of the corpora allata by neurosecretion has been demonstrated in many adult insects, for example *Tenebrio molitor*[2], *Leptinotarsa decemlineata*[4] and *Rhodnius prolixus*[5], and the production of an allatotropic hormone by the larval brain has also been suggested[6–8] We have now investigated the control of corpora allata function in last instar larvae of *Galleria mellonella,* encouraged by the discovery that in this species the implantation of brains at the beginning of the last larval instar causes an extra larval moult[9] Our results show that the corpora allata are activated by a neurohumoral factor from the brain during larval development and that they are inactivated by nervous inhibition just before metamorphosis

We first confirmed that the implantation of brains causes supernumerary moults, by implanting brains dissected from 48–120 h last instar larvae under the dorsolateral abdominal epidermis of water-anaesthetised hosts During the first 48 h of the last larval instar, the hosts responded to the implantation of three brains by undergoing a supernumerary moult (Table 1) Identical results were obtained after the implantation of corpora cardiac–corpora allata or brain–cardiac–allata complexes[10,11] The capacity of the host larvae to respond to the implanted brains was lost about 60 h after the last larval–larval ecdysis

Table 1 Development of last instar larvae implanted with three brains at different times after the last larval–larval ecdysis

Hosts Age at time of implantation (h)	No	Larval–larval ecdysis		Larval–larval ecdysis	
		% of insects	Length of instar (d)	% of insects	Length of instar (d)
12	89	55	5 0	45	8 0
48	9	44	6 3	56	7 4
60	11	9	8 0	91	8 5
120	28	0	—	100	8 3

Brains came from donors 48–120 h after the last larval–larval ecdysis

To distinguish whether the implanted brains activate the corpora allata[12,13] or the prothoracic glands, we performed the same implantations on 0–12 h last instar larvae which had been allatectomised The allatectomised larvae did not respond to the implanted brains, indicating that in the previous experiments the brains were primarily stimulating the corpora allata Thus before the last larval instar, the corpora allata appear to be activated by a factor from the brain During the last larval instar, either the brain no longer produces or releases this factor, or the glands are inhibited from responding to it

We investigated the capacity of brains from sixth and seventh (last) instar larvae to induce extra larval moults in sensitive last instar larval hosts (Table 2) The ability of the brain to activate the corpora allata seems to change during development, being most potent during the first part of the instar and declining just before the moult Implanted brains from 120 h last instar larvae were the least able to elicit extra larval moults This corresponds to the period between 54 and 152 h in the last larval instar when the changes from the larval to the pupal programme of development can no longer be affected by large amounts of exogenous juvenile hormone[11,15] Since brains from 0–72 h last instar larvae can induce an extra larval instar when implanted into sensitive hosts, while the corpora allata lose their sensitivity to implanted brains about 48–60 h after the last larval–larval ecdysis, reactivation of the corpora allata *in situ* might be prevented by nervous stimuli We have found that severing the nerves to the glands 72 h after the last larval–larval ecdysis partially restores their activity (Table 3), since two of our experimental animals moulted into supernumerary larvae, whereas no effect was seen in a comparable number of sham-operated animals The length of the instar to the larval-pupal ecdysis in those animals which had the nervous connections severed was prolonged significantly, indicating at least some restoration of activity of the corpora allata Since a definite, but less pronounced, prolongation of the instar was observed in the sham-operated animals, injury apparently contributes to this effect Most significantly, severence of the nerves rendered host larvae sensitive to the implantation of brains, at a time when unoperated larvae did not respond The fact that only 20% of these animals underwent an extra larval moult is probably due to damage caused to the glands during nerve severence We conclude that there is probably a nervous inhibitory influence on the corpora allata which develops between 48 and 60 h after the last larval–larval ecdysis

Table 2 Induction of extra larval–larval ecdyses by implantation of three brains from donor larvae of different ages into 0–12 h last instar larval hosts

Age of donor	No of larvae	% of insects forming supernumerary larvae	% of insects forming pupae
24–36 h, 6th instar	16	94	6
Premoult 6th instar	16	37	63
0–12 h, 7th instar	34	71	29
48 h, 7th instar	23	61	39
72 h, 7th instar	37	44	56
120 h, 7th instar	16	91	81
Moveable prepupa*	17	35	65
Sham operated	25	0	100

* Eye pigment stage 3–14 (ref 14)

Since the implanted brains activate the corpora allata through the haemolymph, the activating factor appears to be of a neurohormonal nature Further evidence for this comes from the observation that the number of supernumerary larvae resulting from brain implantation increased with the number of brains implanted (Fig 1)

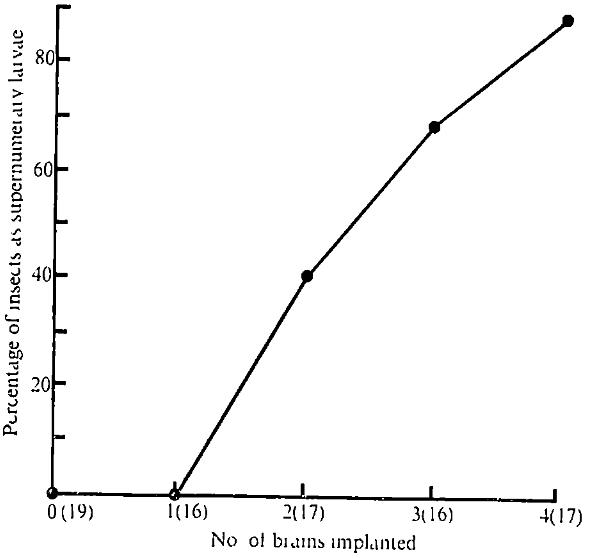

Fig. 1 Extra larval development as a function of the number of brains implanted into larvae 0–12 h after the last larval–larval ecdysis The numbers in parentheses are the numbers of experimental animals

The most prominent neurosecretory cells in the brain of larval *G mellonella* comprise a heterogeneous group found in the pars intercerebralis (ref 16 and our unpublished work) To test whether the activating factor is produced by cells in this region, we destroyed bilateral regions of the brain selectively by microcautery and implanted the cauterised brains into sensitive hosts (Table 4) Significantly fewer extra larval moults were elicited by brains cauterised in the pars intercerebralis This suggests that the allatotropic factor is a neurohormone produced by neurosecretory cells in the pars intercerebralis

Our results show that in larval *G mellonella* the corpora allata are activated by a neurohumoral factor from the brain, possibly a neurohormone produced in the pars intercerebralis A nervous inhibitory influence on gland function probably develops between 48 and 60 h after the last larval-larval ecdysis, subsequently being reinforced by a decrease in the production or release of the allatotropic factor by the brain

Table 3 Development of 72 h last instar larvae after severence of the nerves innervating the corpora cardiaca–corpora allata, and implantation of brains 0–24 h later

Operation	No of larvae	Larval–larval ecdysis		Larval–pupal ecdysis	
		% of insects	Length of instar (d)	% of insects	Length of instar (d)
Host plus three brains	20	0	—	100	7 5±0 8
Nerves severed	31	7	15 0±4 2	93	16 0±7 7
Nerves severed plus three brains	35	20*	16 3±5 5	80	13 2±4 1

Brains came from donors 48–120 h after the last larval–larval ecdysis

* Three animals were intermediates two were score 3, one was score 4 (ref 11)

The regulatory mechanism for the control of the function of the corpora allata is undoubtedly more complex than the situation we have described Juvenile hormone has been reported to stimulate the secretion of ecdysone by the prothoracic glands[17,18], and the corpora allata appear to be influenced by ecdysone, whose production by the prothoracic glands is under the control of neurohormones

Table 4 Induction of extra larval–larval ecdyses by implantation of brains cauterised in different regions in 0–12 h last instar larvae

Operation	No of larvae	% of insects forming supernumerary larvae	% of insects forming superlarvae
Sham cautery	18	72	28
Cautery area 1	24	25	75
Cautery area 2	19	63	37
Cautery area 3	19	58	42
Cautery area 4	20	50	50
Cautery area 5	20	53	47

Each host was implanted with three brains from 0–12 h last instar larvae Area 1, pars intercerebralis, area 2, corpora pedunculata, area 3, anterior to corpora pedunculata, area 4, lateral to corpora pedunculata, area 5, medial to tritocerebrum

from the brain[18] The brain obviously plays a central role in these relationships, and experiments are under way to investigate the possibility of endocrine feedback mechanisms in the brain

Cyclic GMP and cyclic AMP levels in normal and transformed fibroblasts

THE 3′–5′ cyclic nucleotides, cyclic AMP and cyclic GMP have been implicated in the control of the growth of cultured fibroblasts in that early, transient decreases in intracellular cyclic AMP[1–3] and increases in cyclic GMP[4] are observed on reinitiation of the growth of quiescent mouse fibroblasts by serum Moreover additions of high, nonphysiological concentrations (10^{-5} M to 10^{-3} M) of either cyclic AMP or cyclic GMP (or their butyrated analogues) either suppress the induction of DNA synthesis after serum addition[5] or initiate substantial increases in DNA synthesis respectively[4] in quiescent mouse fibroblasts Cyclic nucleotide concentrations in asynchronously-growing cell cultures are an average over the entire cell cycle and depend for cyclic AMP on the proportion of cells in a particular phase The average cyclic AMP level is often correlated with growth rate[6], although this may not be such a reliable parameter for cell growth as the relative proportions of G1, S, G2 and M vary with cell type and the culture conditions[7] The larger changes in cyclic GMP are correlated directly with the initiation of fibroblast growth when cells are moving out of the G0 state or by passage through the M and G1 boundary and are not exhibited during the remainder of the cell cycle (W S, and P S R, unpublished) Thus cyclic GMP concentrations and the ratios of cyclic AMP to cyclic GMP may be more sensitive and reliable indicators of the growth state of a cell

Here we demonstrate that nontransformed fibroblasts show a large difference in cyclic GMP and cyclic AMP content and cyclic AMP cyclic GMP ratios for growing and quiescent fibroblasts, no such differences occur in transformed fibroblasts These results suggest fundamental differences in the control of cyclic GMP concentrations between normal and transformed fibroblasts in monolayer cultures

Addition of fresh medium and 20% serum to quiescent cultures of Swiss mouse 3T3-4A fibroblasts caused early, transient increases in cyclic GMP and decreases in cyclic AMP concentrations, reaching maximum and minimum levels after 10 to 20 min, respectively (Table 1*a*), similar to the changes observed in quiescent BALB/c 3T3 cultures[4] The concentration of cyclic nucleotides present in a cell is more accurately expressed relative to the total protein content rather than the DNA content or the number of cells as both the total protein and the volume of a cell change in harmony during the cell cycle[8] Prostaglandin E_1 (PGE_1) elevates intracellular cyclic AMP concentrations in 3T3-4A cultures by a stimulation of adenyl cyclase activity[1] Addition of PGE_1 with the new medium caused increased levels of cyclic AMP, suppressed the rise in cyclic GMP observed after 20 min, and reduced the induction of DNA synthesis by a third An increase in cyclic AMP presumably inhibits the cyclic GMP increase as PGE_1 does not directly affect the membrane-bound guanyl cyclase (P S R, and W S, unpublished)

Table 1 Kinetics of cyclic nucleotide changes on reinitiation of cell growth

Time (min)	Cyclic AMP	Cyclic GMP	Cyclic AMP/ cyclic GMP
a Serum addition to 3T3			
0	19	0 7	28
5	2 0	3 5	0 6
10 (PGE_1)*	2 4 (4 4)*	3 6 (0 5)*	0 5 (8 4)*
20 (PGE_1)*	3 1 (26)*	2 2 (0 5)*	1 4 (48)*
60 (PGE_1)*	5 8 (9 5)*	2 7 (2 2)*	2 1 (4 3)*

5	7 2	3 2	2 2
10	7 6	3 4	2 3
20	7 6	4 9	1 5
60	8 8	3 6	2 5

a, Swiss mouse 3T3-4A cultures were grown in 9-cm Petri dishes for 10 d (2 5 × 10^6 cells per dish)[17], the medium was then replaced with fresh DEM (ref 17) and 20% serum with* or without 10 μg ml^{-1} prostaglandin E_1 (PGE_1) and cultures were isolated at the stated times for cylic nucleotide determinations[4 19] Parallel cultures were also radioactively labelled with ^{3}H–thymidine from 18–22 h or from 8–32 h after medium change for DNA synthesis and autoradiography respectively[4] The c p m incorporated into DNA per 10^6 cells (% of cells with radioactively labelled nuclei) were 3 4 × 10^3 (1 2%), 200 × 10^3 (91%), and 90 × 10^3 (36%) for the original cultures, cultures with fresh medium, and cultures with fresh medium and PGE_1 respectively *b*, Simian virus 40 transformed 3T3-4A cells (SV3T3) were grown to a density of 6 1 × 10^6 per dish, cell monolayers were washed twice with DEM lacking leucine, and DEM containing 1/200 of the normal leucine concentration and 5% dialysed serum was added back and incubated a further 2 d (5 5 × 10^6 per dish)[12] Then regular concentrations of leucine were restored and cultures were isolated as above Cell density 30 h later was 9 9 × 10^6 per dish, DNA synthesis and cell cycle data are shown in Table 3 Half of each sample for cyclic nucleotide determination was digested with 3′–5′ cyclic nucleotide phosphodiesterase and the values obtained (0 2–0 3 pmol for cyclic AMP and 0 6–0 9 pmol for cyclic GMP) were deducted to yield the final results[4,14] Duplicates agreed to within 15% and results are expressed in pmol of cyclic nucleotide per mg of cell protein[20]

Table 2 Cyclic nucleotide concentrations in growing, resting, and serum-activated cultures

	'Resting' (confluent)	84	8.6	4.5	1.9
	Activated	97	7.0	4.3	1.6
PyBHK transformed hamster	Growing	80	5.6	4.7	1.2
	'Resting' (confluent)	83	7.4	4.3	1.7
	Activated	89	6.2	4.5	1.4

Twenty Petri dish cultures[17] for cyclic nucleotide determinations were isolated after 2 or 3 d on reaching a quarter to half of the final cell density (growing), after 8–9 d (resting) (3–4 d after the cessation of DNA synthesis in nontransformed cells or at confluency for the transformed cells), or after 20 min following addition of fresh DEM and 20% serum to 'resting' cultures (activated) (Table 1). The cyclic nucleotide amounts are expressed in pmol per mg cell protein and DNA synthesis by the percentage of cells with radioactively labelled nuclei after exposure to ^{3}H–thymidine for 24 h before isolation of growing cultures or from 8–32 h after the time of medium change for resting and activated cultures. Serum concentrations and the cell densities upon isolation ($\times 10^6$) of growing and 'resting' (or activated) cultures respectively were for BALB/c 3T3 in 10% serum 0.85 and 2.2, in 2% serum 0.65 and 1.1 (serum growth activated cultures isolated after 10 min instead of 20 min), for Swiss mouse 3T3-4A in 10% serum 1.6 and 2.8, for secondary mouse embryo fibroblasts in 10% calf serum or 0.5% horse serum 2.5 and 6.4, for African green monkey kidney fibroblasts (BSC–1) in 10% serum 0.61 and 4.0, for baby hamster kidney fibroblasts (BHK) in 10% and 1% serum, 2.9 and 0.36 (confluency about 10). for Swiss mouse 3T6 fibroblasts 7.2 and 18.0, for simian virus 40 transformed 3T3-4A (SV3T3) in 10% serum, 2.6 and 12.8 (confluency), and for polyoma virus transformed BHK (PyBHK) in 10% serum, 8 and 25.2 (confluency).

The cyclic nucleotide contents of different fibroblasts were compared when cultures were randomly growing, in a quiescent state mainly as a consequence of the exhaustion of growth factors in serum[9] or in a synchronised growing state 20 min after fresh medium and 20% serum were added to quiescent cultures (Table 2). When growing cells ceased to divide and became quiescent, cyclic AMP levels increased by about two-fold (fourfold for mouse embryos) while cyclic GMP levels decreased by a factor of about two to three. On the initiation of growth of the quiescent cultures, cyclic AMP levels fell three- to fivefold while cyclic GMP rose four- to twelvefold. Because of the parallel but reciprocal changes in cyclic GMP concentrations the cyclic AMP:cyclic GMP ratio reflected these changes more dramatically. It was lower for growing cells (2 to 4), high when cells became quiescent (12 to 30) either when in contact (BALB/c 3T3 in 10% serum) or in sparse cultures (BALB/c 3T3 with 2% serum), and about unity or below in the synchronised growth state (activated for 20 min). Baby hamster kidney (BHK) and mouse 3T6 fibroblasts which contained a significant fraction (2.3% and 10%) of cells synthesising DNA also have the lowest cyclic AMP:cyclic GMP ratios of the 'resting' fibroblasts tested. In contrast, the cyclic nucleotide concentrations for virally transformed fibroblasts SV3T3 and PyBHK did not change significantly between the three growth states (Table 2) and cyclic GMP levels were a factor of two higher than for the growing fibroblasts. Since the transformed cells failed to exhibit density-dependent inhibition of growth[9,10], they were actively synthesising DNA even when the cultures were confluent (Table 2).

Artificially depriving the culture medium of required nutrients is another reversible method of controlling the growth of both nontransformed[11] and transformed[12] fibroblasts in culture. Depending on the depleted nutrient the 3T3-4A fibroblasts cease to grow in the G1 phase or at random, whereas the transformed fibroblasts, SV3T3, only stop at random in the cell cycle. Restoration of the depleted nutrients initiates growth and cell division. Only the 3T3-4A fibroblasts that were synchronously arrested in the G1 phase of the cell cycle by deprivation of histidine and glutamine showed significant increases or decreases in cyclic GMP and cyclic AMP:cyclic GMP ratios, respectively, 20 min after addition of the depleted amino acids (Table 3). The kinetics of the changes were similar to those shown in Table 1 on growth initiation by serum (not shown). Methionine deprivation arrested cells at random in the cell

Table 3 Reinitiation of growth in amino acid-starved cultures

Culture	Labelled nuclei (%)	Cyclic AMP	Cyclic GMP	Cyclic AMP/cyclic GMP
3T3−Met	4	7.3	2.5	2.8
3T3+Met	21	7.7	4.0	2.0
3T3−His−Glu	3	10.0	0.8	13
3T3+His+Glu	86	6.5	12.5	0.5
SV3T3−Leu	1	10.0	3.8	2.6
SV3T3+Leu	67	7.6	4.9	1.6

Swiss 3T3-4A (3T3) and SV3T3 cells were grown for 3 d in complete media (Table 1) (1.0 and 6.1 $\times 10^6$ cells per dish), and then in medium containing 1/100 of the normal concentration of methionine (Met) or histidine and glutamine (His, Glu) for 3T3 (ref. 11) or 1/200 of leucine (Leu) for SV3T3 (ref. 12) (Table 1). After 3 d for 3T3 (1.8 and 1.0 $\times 10^6$ cells for minus Met or His and Glu) or 2 d for SV3T3 (5.5 $\times 10^6$ cells), half the cultures were supplemented with the normal concentrations of the depleted amino acids and nine or ten petri dish cultures were isolated from both the original starved cultures (−) and those cultures reinforced for 20 min with the added ingredients (+). The pmol cyclic nucleotides per mg cell protein and the % of cells with radioactively labelled nuclei after exposure to ^{3}H–thymidine from 8–32 h after additions were recorded as in Table 1. Cell cycle results from the average DNA content per cell measured in a microfluorometer[11] expressed as the percentage of cells in G1, S, G2 were for 3T3–Met 71, 12, 17, for 3T3–His–Glu 94, 0, 6, for growing 3T3–4A (Table 2) 57, 26, 17, for resting 3T3–4A (Table 2) 94, 0, 6, for SV3T3-Leu 38, 29, 23, for growing SV3T3 (Table 2) 45, 30, 25 (ref. 12).

cycle and no comparable changes in cyclic nucleotide concentrations were observed when it was restored (Table 3) Leucine deprivation arrested SV3T3 cells randomly throughout the entire cell cycle (Table 3) and no significant early increases in cyclic GMP levels were observed when growth was initiated by restoration of this amino acid, though cyclic AMP levels fell by about 25% after 20 min (Table 1*b*)

Addition of purified growth-initiating molecules, phytohaemagglutinin or fibroblast growth factor from bovine pituitary glands to quiescent cultures of human peripheral blood lymphocytes[13] or BALB/c 3T3 mouse fibroblasts[14], respectively, caused large early increases in intracellular cyclic GMP but little change in cyclic AMP Conversely addition of PGE$_1$, which raised intracellular cyclic AMP, reversed the induction of DNA synthesis in quiescent 3T3-4 mouse fibroblasts and stopped growth in dividing cultures[1,2] That both fibroblast growth factor and PGE$_1$ stimulated membrane-bound guanyl[14] or adenyl cyclase[1] enzymes, respectively, suggest that cyclic GMP could act as a positive while cyclic AMP acted as a negative intracellular signal for controlling the growth of cultured cells We have shown here that cyclic GMP concentrations as well as those of cyclic AMP (refs 1 and 2) are closely correlated with the growth state of different cultured fibroblasts and that parallel but reciprocal changes are observed in the cyclic nucleotide concentrations in transition between these growth states[15]

The changes in cyclic nucleotide concentrations, particularly those of cyclic GMP, are largely lost when the cells become transformed, whereas the average cyclic GMP concentrations were approximately twice as high in transformed as in nontransformed fibroblasts The failure to observe changes in cyclic GMP for transformed cells probably reflects the failure to arrest the transformed cells in the G1 or G0 phase of the cell cycle Whether this is caused by a lesion in the production of the putative pleiotypic programme of the cell[16,17] or as a consequence of the failure of fibroblastic factors from delivering their growth controlling signals[18] is still uncertain at present

We thank Dr R Dulbecco for support and encouragement, Drs R Holley and D Paul for helpful discussions, and Dr R Burk for criticism of the manuscript This work was supported in part by a fellowship from the Helen Hay Whitney Foundation to P S R, and grants from the American Cancer Society and the National Cancer Institute (USA) to W S and Dr R Dulbecco respectively The prostaglandin was a gift from Dr J Pike of the Upjohn Company

Inhibition of cell growth by oxygenated derivatives of cholesterol

CELLS growing in a chemically defined, sterol-free medium must synthesise cholesterol or, in the case of L cells, desmosterol[1] for membrane formation Studies by others showed that when cholesterol or desmosterol was added to L-cell cultures the exogenous sterol was utilised and the rate of sterol synthesis was diminished, presumably by a negative feedback mechanism[2,3] Our observations[4], however, provide new information regarding the structures of sterols that affect sterol synthesis Exogenous cholesterol and various metabolically related steroids do not inhibit sterol synthesis in mouse liver cell or fibroblast cultures under conditions where derivatives of cholesterol oxygenated in the 7, 20, 22 or 25 positions are highly inhibitory These inhibitory sterols, at concentrations of 0 02–0 2 μg ml^{-1} specifically depress the activity of the regulatory enzyme in the sterol synthetic pathway, 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase (EC 1 1 1 34), within 6 h

We now report that prolonged incubation of L cells with the inhibitory steroids diminishes the concentration of cellular desmosterol, results in the reduction or cessation of the growth of the culture, and creates a requirement for an external supply of an appropriate sterol or for a sterol precursor further along the biosynthetic pathway than HMG-CoA

L cells were grown in chemically defined medium[4] in Falcon culture flasks (25 cm^2) for 1–3 d before the introduction of the experimental media as described below The sources of the sterols and procedures used to purify them have been reported previously[4] Steroids suspended in a solution of 5% crystallised bovine albumin were added to cultures previously refed with fresh medium so that the final concentration of albumin was 0 05% or 0 1% Control cultures were fed medium containing an equivalent amount of albumin The cultures were incubated on a rotating table (20 r p m) at 37° C and the medium was renewed every 3 d At the end of the incubation period cells adhering to the flask were washed twice with physiological saline, digested with 0 1 N KOH and assayed for protein[5,6] The amount of cellular protein in a culture is a good measure of cell growth[6,7], at least during the log phase of L-cell culture[8] Our preliminary studies showed that there was a good correlation between cell number and the amount of protein or DNA in growing L-cell cultures and in cell cultures incubated with different steroids as described below

The most potent inhibitor of cell culture growth was 25-hydroxycholesterol followed, in order of decreasing activity, by 20α-hydroxycholesterol, 7-ketocholesterol, and 7α-hydroxycholesterol (Fig 1*a*) The first three sterols inhibited growth of cultures by more than 90% at 1, 2 5 and 10 μg ml^{-1}, respectively In contrast to results obtained

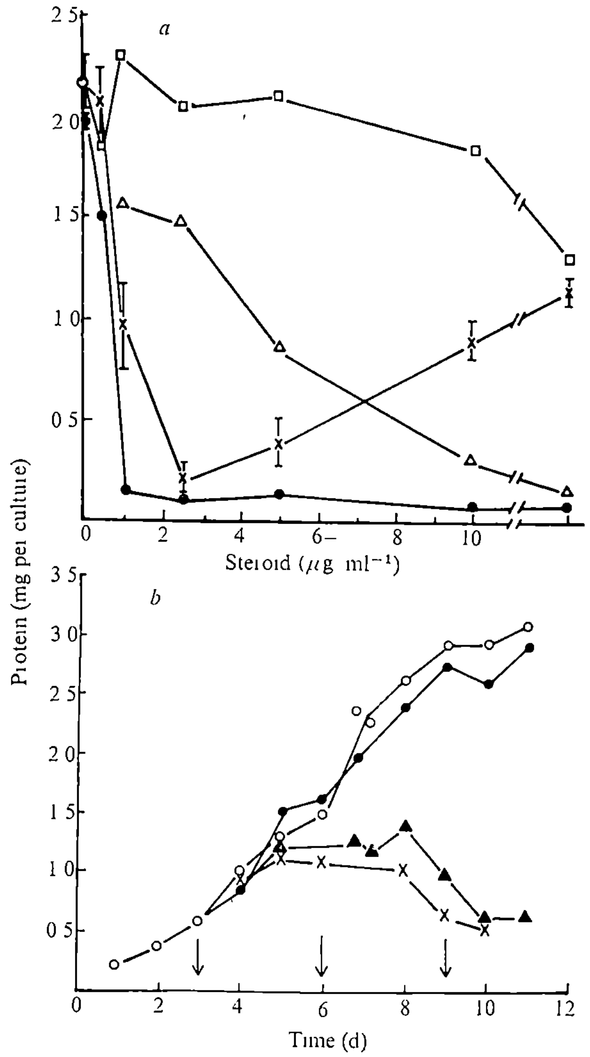

Fig 1 *a*, Inhibition of cell growth by some oxygenated derivatives of cholesterol Cultures were grown for 2 d in normal medium then in medium containing indicated concentrations of 25-hydroxycholesterol (●), 20α-hydroxycholesterol (×), 7-keto-cholesterol (△), or 7α-hydroxycholesterol (□) Cultures were refed with experimental or control media after a further 3 d and cellular protein was analysed 2 d after refeeding Vertical lines represent range of values for at least 3 replicate flasks *b*, Effects of 20α-hydroxycholesterol alone or in combination with acetate or mevalonate on the time course of cell growth Cultures were grown for 3 d in normal medium then (first arrow) in control medium (○) or in medium containing 20α-hydroxycholesterol, 10 μg ml^{-1} (▲), 20α-hydroxycholesterol, 10 μg ml^{-1} and MVA, 1 mg ml^{-1} (●), or 20 α-hydroxycholesterol, 10 μg ml^{-1} and acetate, 1 mg ml^{-1} (×) The cultures were refed with control or experimental media on days indicated by the second and third arrows

with the other inhibitory steroids, cell growth improved when 20α-hydroxycholesterol was increased beyond that required for maximum inhibition, possibly due to the utilisation of this diol to meet the sterol requirement for cell growth Under similar conditions, 7α-hydroxycholesterol at 10 μg ml^{-1} was not inhibitory but at 50 μg ml^{-1} did inhibit growth by 50% In experiments not shown, 7β-hydroxycholesterol was more inhibitory than 7α-hydroxy-cholesterol

The relative effectiveness with which these sterols inhibited the growth of cultures correlated well with their previously reported capacities to inhibit sterol biosynthesis and to depress levels of HMG-CoA reductase activity[4] Sterol concentrations required to arrest growth within 3 or 4 d, however, were several times higher than those necessary to inhibit sterol synthesis within 6 h The apparent discrepancy between these values may indicate that sterol synthesis must be almost totally blocked to obtain the marked depression in the growth of the cultures that we observed The extent to which cell growth could be adversely affected by an inhibitory sterol also depended on the stage of growth of the culture A growing, sparse culture was far more susceptible to inhibition than a nearly confluent, dense culture

Figure 1*b* illustrates the time course of the inhibitory effect of 20α-hydroxycholesterol on the growth of cultures The amount of protein in the cultures increased for the first 2 d after the addition of the sterol, remained essentially constant for about 3 d, then declined Supplementation of the medium with mevalonate (MVA), the product of the reaction catalysed by HMG-CoA reductase, counteracted the effect of 20α-hydroxycholesterol and resulted in a normal rate of growth In contrast, supplementation with acetate did not relieve the inhibitory effects of the sterol

In other experiments the inhibitory effect of 20α-hydroxy-cholesterol, 25-hydroxycholesterol or 7-ketocholesterol was abolished by the addition of desmosterol or MVA Concentrations of desmosterol and MVA required to fully counteract inhibition were about 25 μg ml^{-1} and 1 mg ml^{-1}, respectively Addition of MVA or desmosterol alone to control cultures did not appreciably alter the cell growth, suggesting that, under usual culture conditions, the rate of growth was not limited by the rate of sterol synthesis The abilities of various steroids and their precursors to counteract the inhibitory effect of a 20α-hydroxycholesterol on the culture growth are compared in Table 1 Cholesterol was nearly as effective as desmosterol, whereas cholestanol, Δ^7-cholestenol, cholest-4-en-3-one and cholest-5-en-3-one were moderately effective Other steroids, HMG, or acetate, showed little or no ability to counteract inhibition by 20α-hydroxycholesterol

Estimates of cellular desmosterol after incubation with the inhibitory sterols alone or in combination with the various additions to the medium shown in Table 1 were made after hydrolysing the washed cells with 1 N KOH in 50% ethanol for 2 h and extracting the neutral fraction with ether Sterols in the extracts were analysed by gas chromatography as the free sterols or after conversion to the trimethylsilyl ethers[4,9] After 5 d of incubation with the inhibitory sterols in amounts sufficient to inhibit cell growth by 70% or more, desmosterol concentration in the surviving cells was less than 1 μg mg^{-1} protein, markedly reduced from that of the control cells (11 4±4 μg mg^{-1} protein) When the growth inhibitory effects of 20α-hydroxy-cholesterol, or 25-hydroxycholesterol were counteracted by the addition to the medium of a non-inhibitory sterol, concentrations of desmosterol in the cells remained low

Table 1 Effect of sterols and their precursors on the growth of cells incubated with 20α-hydroxycholesterol

Additional compounds	Cellular proteins (% of the control)
None	30 ± 4 (4)*
Desmosterol	95 ± 3 (4)
MVA (sodium salt)	92 ± 1 (4)
Cholesterol	77 ± 10 (5)
5α-Cholestanol	68
Δ^7-Cholestenol	67
Cholest-4-en-3-one	57
Cholest-5-en-3-one	49
5α-Cholestan-3-one	36
β-Sitosterol	35
HMG (sodium salt)	17 ± 2 (3)
Acetate (sodium salt)	17 ± 1 (3)

All flasks except controls were incubated for 5 d with medium containing 20α-hydroxycholesterol (10 μg ml^{-1}) and additional compounds as indicated (steroids, 50 μg ml^{-1} MVA, HMG, and acetate, 1 mg ml^{-1})

*Mean ± s e Numbers in parentheses indicate number of experiments

If, however, the medium contained mevalonate instead of a non-inhibitory sterol, desmosterol increased to 12.8±2.6 μg mg^{-1} protein, and several unidentified sterol peaks were also present on the chromatogram. Small amounts of the inhibitory sterols and larger amounts of the non-inhibitory sterols administered with the inhibitors were detected in the cell extracts.

The results of these experiments demonstrated that L cells became severely deficient in desmosterol when incubated with certain oxygenated derivatives of cholesterol which specifically inhibit sterol biosynthesis at the level of HMG-CoA reductase. The growth of the cultures was then greatly depressed unless an appropriate sterol or sterol precursor was supplied exogenously. Several explanations of the effect of the inhibitory sterols on culture growth can be brought forward. Possibly the inhibitory sterols compete with desmosterol for sites in the membrane with resulting effects on membrane function. Specific repression of HMG-CoA reductase activity by the inhibitors would then be a coincidental and unrelated effect. We believe that it is more likely that the effects of the inhibitors on cell growth stem from repression of the enzyme activity and the subsequent restriction of sterol synthesis. Partial depletion of cholesterol from erythrocytes and mycoplasma results in increased membrane fragility[10,11], so that the growth retardation of L-cell cultures that were unable to synthesise sterols may have been due to membrane instability and cell death. On the other hand, it is now apparent that altering the sterol concentration of artificial cell membranes, and membranes of erythrocytes or mycoplasma changes the fluidity of the membrane, the rates at which various substances are transported through the membrane, and the activities of membrane-localised enzymes[12-14]. Thus, the inhibitory sterols may influence growth of the culture in ways other than by increasing membrane fragility.

For the first time the amount and kind of sterol in living mammalian cells can be manipulated through the use of specific inhibitors of sterol synthesis so that it should be possible to investigate in detail the role of sterols in membrane structure and function and their relationship to cell growth.

Morphological and functional maturation of human thymic epithelium in culture

ORGAN culture of embryonic avian and murine thymus[1-5], as well as explants of guinea pig and rabbit thymus[6-10], have been observed to produce outgrowths which in some cases were described as predominantly lymphoid in nature, epithelial in other cases. Two publications have described human embryonic thymus in culture, using the plasma clot technique[9,10]. We have established epithelial outgrowths from explants of human thymic tissue and maintained these cultures for periods up to 3 months.

Fresh thymic tissue was obtained at surgery from 20 children, ranging in age from 1 week to 13 yr, with various surgically correctable cardiac lesions. Capsular tissue and haemorrhagic areas were dissected away and the remaining tissue was finely minced in Dulbecco's modification of Eagle's medium, containing 100 units ml^{-1} of penicillin, 100 μg ml^{-1} of streptomycin, and 2.5 μg ml^{-1} of amphotericin-B, supplemented with 30% foetal bovine serum (FBS, Flow Laboratories). The preparation

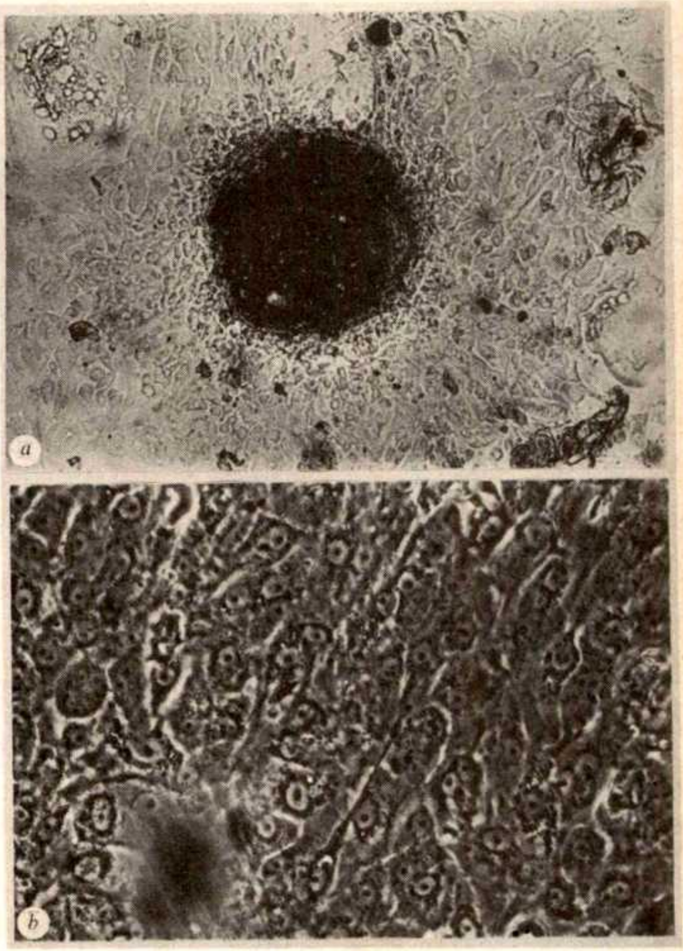

Fig. 1 Living cultures of human thymic epithelium at 30 d. *a*, The primary explant is present as a dense central mass with a surrounding monolayer of large epithelial cells in a mosaic-like arrangement (× 26); *b*, phase contrast shows the cells to have a large central nucleus with a prominent central nucleolus and marked cytoplasmic granularity (× 104).

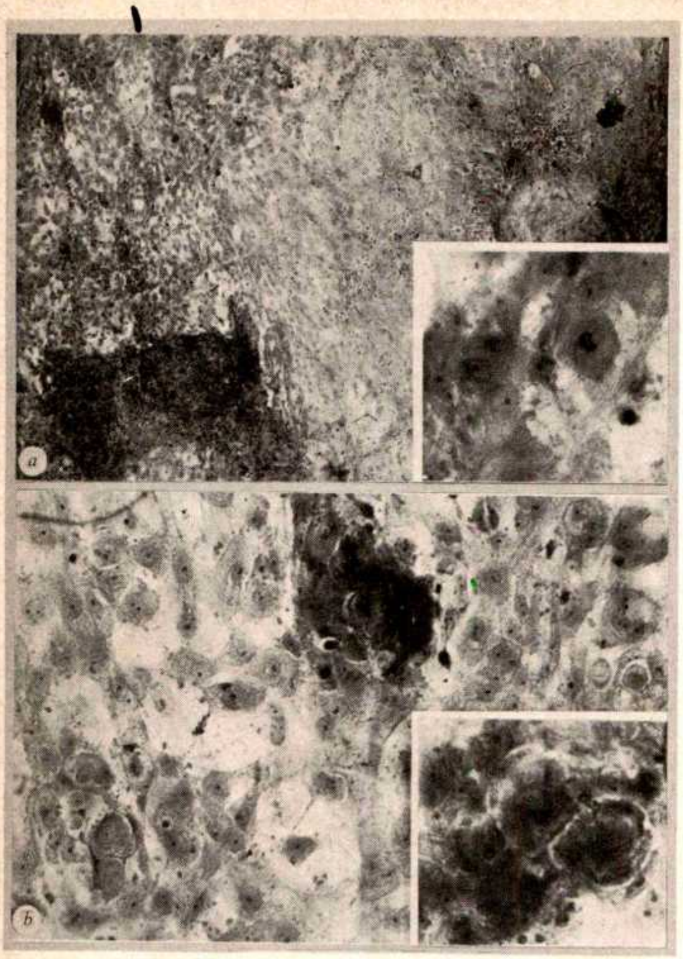

Fig. 2 Ten day culture of human thymus on glass coverslip, fixed *in situ* and stained with haematoxylin and eosin. *a*, Two primary explants are present as dense masses of dark-staining cells, with the epithelial outgrowth spreading between the two explants as sheets of large cells with abundant, somewhat granular cytoplasm (× 3.76). Inset, mitotic figure at the periphery of advancing epithelial growth (× 60.16); *b*, cell aggregates resembling Hassal's corpuscles in various stages of development; left lower corner: a group of cells showing early cyst formation with cell crescenting (× 37.60). Inset, dense aggregate of cells arranged in concentric patterns around central amorphous eosinophilic material (× 60.16).

was then washed with a threefold volume of the same medium, allowed to settle for 5 min at room temperature, and the resultant cell suspension removed by pipette. The tissue fragments remaining were washed three times by this method, then transferred to culture. In most cases the fragments, in a small volume of medium sufficient only to cover the culture surface, were added to plastic tissue culture flasks (Falcon number 3012 and 3024). In several cases, fragments were also cultured in plastic tissue culture dishes (Falcon number 3005) with and without 22 mm glass coverslips, to be subsequently fixed and stained for cell morphology. Incubation was at 37° C in a humidified atmosphere containing 5% CO_2. On day 3, an equal volume of fresh medium was added.

By days 5–7 an epithelial outgrowth, twice the diameter of the explant, was observed. The medium was replaced twice weekly until a confluent monolayer was obtained, when the FBS concentration in the medium was reduced to 20%. Medium collected from the cultures (conditioned medium) was centrifuged at 550*g* for 10 min at 10° C and the supernatant removed and stored at −20° C. In all flasks an outgrowth of large epithelial cells from the explants was seen (Fig. 1) which produced a confluent monolayer, usually by day 14. Cells morphologically identified as fibroblasts were present in all cultures and persisted in most cases as a 5–10% contamination of the monolayer.

Explants grown on coverslips were fixed *in situ* and stained with haematoxylin and eosin. Aggregates of cells arranged concentrically around central amorphous eosinophilic material were seen scattered singly and in groups in the epithelial outgrowth, both adjacent to and remote from the primary explanted tissue (Fig. 2). These resembled Hassal's corpuscles as seen in sections of normal thymic tissue. Cultures fixed and embedded *in situ* in plastic flasks were examined with the electron microscope and showed desmosome formation between cells, confirming their epithelial nature.

Decrease in the concentration of FBS in the medium below 30% at the time of initial explantation resulted in a proportionate decrease in the rate of epithelial growth but had no effect on fibroblast growth. Consequently, cultures with 20% FBS were overgrown by fibroblasts within 30 d, while those with 10% FBS were overgrown in 14–20 d. When single cell suspensions were cultured in the same conditions, fibroblast growth predominanted. Thymic lymphocytes showed a gradual decrease in number with time in culture, as shown by Wright-Giemsa staining and E rosette formation (a marker of T lymphocytes)[11] of cells shed into the medium from the monolayers, until none was detectable by these means at 30 d in culture.

Conditioned medium collected from the cultures and stored frozen was examined for its ability to influence the capacity of human marrow cells to form rosettes with sheep erythrocytes at 4° C (E rosettes). Marrow obtained by aspiration was separated on Isopaque-Ficoll gradients[11] to remove erythrocytes and enrich for lymphoid cells. Cells from the gradient interface were washed three times with phosphate-buffered saline. Some of the cells were resuspended in PBS to a concentration of 3×10^6 nucleated cells ml^{-1} and assessed for rosette formation after 2 h at 4° C (ref. 11). Rosettes were also enumerated by counting the remaining cells after incubation for 180 min at 37° C with fresh medium, conditioned medium from thymus cultures, and conditioned medium from Chang human liver cells (Flow Laboratores). The results (Table 1) suggest that conditioned media from confluent human thymic epithelial monolayers only were capable of increasing the capacity of unfractionated human marrow cells to form rosettes with sheep erythrocytes in the cold, while non-lympoid cells (Chang human liver), peripheral blood lymphocytes, tonsillar lymphocytes, and cells from an established line of B lymphocytes were unaffected by the conditioned media. The most effective thymic conditioned media were obtained when thymic lymphocytes were no longer present in the cultures.

Table 1 Percentage of E rosettes

Test media	Marrow A	Marrow B	Marrow C	Cell preparation: Peripheral blood lymphocytes	Tonsillar lymphocytes	Cultured human lymphocytes	Cultured human liver (Chang)
Saline	5	17	14	50	29	0	0
Medium	10	12	12	37	21	0	0
Chang	13	13	13	49	24	0	0
Thymus	22	33	32	46	27	0	0

Bone marrow cells from three donors (A, B, and C) were separated on Isopaque-Ficoll gradients, washed three times with phosphate-buffered saline (PBS) and adjusted to 3×10^6 nucleated cells ml^{-1}. A portion of cells were resuspended in PBS and examined for rosette formation with sheep erythrocytes at 4° C (E rosettes). Other portions were resuspended in 1 ml of test medium: fresh medium containing 20% FCS; Chang: conditioned medium from confluent monolayers of Chang human liver cells, stored at −20° C; thymus: conditioned medium from various confluent monolayers of human thymus epithelium, stored at −20° C), incubated at 37° C for 3 h, washed twice with PBS, resuspended in PBS to 3×10^6 nucleated cells ml^{-1}, and examined for formation of E rosettes. Rosettes were evaluated after 2 h at 4° C, and are expressed as a % of nucleated cells present. The capacity for formation of E rosettes of the control cells was unaffected by the thymus culture conditioned media, but the marrow cells showed an increase in E rosette formation with these conditioned media.

A differentiation process within the thymus of lymphocytes originating from stem cells in haematopoietic tissues is central to the concept of a distinct thymus-derived or T-cell population of circulating lymphocytes[12] Evidence for cell-free thymic differentiation factors has been based on reconstitution *in vitro* and *in vivo* of several immune functions and T-cell associated markers in thymectomised and nude mice, using extracts of fresh bovine and murine thymic tissue[13-17] The epithelial stroma of the thymus has been suggested as the source of such differentiation factors[18] Our observations suggest that an epithelium of apparent thymic nature may be obtained *in vitro* from human tissues and that this epithelium may be a source of a factor or factors with biological activity similar to those extracted from fresh bovine and murine thymus

This work was supported by the Medical Research Council of Canada (MA 4875) and the National Cancer Institute of Canada The thymus specimens were provided by the Department of Cardiovascular Surgery and the tissues for electron microscopy and light microscopy were prepared by the Department of Pathology, The Hospital For Sick Children, Toronto Ontario

Asbestos induces selective release of lysosomal enzymes from mononuclear phagocytes

THE association of asbestos inhalation and lung disease has been recognised for many years[1] Asbestosis is a chronic inflammatory reaction in the terminal bronchioles and alveoli of the lung with considerable fibrosis leading to distortion and eventual obliteration of the alveoli There is also an association between asbestosis and the development of bronchogenic cancer[2] and Wagner *et al*[3] have noted the occurrence of diffuse pleural and peritoneal mesotheliomas in individuals occupationally exposed to asbestos dust and in experimental animals following intrapleural injection of asbestos

It as accepted that the initial event after inhalation of toxic particules such as asbestos is their attachment to and often phagocytosis by mononuclear phagocytes (MP) in the pulmonary alveoli[4] As we consider that MP play a central role in the generation of chronic inflammatory lesions[5], we have analysed the interaction of this type of cell with asbestos *in vitro* Previous studies have illustrated the phagocytosis of asbestos by MP (refs 4 and 6) while biochemical evidence of the cytotoxic effects of relatively high doses of asbestos on MP has been provided by Miller and Harington[7] We now show that asbestos, in common with several other substances such as dental plaque[8], immune complexes[9], streptococcal cell walls[10,11] and carrageenan[12]—all of which cause chronic inflammation *in vivo*—induces a rapid, massive and selective release of lysosomal enzymes from MP The release occurs in the absence of any detectable cell death and is accompanied by considerable increases in cellular levels of nonlysosomal enzymes

Our studies have been carried out with cultures of mouse peritoneal MP which are derived from the same bone marrow precursors as the majority of alveolar macrophages[13,14] and are obtainable in sufficient quantities for detailed biochemical investigation MP exposed to asbestos (UICC chrysotile A, 1–50 μg ml^{-1}) show characteristic morphological changes The cells phagocytose asbestos and an increase in the number of cytoplasmic vacuoles, probably secondary lysosomes, is seen At higher doses (25–50 μg ml^{-1}) the cells tend to form clusters and some rounding is seen although the majority of cells retain the cytoplasmic extensions characteristic of normal MP

Measurement of the total level of lysosomal enzymes in MP cultures after exposure to asbestos for 24 h shows that in general there are no significant changes (Table 1) There is, however, a marked redistribution of lysosomal enzyme activity between cells and culture medium (Table 1), significant increases in the proportions of enzymes in the culture medium being seen with concentrations of asbestos as low as 1 μg ml^{-1} This release is directly proportional to the concentration up to 50 μg ml^{-1} The absolute amount of enzyme activity in the culture medium also increases in a dose-dependent fashion

The selective nature of the lysosomal enzyme release is illustrated in Fig 1 Asbestos at concentrations up to 50 μg ml^{-1} causes no significant increase in the amount of

Peritoneal exudates were collected from outbred Swiss mice of either sex 3 d after intraperitoneal injection of 2 ml of proteose-peptone cell suspensions (5 ml) adjusted to a count of 0 8 × $10^6\ ml^{-1}$ were plated in 48-mm Petri dishes (Nunc Jobling Laboratories Division, Stone, Staffs, UK) After culture for approximately 1 h at 37° C in a 5% CO_2 in air atmosphere the medium containing non-adherent cells was removed and the remaining cell sheet washed four times with 4 ml aliquots of phosphate-buffered saline The cells were then cultured overnight in M199 containing 10% (heat-inactivated at 56° C for 30 min) swine serum (Bio-cult Laboratories Ltd , Glasgow, Scotland), Chrysotile asbestos (UICC standard) was sonicated (MSE ultrasonic disintegrator) in serum-free M199 for 2 min M199 and swine serum was then added to give the desired concentration of asbestos and a final swine serum concentration of 10% Asbestos was preincubated in medium overnight Before adding asbestos the cultures were washed twice with phosphate-buffered saline After exposure to asbestos for 24 h the cultures were assayed for various enzymes After removal of the culture medium the cells were removed in 0 1% TX-100 in 0 9% w/v sodium chloride containing 0 1% bovine serum albumin The samples were assayed for N–acetyl–β–D–glucosaminidase[15], β–gluroronidase[16] and β–galactosidase[17] activity by spectrophotometry on a Gilford N–300 spectrophotometer Each value represents the mean ± standard deviation of four observations

* $P < 0\ 05$

† $P < 0\ 01$.

lactate dehydrogenase detected in the culture medium Moreover, even small amounts of asbestos induce highly significant increases in cellular levels of this enzyme (Fig 1, $P > 0\ 01$ at 2 $\mu g\ ml^{-1}$ asbestos) This increase continues in a dose-dependent manner up to 10 $\mu g\ ml^{-1}$ asbestos, above which lactate dehydrogenase activity remains at a constant elevated level Similar increases were observed with another non-lysosomal, smooth membrane associated enzyme, leucine-2-naphthylamidase

The time dependence of the selective release of lysosomal enzymes caused by asbestos is shown in Fig 2 MP cultures exposed to asbestos (50 $\mu g\ ml^{-1}$) show no change compared to control cultures, in the distribution of a representative lysosomal enzyme, β-galactosidase, between cells and culture medium for the first 3 h By 4 5 h, however, a highly significant increase ($P < 0\ 01$) in the amount of β-galactosidase in the medium is seen Subsequently a rapid rise in the release of enzyme into the culture medium occurs so that by 24 h approximately 70% of the total enzyme activity is found in the culture medium As in the other experiments described in Table 1 and Fig 1, this release occurs with no detectable loss of cellular lactate dehydrogenase into the culture medium and significant increases in cellular levels of this enzyme at 24 h The delay in release is most probably due to the coating of ingested asbestos fibres with plasma proteins These proteins are removed within secondary lysosomes by proteolytic digestion thereby exposing the membrane reactive sites, probably magnesuim ions[19], on the asbestos fibres It is thought that the magnesium groups of asbestos interact with membrane sialoglycoproteins[20] and it is possible that such an interaction leads to the formation of protein clusters in membranes, a phenomenon observed during exocytosis in other systems[21] The toxic effect of silica on MP is well established and is attributed to the formation of hydrogen bonds between hydroxyl groups of silicic acid and membrane phospholipids Silica does not cause any selective release of lysosomal enzymes (P D , A C A , J A , A B and S W , unpublished), the appearance of acid hydrolases in the culture medium being accompanied always by lactate dehydrodgenase These observations support the concept that clustering of membrane proteins is an essential prerequisite to membrane fusion such as occurs during exocytosis[22]

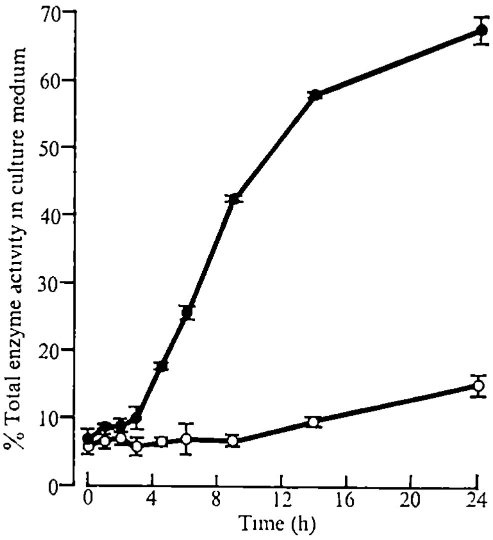

Fig 2 The time dependence of β- galactosidase release from MP induced by asbestos MP cultured in the presence (●) and absence (○) of asbestos (50 $\mu g\ ml^{-1}$) were removed at various times for enzyme assay Each value represents the mean ± standard deviation of four observations Experimental conditions as described in Table 1

The sensitivity of MP cultured *in vitro* to toxic particules such as asbestos and silica provides a simple and sensitive way of screening various particulate substances for possible toxic effects It is insufficient to monitor cell viability, however We have demonstrated that asbestos can release a large proportion of cellular content of MP acid hydrolases without detectable cell death It is essential to determine the distribution of lysosomal enzymes between cells and culture medium This type of estimation is particularly relevant since several agents which cause chronic inflammation *in vivo* induce selective release of lyososomal enzymes from MP *in vitro*[8–12], accordingly we have found (M Dym, P D , and A C A , unpublished) that asbestos produces an intense granulomatous reaction after intramuscular injection in mice

After intrapleural injection of asbestos, a marked mononuclear reaction is also observel, this subsides shortly before mesotheliomas appears[23], raising the possibility that the mononuclear phagocytes in the granuloma prevent the multiplication of malignant cells[24] so delaying the appearance of the tumour

The results reported here have relevance in at least four different fields of study First, the experimental system used provides a simple and sensitive *in vitro* test for the possible cytotoxicity of particulate substances Second, our observations on the selective release of lysosomal enzymes from MP by asbestos provide further support for the possibility that this phenomenon may be responsible for certain aspects of tissue damage seen in chronic inflammation[5,12] Third, the use of biologically active substances of defined chemical structure such as asbestos may provide a useful research tool for determining the nature of membrane constituents involved in changes which lead to membrane fusion[22] Fourth, some granuloma-inducing material other than asbestos might be administered by intrapleural injection to persons who have in the course of their occupations been exposed to asbestos so as to maintain a local granulomatous reaction which might prevent the appearance of mesotheliomas and bronchogenic cancer

Modulation of corticotrophin-releasing factor release from hypothalamic synaptosomes

NERVE endings (synaptosomes) isolated from the mammalian hypothalamus contain the hypophysiotrophic hormones which regulate adenohypophysial function Edwardson *et al* have shown[1] that release of these neurosecretory substances can be elicited from incubated hypothalamic synaptosomes by electrical or potassium stimulation and the release mechanism has been shown[2] to be calcium dependent We report here that steroid hormones administered both *in vivo* and *in vitro* and neurotransmitter substances given *in vitro* modulate the release of corticotrophin-releasing factor (CRF) from synaptosomes prepared from rat and sheep hypothalamus

Adult rats were given corticosterone acetate in drinking water (20 μg ml^{-1}) for a period of 20 h (average dose, 300 μg per rat) before being killed Synaptosomes were prepared from the hypothalami by a modified[3] version of the method of Gray and Whittaker[4] and suspended in Krebs-bicarbonate medium containing 10 mM glucose Suspensions of synaptosomes were incubated and stimulated electrically in Warburg respirometer vessels fitted with concentric gold ring electrodes as described previously[1] After incubation the preparations were centrifuged and the supernatant medium was tested for CRF activity Paired halves of rat adenohypophyses were incubated in 1 ml of the medium and adrenocorticotrophic hormone (ACTH) release was measured by radioimmunoassay[5] The antiserum used was raised against the species common, steroidogenic α1-24ACTH and does not show significant cross reaction with pituitary melanocyte-stimulating hormone

Medium from stimulated synaptosomes prepared from untreated rats gave a 61% increase in ACTH release compared with medium from unstimulated preparations (Table 1) Pretreatment with corticosterone completely abolished this response This was due to absence of CRF rather than to an inhibitory effect of the medium on the pituitary response, since a test stimulus of 40 mU vasopressin added with the same synaptosome medium produced a 144% increase in ACTH release

Table 1 The effect of *in vivo* pretreatment with corticosterone on the release of CRF by synaptosomes from rat hypothalamus

Preparation	No of experiments	ACTH released (ng ml^{-1}) Unstimulated	ACTH released (ng ml^{-1}) Electrically stimulated	% Increase
Untreated	5	28 1 ± 4 3	45 9 ± 8 5*	61
Corticosterone pretreatment *in vivo*	6	20 0 ± 2 7	19 8 ± 2 4	0
Corticosterone pretreatment *in vivo* + vasopressin test *in vitro*	6	18 6 ± 2 0	45 5 ±.4 2	144

Values were determined by radioimmunoassay using α1-24 antibodies and represent ACTH released from paired halves of rat adenohypophyses during a 45 min incubation period at 37° C with synaptosome supernatant Corticosterone was administered in the drinking water for 20 h before preparation of synaptosomes (average dose 300 μg per rat) A dose of 40 mU ADH was added to medium from stimulated synaptosomes prepared from corticosterone pretreated rats to show that the response of the test pituitary was normal

*Wilcoxon test, $P < 0 05$

Table 2 The effect of steroids on the release of CRF produced by electrical stimulation of synaptosomes from the sheep hypothalamus

Hormone	Concentration (M)	No of experiments	ACTH released ng ml^{-1} Unstimulated	Stimulated	% Increase
None	—	10	28.5 ± 4.0	59.3 ± 7.5*	108
Corticosterone	7.5×10^{-7}	6	31.3 ± 4.2	36.3 ± 5.9	16
Cortisol	6.0×10^{-7}	5	49.2 ± 13.3	48.4 ± 13.1	0
Cortisol	6.0×10^{-8}	6	62.3 ± 8.2	62.9 ± 12.0	10
Cortisol	6.0×10^{-9}	5	49.1 ± 4.8	65.4 ± 8.1	33
Deoxcorticosterone	8.0×10^{-7}	6	34.7 ± 4.0	58.9 ± 8.7†	70
Deoxycortisol (Substance S)	8.5×10^{-7}	5	43.4 ± 7.5	88.2 ± 18.0‡	101
Progesterone	9.5×10^{-7}	3	42.1 ± 6.4	68.2 ± 13.1	62
Oestradiol	1.1×10^{-6}	3	37.6 ± 6.2	57.0 ± 8.5	52
Deoxycortisol + cortisol	8.0×10^{-7} 6.0×10^{-7}	3	21.3 ± 4.3	42.2 ± 6.0	99

Values were determined by radioimmunoassay, as explained in Table 1 (means ± s.e.m.). Steroids were present during a 35 min incubation of synaptosomes and electrical stimulation was for 25 min. Wilcoxon test, $^*P<0.005$, $^\dagger P<0.025$, $^\ddagger P<0.05$.

A direct action of corticosteroids on the nerve ending was shown in further experiments with synaptosomes from the hypothalami of sheep killed by exsanguination. This species was chosen because of the relatively large amount of hypothalamic tissue available compared with the rat, and the synaptosomes were prepared as described previously. Steroid hormones were added to synaptosome suspensions which were incubated for 15 min without stimulation, followed by 25 min electrical stimulation. Hormones were added to the controls after stimulation to eliminate any differences due to inhibition of ACTH release by steroid in the medium. Where solubility of the steroid hormones in medium did not permit direct addition to the synaptosome suspension, they were first dissolved in absolute ethanol, placed in the Warburg vessels and evaporated to dryness before the synaptosomes were added.

Medium from synaptosomes stimulated in the absence of steroids produced a 108% increase in ACTH secretion compared with medium from the unstimulated preparation (Table 2). This stimulation of ACTH release was reduced to 16% by the presence of corticosterone at 7.5×10^{-7} M and completely abolished by cortisol at the same concentration. These concentrations of steroid are comparable with amounts present in the circulation but may not be physiological because of the absence of the plasma proteins to which they are normally bound. Cortisol, the chief glucocorticoid in the sheep, did however, block CRF release at 6.0×10^{-8} M and even at 6.0×10^{-9} M produced a substantial inhibition. The small size of this effective dose, which approximates to the levels of unbound cortisol in blood measured during stress, and its action within a relatively short time suggest that the neurosecretory nerve terminal may be an important site of action in the fast feedback control of ACTH release by corticosteroids which has been described recently[6].

The results in Table 2 show that there is some variation in the control values for ACTH secretion. The assay procedure involved the use of paired halves of adenohypophyses for simultaneous testing of stimulated and unstimulated preparations, however, and a valid comparison can be made between these two groups using the Wilcoxon matched-pairs signed-ranks test.

Results obtained with other steroids, suggest that the inhibitory effect of CRF release may be of a relatively specific nature. Progesterone and 17β-oestradiol at a higher molar concentration than cortisol produced a partial inhibition of CRF release. It has been shown[7], however, that a hormone such as 17αOR-progesterone, which has no glucocorticoid activity, may suppress the stress-induced release of ACTH in rats. The failure of deoxycortisol, the immediate precursor of cortisol in adrenal steroidogenesis, to inhibit CRF release is of interest. Preliminary experiments have shown that after preincubation with deoxycortisol, cortisol is no longer effective in inhibiting the electrically

Table 3 The effect of neutrotransmitters on the release of CRF by synaptosomes isolated from the sheep hypothalamus

Test	Concentration (M)	No of experiments	ACTH release (ng ml^{-1}) Control	Experimental	% Increase
Electrical stimulation (E)	—	10	28.5 ± 4.0	59.3 ± 7.5*	108
Acetylcholine (E)	4.4×10^{-11}	5	45.3 ± 7.8	76.9 ± 13.3	69
Acetylcholine (E)	2.2×10^{-10}	5	44.7 ± 7.4	102.2 ± 22.0†	142
Acetylcholine (E)	4.4×10^{-9}	6	38.4 ± 6.1	123.7 ± 15.2*	223
Atropine (C, E) + acetylcholine (E)	2.9×10^{-9} 4.4×10^{-9}	6	34.7 ± 6.7	41.8 ± 7.3	21
Dopamine (E)	6.5×10^{-8}	4	25.9 ± 5.4	25.7 ± 3.5	0
Dopamine (C, E) + acetylcholine (E)	6.5×10^{-8} 2.2×10^{-10}	6	49.9 ± 3.8	62.6 ± 6.4	25
Dopamine (C, E) + electrical stimulation (E)	6.5×10^{-8}	6	48.3 ± 5.6	52.8 ± 2.3	9
Noradrenaline (C, E) + acetylcholine (E)	6.0×10^{-8} 2.2×10^{-10}	3	29.6 ± 1.7	69.6 ± 19.4	135
5-Hydroxytryptamine (C, E) + acetylcholine (E)	5.5×10^{-8} 2.2×10^{-10}	3	32.9 ± 5.0	79.7 ± 6.4	142

Values were determined by radioimmunoassay as explained in Table 1. Where a single neurotransmitter is indicated as the test, this was present in the experimental flask (E) only. Where the effects of neurotransmitters or atropine on the release of CRF evoked by electrical stimulation or acetylcholine were investigated the former agents were present in both control (C) and experimental (E) flasks. Neurotransmitters were present during the 35 min incubation of synaptosomes and electrical stimulation, when used, was for the last 25 min of this period. CRF release in the presence of noradrenaline and 5-hydroxytryptamine alone did not differ significantly from control unstimulated values. None of the transmitters at the concentration used had a direct effect on the pituitary response to medium from stimulated synaptosomes. Wilcoxon test, $^*P<0.005$, $^\dagger P<0.025$

stimulated release of CRF and the results suggest that competitive inhibition may occur for binding sites which exist at the level of the nerve terminal These results are in good agreement with those[5] obtained from *in vivo* studies on the interactions of corticosteroids involved in feedback control of ACTH secretion The findings are of particular interest in that they suggest a physiological action of a steroid hormone which does not involve a nuclear site

Further evidence that the neurosecretory terminal is an important target for substances involved in the modulation of the hypophysiotrophic activity of the hypothalamus was obtained when neurotransmitter substances were added to suspensions of synaptosomes prepared from the sheep hypothalamus (Table 3) Acetylcholine in concentrations varying from $4\ 4\times10^{-9}$ to 10^{-11} M stimulated the release of CRF in a dose-dependent manner The response was not enhanced by eserine (results not shown) but it was blocked in the presence of atropine ($2\ 9\times10^{-9}$ M) suggesting the existence of specific cholinergic receptors on the CRF containing nerve terminal Dopamine ($6\ 5\times10^{-8}$ M) blocked the release of CRF produced by acetylcholine or electrical stimulation Noradrenaline at similar concentrations caused only a partial inhibition of CRF release and 5-hydroxytryptamine was without effect The results are compatible with findings obtained in the whole animal[9-11] and with the isolated hypophysiotrophic hypothalamus[12] *in vitro* and are consistent with an excitatory cholinergic and inhibitory dopaminergic modulation of CRF secretion The effects obtained with acetylcholine and dopamine on synaptosomes probably require that axo-axonal endings be present in the median eminence if the results obtained *in vitro* are to to be considered as having any relation to what may be happening *in vivo* While it seems likely that such dopaminergic terminals exist[13] there is at present no anatomical evidence for a cholinergic synapse with neurosecretory neurones in the median eminence In view of the specificity and sensitivity of the effect obtained with acetylcholine, however, we suggest that humorally mediated neurotransmitter may be active at the nerve ending *in vivo* The findings obtained with steroids and neurotransmitters emphasise the potential importance of control mechanisms which may operate at the level of the neurosecretory nerve terminal in neuroendocrine integration

Seasonal variation in sensitivity of guinea pig tissues to agonists

WE have observed a marked and consistent seasonal variation in the sensitivity of guinea pig tissue to acetylcholine (ACh) Ilea taken from guinea pigs during the summer months (May to September) were much less sensitive to the stimulant effect of ACh than those removed during the winter (November to February) Dawson, Hemsworth and Stockham[1] also noted that the response of the ileum to spasmogens varied widely at different times of the year, but they gave no specific details

The purpose of these preliminary investigations was to see whether two other smooth muscle stimulants, 5-hydroxytryptamine (5-HT) and potassium chloride (KCl), which act in different ways from that of ACh, showed a similar change in sensitivity The stimulant action of 5-HT is mediated mainly through stimulation of nervous elements causing the release of endogenous ACh, but it also has some direct action on the longitudinal muscle[2] KCl is believed to use a different source of calcium from that of ACh when causing contraction of smooth muscle[3]

To see whether heart muscle also showed different sensitivity in the summer and winter we studied the positive chronotrophic effect if isoprenaline on isolated guinea pig atria

Male guinea pigs weighing 250–500 g were used They were housed in uniform conditions, three per cage in rooms maintained between 22° C and 25° C throughout the year The animals were fed on a standard diet of food pellets, (Amber Ltd) mixture number 19350 The pellets were coated with absrbic acid, 1 mg g^{-1} The average daily intake of ascorbic acid was 50–60 mg per guinea pig

Guinea pigs were killed by cervical dislocation and a 4 cm piece of ileum was removed about 20 cm from the ileocaecal junction The ileum was suspended in a 5 ml isolated organ bath containing Krebs-Hensleit solution aerated with a mixture of 95% O_2 and 5% CO_2, at a tension of 1 5–2 g, and maintained at a temperature of 36°–37° C Responses of the ileum to the spasmogens were recorded isotonically with a Statham strain gauge on a multichannel polygraph

Isolated guinea pig atria were set up under the same conditions, but the temperature was reduced to 30°–31° C Dose-response curves were established to ACh, 5-HT and KCl on guinea pig ileum by adding the drug at 2 min intervals, the bath fluid was changed after each dose On isolated atria cumulative dose-response curves for the increase in chronotrophic effect were obtained for isoprenaline by adding increasing amounts of the amine to the bath and washing out only after a maximum increase in rate was achieved, as described by Weinstock *et al*[4]

The concentration of drug in each case required to give 50% of the maximum response (ED_{50}) was determined The winter and summer values, for the ED_{50} for ACh, 5-HT, KCl and isoprenaline are shown in Table 1

The change from summer to winter brought about a general increase in sensitivity (lower ED_{50}) of both cardiac and smooth muscle to adrenergic and cholinergic agents Moreover, the difference in responsiveness of the ileum in the winter from that in the summer was much greater for ACh and 5-HT than for KCl Such a change in response of smooth muscle to agonists is reminiscent of the nonspecific increases in sensitivity seen after de-

Table 1 Seasonal responses of isolated guinea pig tissues to various agonists

Tissues	Drug	Season	*n*	ED$_{50}$ mean ± s e (ng ml^{-1})	Level significant (between winter + summer values)
Ileum	Acetylcholine	Nov–Feb 1971–72	6	2 7 ± 0 8	0 001
Ileum	Acetylcholine	May–Sept 1972	13	40 0 ± 4 7	
Ileum	Acetylcholine	Nov–Feb 1972–73	9	6 5 ± 0 6	0 002
Ileum	Acetylcholine	May–Sept 1973	15	44 6 ± 10 2	
Ileum	Acetylcholine	Nov–Feb 1973–74	12	6 0 ± 1 1	
Ileum	5-Hydroxytryptamine	May–Sept 1973	6	1,250 ± 25	0 001
Ileum	5-Hydroxytryptamine	Nov–Feb 1973–74	8	16 9 ± 3 3	
Ileum	Potassium chloride	May–Sept 1973	6	0 79 ± 0 17 mg ml^{-1}	0 05
Ileum	Potassium chloride	Nov–Feb 1973–74	5	0 31 ± 0 06 mg ml^{-1}	
Atria	Isoprenaline	May–Sept 1973	8	3 60 ± 0 68	0 001
Atria	Isoprenaline	Nov–Feb 1973-74	5	0 184 ± 0 004	

centralisation or reserpine treatment, Westfall[5] found that the increase in response of the guinea pig vas deferens to noradrenaline and methylfurmethide (a cholinergic stimulant) was greater than that to KCl

Dawson, Hemsworth and Stockham[1] found that a daily intake of 50 mg of ascorbic acid in the diet of guinea pigs resulted in an increase in sensitivity of the ileum to spasmogens As in our study the animals received this amount of ascorbic acid daily throughout the year, however, we have to seek a different explanation for the seasonal supersensitivity

All our experiments were carried out in solutions of identical calcium and magnesium ion concentration, which suggests that the difference in seasonal response, like that after decentralisation, may be related to a change in some property of the membrane binding site for calcium It does not seem to be due to a change in blood level of thyroxine, since it has been shown that this hormone increases sensitivity of the guinea pig heart to catecholamines but decreases the responsiveness of the ileum to ACh (ref 6) It may, however, be related to cyclic enzymatic or other endocrinological changes Johansson and Santuria[7] reported that the guinea pig heart has a higher noradrenaline level in the summer than in the winter, which could explain the reduced sensitivity to exogenous isoprenaline They also found that serum calcium and potassium were higher in the winter than in the summer

We would be interested to hear whether a similar change in sensitivity of guinea pig tissues occurs in other laboratories, particularly in those in which winter falls in June-July and whether tissues from other laboratory animals are similarly affected

Morphological evidence for an experimentally induced synaptic field

WHEN fibres in the central nervous system (CNS) of invertebrates and lower vertebrates are interrupted, regenerating axons grow beyond the lesion and form new synapses on denervated neurones In the leech CNS, however, we have seen synapses formed by the regenerating fibres at the site of the lesion The formation of synapses in regions where they are normally absent raises important questions about the manner in which axons grow to their targets and form orderly connections

The CNS of the leech consists of segmental ganglia and longitudinal connectives The ganglia have a cell rind formed by nerve cell perikarya and a central fibrous neuropile containing most of the synapses The neuropiles are joined together by the connectives, which include axons of interneurones and sensory nerve cells The axons (0 1–9 μm in diameter) run caudally and rostrally and form three longitudinal bundles of fibres associated with the cytoplasm of two giant glial cells The cells are found in the two lateral bundles and their nuclei lie between successive ganglia[1–4] Many of the nerve fibres are enclosed individually within invaginations of the giant glial cell processes, and synaptic junctions are rare in the nerve bundles

A lesion in a connective interrupts the neural pathways linking the ganglia[5,6] and damages the giant glial cells Transected axons soon grow across the lesion, however, and form a neuroma enclosing a different kind of glial cytoplasm Since the animals soon swim normally again, functional connections between the isolated parts of the nerve cord must be re-established during regeneration A plausible explanation for this would be that regenerating fibres grow along the injured connective, and synaptic connections are restored at the ganglionic neuropile We have found, however, that regenerating axons build up a new neuropile at the site of the lesion This neuropile includes a synaptic field very similar to that in the ganglionic neuropile

Twelve leeches of the species *Macrobdella decora* were anaesthetised with 8% ethanol and lesions were placed at the centre or at one end of the connective joining either ganglia 3 and 4 or 4 and 5 Each lesion was a discrete or extensive crush that often also involved the immediate walls of the haemocoelom which encloses the entire nerve cord Although lesions resulted in abnormal swimming, normal behaviour resumed within 4 weeks Animals survived in tanks with deionised water at 20–25° C and were killed 4, 19, 30, 55, 86 and 111 d after the operation We started examining 4-d-old neuromas because at this stage axons growing from both stumps of the severed connective met across the lesion

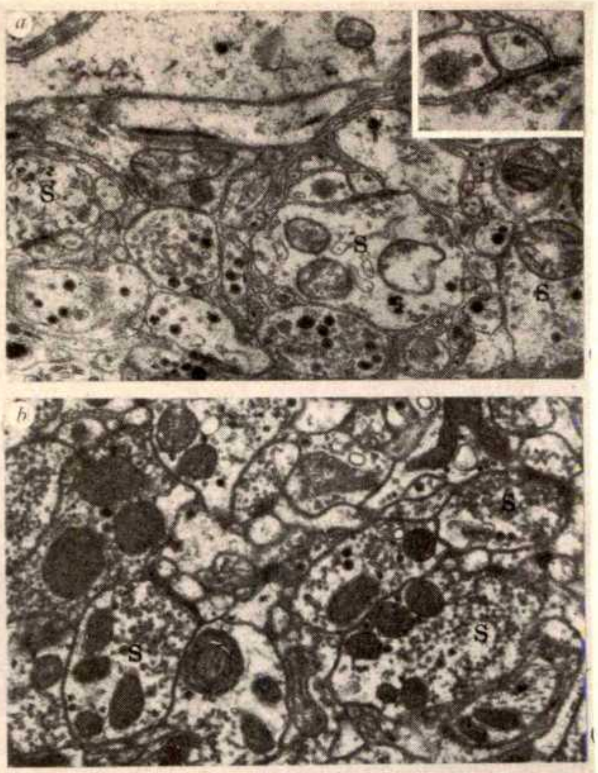

Fig. 1 Low magnification electron micrographs of 111-d-old neuroma (*a*) and normal ganglionic neuropile (*b*) that demonstrate the striking structural similarity between both kinds of neuropiles. Divergent types of synaptic clusters (S) are shown. Inset shows the specialised junction formed between the postsynaptic fibres. (*a*, × 16,280; inset, × 29,304; *b*, × 14,080).

Light microscopy showed that the lesions damaged part of the haemocoelom walls and underlying nerve connective, leaving cell debris which was ultimately removed by macrophages. Meanwhile many axons, growing from both ends of the lesion, advanced towards each other across the haemocoelom walls and formed a neuroma. Serial sections revealed the absence of giant glial cell cytoplasm across the nerve tissue, which consisted of many small and a few large fascicles near the twisted haemocoelomic canal.

Electron microscopy of neuromas of different ages confirmed the absence of giant glial cell cytoplasm, but revealed that of many small glial cells, not found in the normal connective. In very young neuromas (4 d), most immigrating glial cells appeared to be confined to the surface of regenerating tissue. In older neuromas, however, such cells were widespread.

The neuroma gradually transformed into a neuropile-type structure (Fig. 1*a*), with the nerve processes resembling those of the ganglionic neuropile (Fig. 1*b*). Thus, many neural profiles lacked a glial lining, or it extended only partly around their perimeter, leaving more direct surface contact between the nerve fibres than in the normal connective. Axons frequently formed axo-axonic synapses and contained many vesicular profiles of both granular (600–1,200 Å in diameter) and agranular (400 Å in diameter) types. The latter were particularly numerous in the presynaptic axons, mostly lying adjacent to the synaptic membrane. Here there was also electron dense material that was usually thicker than that associated with the postsynaptic membrane. The synaptic cleft measured approximately 180 Å in diameter (Fig. 2).

In both ganglionic and experimentally induced neuropiles, axo-axonic synapses were mostly in clusters, usually including one presynaptic and several postsynaptic fibres. Thus, the key feature of organisation of the synaptic clusters was divergence (Figs 1 and 2). When clusters included more than one afferent fibre, however, there was sometimes convergence. The extracellular space between postsynaptic fibres often narrowed and specialised neural junctions were formed (Fig. 1*a*).

Synaptic clusters were present in 4-d-old neuromas (Fig. 2*a*) and their numbers increased during the first weeks after the operation. The fact that a synaptic field was still present in the oldest neuromas we examined (111 d) is indicative of its nontransient character (Figs 1*a* and 2*b*).

What causes the regenerating nerve fibres of the leech to form an extraganglionic synaptic field at the site of injury? First, it seems likely that local conditions at the lesion favour direct interaction between growing axons. One such condition is the early absence of glial cell barriers throughout the regenerating tissue. This is associated with both the failure of the giant glial cells to repair damaged parts and the delayed invasion of the neuroma by glial cells. The competence of axons to synapse is probably associated with the early availability of new synaptic sites at the axon surface. These sites may arise, at least in part, as a consequence of collateral axon sprouting, which can be induced by, for example, partial denervation and nerve injury[7–12]. Some collateral axonal sprouts may come from undamaged nerve fibres. However, it is reasonable to suspect that most would originate from regenerating fibres growing across the lesion site. This view is supported by the fact that transected axons in the nerve connectives of the leech sprouted vigorously compared with those in the CNS of higher vertebrates[12,13]. Finally, there is evidence that axonal sprouts can form new synaptic junctions when they meet the receptive surface of a neurone or muscle cell[12,14].

What type of neurones form synapses at the neuroma? Many neurones of neighbouring ganglia are linked synaptically[6] and many of them recover their junctions after partial severance of a nerve connective[15,17]. Thus many neurones may re-establish at least some of their specific connections at the neuroma. This implies that many of the synapses would

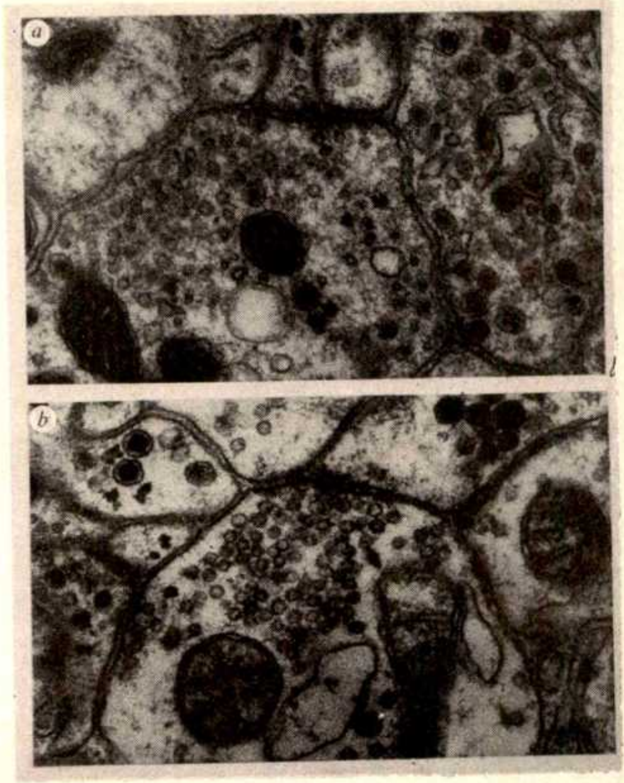

Fig. 2 High magnification electron micrographs of synaptic clusters in 4-d-old (*a*) and 111-d-old neuromas (*b*). In both cases, the cluster includes a single presynaptic fibre (× 40,480).

be formed between the central processes of neurones growing from opposite stumps of the severed connective. The fact that the conduction of action potentials is regained across the neuroma[15] and that some regenerating fibres grow beyond this structure (our unpublished work) suggests that axons also restore their specific connections at the ganglionic neuropile. Hence, a given pair of neurones of successive ganglia might renew their interconnections completely either at one or both neuropiles. Alternatively, many of the synapses found at the neuroma may be duplicates of those formed by the same regenerating fibres at the level of the ganglia. Thus, there would be a factor of redundancy in regenerated synapses. This might explain some consistent differences between regenerated and normal synapses with regard to the balance of excitation and inhibition[17].

Effect of prostaglandins E_1, E_2 and $F_{2\alpha}$ on human blood coagulation

As prostaglandins are being used to induce labour and abortion in some women, it is necessary to know the effect of these compounds on the blood coagulation system. We have investigated this problem using plasma from normal women and prostaglandins E_1, E_2 and $F_{2\alpha}$ (Upjohn).

The prostaglandins, dissolved in absolute ethanol, were added to samples of the plasma to give a final concentration of 1, 10 and 100 ng ml^{-1}. Each 0.1 ml of plasma contained the equivalent of 1.0 ng of ethanol, which was added to similar samples of plasma during control runs of coagulation tests. After the addition of prostaglandins, aliquots of plasma were incubated for 1 h at 37° C to determine whether there was any conversion to prostaglandins A_1 or B_1[1,2]. While preparing 'platelet-rich plasma' we minimised the release of prostaglandin from the platelets. We used slightly modified versions of established methods to study blood coagulation in ten samples of plasma from each of ten subjects. To 0.2 ml of control and prostaglandin-treated plasma we added one of the following: thromboplastin, to measure prothrombin time[3]; cephaloplastin (Dade, Miami) to measure partial thromboplastin time[4], and thrombin (0.7 U per 0.1 ml, Fibrinex, Ortho) to measure thrombin clotting time. Percentage clot retraction was estimated by addition of 0.1 ml of cephaloplastin to 0.8 ml of platelet-rich plasma, followed by 0.1 ml of 0.1 M $CaCl_2$ in 1.0-ml graduated tubes into which were inserted applicator sticks. This mixture was incubated for 30 min at 37° C. After removal of the clot adhering to the stick, the remaining fluid was estimated as the percentage of the original 1.0 ml.

Plasma factors, V, VII, VIII, IX, X, XI and XII were determined by a modification of the test for prothrombin and partial thromboplastin time, using plasma from subjects deficient in the various factors as the vehicle for the clotting effect on control and prostaglandin-treated plasma. The plasma factor assays for the several prostaglandins *in vitro* were assessed at the 100 ng level only. Coagulation tests were also carried out on plasma from several pregnant women receiving prostaglandin $F_{2\alpha}$ or Pitocin for induction of labour, or Pitocin for abortion, and from women at the time of delivery (unpublished results of R. K. Laros).

None of the prostaglandins in concentrations of 1–100 ng ml^{-1} affected the coagulation tests or the plasma factor assays. Similarly, none of the plasma from the *in vivo* study (unpublished results of R. K. Laros) yielded any significant deviation from normal values for prothrombin time, partial thromboplastin time, thrombin clotting time or percentage clot retraction. *In vivo* studies on patients receiving prostaglandin $F_{2\alpha}$ as a means of inducing abortion also independently supports this conclusion[5]. None of the plasma samples converted the added prostaglandins to A_1 or B_1, although this has been described elsewhere[1]. Tables 1 and 2 summarise the *in vitro* findings.

Table 1 Effect of prostaglandins E_1, E_2 and $F_{2\alpha}$ on coagulation tests on human blood plasma

Prostaglandin	ng	Mean* PT (S)	Mean† PTT (S)	Mean‡ TCT (S)	Mean§ clot retraction
E_1	1	10.2	31.3	8.8	83.0
E_1	10	10.1	30.3	8.8	80.0
E_1	100	10.2	32.5	8.8	70.0
E_2	1	10.1	32.0	8.3	80.0
E_2	10	10.3	32.2	8.8	80.0
E_2	100	10.3	32.5	8.8	85.0
$F_{2\alpha}$	1	10.0	31.0	8.8	85.0
$F_{2\alpha}$	10	10.2	32.0	8.8	75.0
$F_{2\alpha}$	100	10.3	31.0	8.3	80.0
Mean Control		10.2	30.5	8.8	80.0

Clot retraction is expressed as percentage of control. PT, Thromboplastin time; PTT, partial thromboplastin time; TCT, thrombin clotting time.
* Range, 10–16 s.
† Range, 30–33.0 s.
‡ Range, 8.0–9.0 s.
§ Range, 70.0–90.0%.

Prostaglandins E_1 and E_2, apparently at physiological (1.0 ng ml^{-1} plasma) as well as the pharmacological levels we used, do not affect the clotting mechanism other than by inhibiting platelet aggregation and adhesiveness on the part of prostaglandin E_1. Blood samples from patients obtained before infusion of prostaglandin $F_{2\alpha}$ and at delivery, when prostaglandin concentrations are maximum and immediately *post partum* were relatively unchanged, although significant coagulation abnormalities developed in patients being aborted with the aid of Pitocin (unpublished results of R. K. Laros).

Table 2 Effect of prostaglandins E_1, E_2 and $F_{2\alpha}$ on plasma coagulation factors tests

Prostaglandin	ng	Mean factor V	Mean factor VII	Mean factor VIII	Mean factor IX	Mean factor X	Mean factor XI	Mean factor XII
E_1	100	104	100	73 0	90 0	100	102 0	88 0
E_2	100	101	147	117 0	87 0	113	83 0	92 0
$F_{2\alpha}$	100	104	100	77 0	90 0	100	96 0	106 0
Control (1 ng ethanol)		100	100	100 0	100 0	100	100 0	100 0

Values are expressed as mean percentage of control
Ranges for factors V, 100–108, VII, 100–150, VIII, 70-110, IX, 90–100, X, 100–106, XI, 100–104, XII, 80–100

Prostaglandins seem to affect haemostasis through the platelet The ability of prostaglandins to interfere with platelet aggregation has been well established and may represent one of the major effects of prostaglandins on the clotting mechanism, although less well documented Ferri *et al*[7] noted a shortening of the recalcified clotting time in citrated rat blood, suggesting the development of a hypercoagulable state Kloeze[9], on the other hand, also working with rat plasma could not alter the prothrombin time, but changed the thromboelastogram pattern of prostaglandin-containing blood, an effect probably related to platelet function In contrast to our findings, Murer[9], comparing different systems of clot retraction, noted an inhibitory effect of prostaglandin E_1 on diluted calcium-deficient plasma solutions clotted with thrombin Addition of calcium reversed the inhibition, resulting in normal clot retraction Suspensions of washed platelets where clots were formed by fibrin monomers and calcium also were inhibited by prostaglandin E_1 and were not improved by further addition of calcium[9] Addition of calcium to the platelet-rich plasma alone in our system was unaffected by prostaglandins E_1, E_2 and $F_{2\alpha}$

Haemostasis therefore does not seem to be altered significantly by prostaglandins E_1, E_2 and $F_{2\alpha}$, and thus haemorrhagic or thrombotic complications would not be expected to represent a hazard in their therapeutic use

Biochemical marker in dominantly inherited ectodermal malformation

ALTHOUGH several hundred dominantly inherited human malformations have been described[1], the mode of action of the mutant genes responsible for them is, in nearly all cases completely unknown, because of the lack of suitable biochemical markers Here we describe a well defined biochemical abnormality in the keratin of mice bearing the dominantly inherited Naked trait

The mouse phenotype known as Naked (N) has been described elsewhere[2–4] In the heterozygote, the hair breaks off close to the root causing patchy depilation which begins around the eyes and spreads to the tail Before depilation is complete, hair growth begins again on the head, and the mouse grows successive waves of hair passing from head to tail, reflecting the normal moult pattern Mice homozygous for this mutation, have almost no hair or nails, and usually die within 10 d of birth

We have investigated the amino acid composition of Nn hair and found it to be significantly different from that of wild type hair We used mice of the NS-FR strain, inbred by brother–sister mating for 57 generations with forced heterozygosis for the N and albino genes Eight mice were examined Four were heterozygous Naked (Nn) and four were homozygous for the normal allele (nn) Each of the groups comprised two black and two albino mice

Three replicate samples of hair shaft (2 mg each) were taken from each mouse, washed with water and defatted in petroleum ether, dried and added to 5 ml of redistilled 6 N HCl in a hydrolysis tube, which was then evacuated, sealed and heated at 110° C for 24 h The contents of the tubes were then evaporated under vacuum to dryness and the residues were dissolved in *p*H 2 2 citrate buffer at a concentration of 0 15 mg of protein ml^{-1} The amino acid composition of the resulting solution was determined on a Jeol analyser A standard mixture of amino acid was analysed at every sixth run

The amino acid composition of the hair samples (Table 1) is expressed as the percentage of moles represented by each amino acid An analysis of variance was carried out to determine the effect of the N mutation, the albino mutation and the interaction between them The albino gene causes no significant change nor does it interact significantly with the N mutation The latter, however, causes two significant changes in amino acid composition a 30 4% reduction in the tyrosine content (3 23 against 4 67 mol %) and a 20 4% reduction in the glycine content (8 41 against 10 51 mol %) Since the probability of finding *n* or more differences, at significance *P* or less among *N* variables is $p^{n} N!/(N-n)!n!$, the probability that this is a chance finding is 0 00015 A few samples of hair were hydrolysed for 48 and 72 h to estimate rates of amino acid destruction The corrected values for glycine (mol %) are normal 9 37, naked 7 72, and for tyrosine normal 4 58, naked 3 25 The differences between genotypes thus persist when values are corrected for destruction For these reasons, observed reductions in tyrosine and glycine are almost certainly the result of the mutation

In 1964, Dedeurwaerder *et al*[5] extracted from wool a protein fraction containing 27 mol % of glycine and 11 mol % of tyrosine The proteins comprising this fraction are now known as the high-gly, high-tyr (HG) proteins It was apparent from electron microscopic studies of the wool after extraction of the HG proteins, that they are located in the intercellular membrane complex In fact, the removal of HG proteins releases intact cells from the fibre A complete sequence of an HG protein has now been published[6] It has a molecular weight of 6,950 and contains 23% glycine and 19% tyrosine

It has been shown that the HG protein content of a hair is roughly proportional to its tyrosine content[7] and, extrapolating from keratin samples whose tyrosine content and HG protein content have both been determined, we estimate that murine hair contains 20–25% by weight of HG proteins Murine hair contains more tyrosine than any animal hair so far investigated[8]

The composition of murine HG protein has been determined[8] It contains roughly three times as much glycine and four times as much tyrosine as whole hair A defi-

§ $0\ 025 < P <0\ 05$

ciency of HG protein would therefore explain the low tyrosine and glycine contents of naked hair A consideration of other amino acids is also consistent with an HG deficiency There is twice as much phenylalanine in HG protein as in whole hair and there is a deficiency of this amino acid significant at the $P=0\ 05$ level, in naked hair On the other hand there is less leucine, lysine and proline in HG than in whole hair and the relative amounts of these amino acids are increased in naked hair ($P<0\ 05$, $<0\ 05$ and $<0\ 005$, respectively) The amino acids which are present in HG protein and in whole hair, in roughly equal amounts are unchanged in naked hair, for example, histidine We can make a rough estimate of the amount of HG protein which would have to be removed from normal hair If normal hair, mutant hair and HG protein contain respectively n, m and h mol % of a given amino acid, then

$$(n-m)/h-m)=p,$$

where p is the proportion of HG protein lost[9] The mean value of p obtained by considering several amino acids is 0 12 Thus, an amount of HG protein equal to about 12% of the total hair by weight is missing in the naked mutant

Since the HG fraction is very heterogeneous[8], this almost certainly represents the loss of several molecular species

The original reason for investigating this mutation in the mouse was its close resemblance to the dominantly inherited human disease, hydrotic ectodermal dysplasia[10] The amino acid changes in this disease are quite different, however Ectodermal dysplasic hair contains less cystine, proline and serine and more tyrosine and phenylalanine than normal hair and its glycine content is unchanged It is probably caused by the loss of a matrix component[11-13] The entirely different nature of the two superficially similar phenotypes underlines the danger of accepting animal diseases as models for human ones without a knowledge of the underlying mechanisms

The results also demonstrate the advantage of using isogenic, animal strains The amino acid composition of human hair, both normal and dysplasic is very variable and the difference between them is much less clear, presumably as the result of the action of modifying genes The genotypes of the mice, on the other hand, differ only at the locus whose effects we wish to observe

Meanwhile, an exploration of the protein fractions in the Naked mouse hair and comparison with those in normal hair should further elucidate the gene action in this mutation

DNA polymerase activity determined by the ultraviolet-protecting plasmid, R-Utrecht

CERTAIN plasmids, including the colicin factor *Collb* and the drug resistance transfer factor R-Utrecht, reduce the susceptibility of wild-type cells of *Salmonella typhimurium* to the lethal effects of ultraviolet irradiation while at the same time increasing their susceptibility to the mutagenic effects[1,2] These alterations in ultraviolet response may result from plasmid-borne genes whose products participate in repair of single-strand gaps in DNA (ref 2) Here I present evidence which indicates that at least part of the ultraviolet protection conferred on wild-type cells by R-Utrecht can be attributed to a plasmid-coded DNA polymerase which participates in repair of single strand gaps

The strains used are derivatives of *S typhimurium* strain M7471, which is of the 'FIRN' wild-type and differs from LT2 by absence of fimbriae and failure to ferment inositol and rhamnose[3] The parent strain, SL4525, has the following genotype M7471 (*ColEl-30*) *leu-1051* *malB479* *cysI1173* *hisC527* (amber) *gal-459* Strain SL4702 is a derivative of SL4525 detected as a clone which failed to release colicin El This strain shows increased sensitivity to ultraviolet and ionising radiation because of a deficiency in the enzyme DNA polymerase I, and the mutation it carries has been designated *polA1* (ref 4) Strains SL4525/R-Utrecht and SL4702/R-Utrecht were obtained by selection of clones resistant to tetracycline following conjugation with *S typhimurium* strain SL1156/R-Utrecht (an LT2 derivative) The characteristics of this strain and of the R-Utrecht plasmid have been described previously[2]

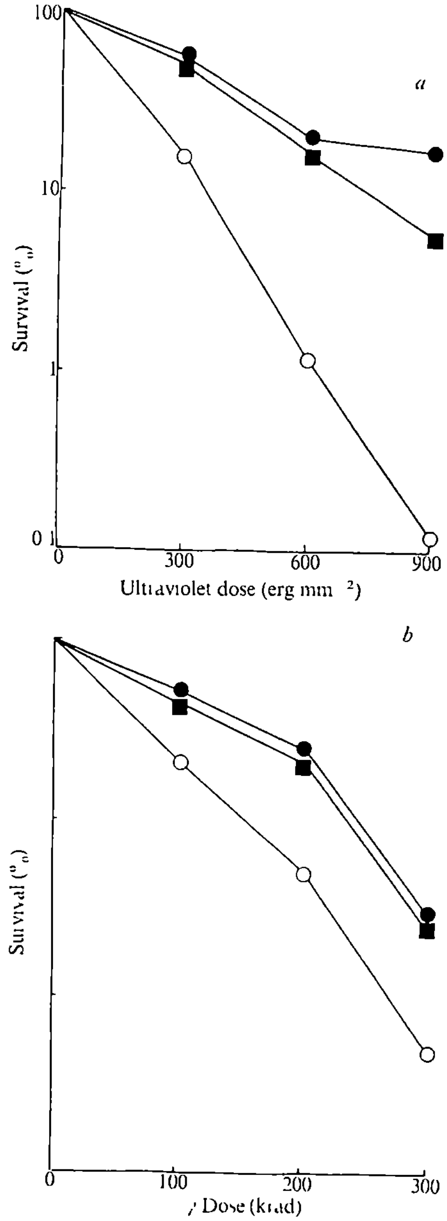

Fig 1 Host–cell reactivation of preparations of bacteriophage ES18 exposed to, *a*, ultraviolet irradiation and, *b*, γ-irradiation Phage suspended in saline were irradiated, diluted in broth and titrated on the various strains by the drop-on-lawn method[4] ■, SL4525 (POL$^+$), ○, SL4702 (*polA1*), ●, SL4702/R-Utrecht (*polA1*/R-Utrecht)

Among other properties, the *polA1* strain of *S typhimurium* (SL4702) shows reduced ability to effect host–cell reactivation (HCR) of bacteriophages which have been damaged by ultraviolet or ionising radiation (D G M, unpublished) Figure 1 confirms this finding, showing that preparations of the *Salmonella* phage ES18 which have been exposed to ultraviolet or γ-irradiation plate with lower efficiency on strain SL4702 than on the wild-type parent strain SL4525 Tests with derivatives of these strains carrying the R-Utrecht factor showed that this plasmid has no detectable effect on the HCR capacity of strain SL4525 for either phage preparation (results not shown), and that this plasmid increases the HCR capacity of strain SL4702 for both ultraviolet and γ-irradiated phages to a level approximately equal to that of the wild-type parent strain SL4525 (Figs 1*a* and *b*)

Those results suggest that R-Utrecht provides cells of the *polA1* strain with a plasmid gene product which can participate in repair of single-strand gaps produced in phage DNA either indirectly as a result of excision of ultraviolet-induced photoproducts or directly as a result of exposure to ionising radiation, and that this gene product is therefore functionally equivalent to the chromosomal *polA*$^+$ gene product (DNA polymerase I) On this hypothesis, cells of a *polA1*/R-Utrecht strain of *S typhimurium* would be expected to contain an enzyme capable of carrying out the process known as repair resynthesis or repair replication (that is, resynthesising DNA in the region of a DNA strand gap using the intact opposite strand as a template) The chromosomally-determined enzyme believed to be mainly responsible for this process in normal cells is of course DNA polymerase I, an enzyme whose activity can be detected even in crude assay systems and certainly much more readily than either of the other two known cellular DNA polymerases (II and III)[5-7]

Assays for DNA polymerising activity were therefore performed on crude extracts obtained by treatment of strains SL4702 (the *polA1* mutant), SL4702/R-Utrecht, and SL4525 (the *polA*$^+$ parent strain) As expected from previous work[4] the results (Fig 2) show first that crude extracts of strain SL4702 contain no detectable DNA polymerising activity They also show that the derivative of strain SL4702 carrying R-Utrecht has about 25% of the DNA polymerising activity found in extracts of the wild-type parent strain SL4525 It therefore seems clear that a new DNA polymerising activity is associated with the acquisition of R-Utrecht by strain SL4702 Further experiments have shown that the continued presence of R-Utrecht is necessary for this activity to be found in cells derived from strain SL4702, since spontaneous R$^-$ segregants of the R$^+$ strain have no detectable polymerase activity

It has been assumed so far that the enzyme which contributes to DNA repair in *polA1* cells carrying R-Utrecht and which is responsible for the DNA polymerising activity found in such cells is directly coded by the plasmid There are other possibilities, however For example, the effect of the plasmid could be to derepress a chromosomal gene specifying a DNA repair enzyme which has DNA polymerase activity If so, the chromosomal gene most likely to be implicated is the *polA* gene itself, since detection of either of the other two known cellular DNA polymerases (II and III) in the crude assay system used here is improbable It then becomes necessary to assume that the *polA1* mutation in strain SL4702 leaves the *polA* gene product with some residual DNA repair and polymerising activity which can be amplified by plasmid-directed derepression In fact, it is necessary to extend this assumption

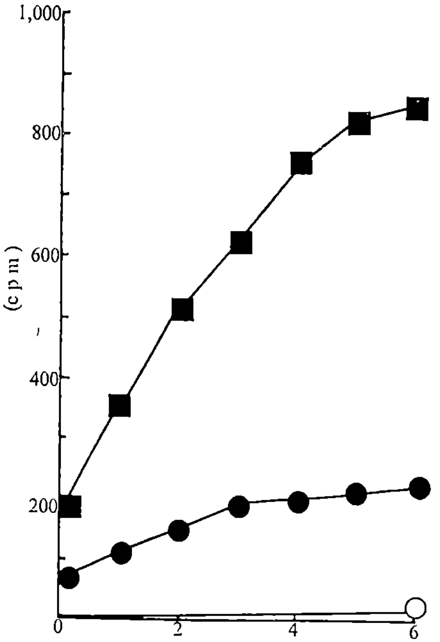

Fig. 2 Assays for DNA polymerase activity of strain, ■, SL4525 (POL$^+$), ○, SL4702 (*polA1*), and, ●, SL4702/R-Utrecht Bacteria grown on the surface of a solid medium were suspended in 0 1 M Tris, 0 01 M $MgSO_4$ (*p*H 7 4) at a concentration of about 1×10^{10} ml^{-1} Crude extracts of these suspensions were then prepared by sonication in a 150 W MSE ultrasonic disintegrator The resulting extracts were centrifuged at 1,000*g* for 10 min To 0 9 ml of each supernatant, 0 1 ml sonicated calf thymus DNA was added (final concentration 20 μg ml^{-1}), and, 5 min later 0 3 ml triphosphate solution (final concentrations 100 nmol ml^{-1} dGTP, dCTP, dATP and 0 6 nmol ml^{-1} ^{3}H-TTP) Samples of 0 02 ml were taken from each reaction mixture and dried on Whatman No 1 filter paper disks (2 5 cm diameter) The disks were immediately placed in cold 5% trichloroacetic acid, 1% sodium pyrophosphate for at least 2 h then rinsed with 95% ethanol, dried, and counted in a scintillation counter

to four other independently-isolated *polA* mutants of *S typhimurium* since R-Utrecht has similar effects in all five strains It seems equally improbable that a plasmid-determined suppressor of any known type could explain the effects of R-Utrecht in the five different *polA* mutants, especially since one of the mutants (*polA3*) is known to be suppressible by ochre and amber suppressors whereas the others are known not to be (D G M, and M R Beazer, unpublished)

On balance, therefore, it seems highly likely that the R-Utrecht plasmid codes directly for a DNA polymerase which resembles the chromosomal DNA polymerase I in being readily detectable in assays performed on crude cell extracts and in contributing to repair of single-strand gaps in DNA Such an enzyme presumably provides R$^+$ derivatives of wild-type strains of *S typhimurium* with additional DNA polymerising activity, and thus may account, at least in part, for their increased resistance to the lethal effects of ultraviolet and ionising radiation This would seem to be a reasonable assumption, since there is evidence from other studies that strains of *S typhimurium* which have increased levels of DNA polymerase I activity (probably as a result of mutation of chromosomal genes in this case) show increased resistance to both ultraviolet and ionising radiation[8]

Plasmid-coded DNA polymerases may well have other functions quite apart from their role in DNA repair For example, they may be responsible for the special type of DNA replication (known as transfer replication) which is thought to be involved in the transfer of plasmid (and in some cases chromosomal) DNA from a donor to a recipient cell during conjugation[9], or alternatively they may be involved in some aspect of the replication and stable maintenance of plasmid DNA within the bacterial cell In the latter situation, possible roles which might be attributed to plasmid-coded DNA polymerases will depend upon whether they resemble the multifunctional DNA polymerase I of *Escherichia coli* in properties other than just ease of detection in crude assay systems (for example, in having exonuclease activities as well as their polymerase activity) Thus, until a particular plasmid enzyme has been studied in detail, the exact role (or roles) which it plays in the cell must remain a matter for speculation

Altered rate of DNA replication in ageing human fibroblast cultures

SINCE the demonstration that diploid human fibroblasts have a limited lifespan in culture[1,2] and that the lifespan in culture is a function of the age of the donor[2,3], many explanations of fibroblast ageing have been offered[4] The production of error-containing enzymes by either an 'error catastrophe'[5,6] or somatic mutation has been suggested as one possible cause[4,7] Errors in the enzymes which replicate the cellular DNA might have the gross effect of slowing the rate of DNA replication Here we examine the rate of DNA chain elongation and the distance between DNA synthesis initiation sites in senescent and control fibroblasts by DNA fibre autoradiography

Asynchronous cultures established from the male foetal lung fibroblast strain MRC-5[7,8] were pulse-labelled with ^{3}H-thymidine and prepared for DNA fibre autoradiography[9–11] Parallel experiments were performed with a visibly senescent culture (culture passage 58) and a control nonsenescent culture (passage 16) The strain MRC-5 generally becomes visibly senescent after about 50 passages and ceases growth after 60–70 passages[7]

Tandem arrays of grain tracks, similar to those observed in other eukaryotic systems[9–13], were observed in autoradiographs prepared from both passage 58 and passage 16 cells The length of individual tracks in these arrays from cells labelled for 10, 20 and 30 min is shown in Fig 1 For each of the three pulse experiments, the length of tracks from the passage 58 cells were significantly smaller ($P<0\ 05$) than those from passage 16 cells The average track lengths for passage 58 and passage 16 cells were respectively for the 10 min pulse, 7 μm and 10 μm,

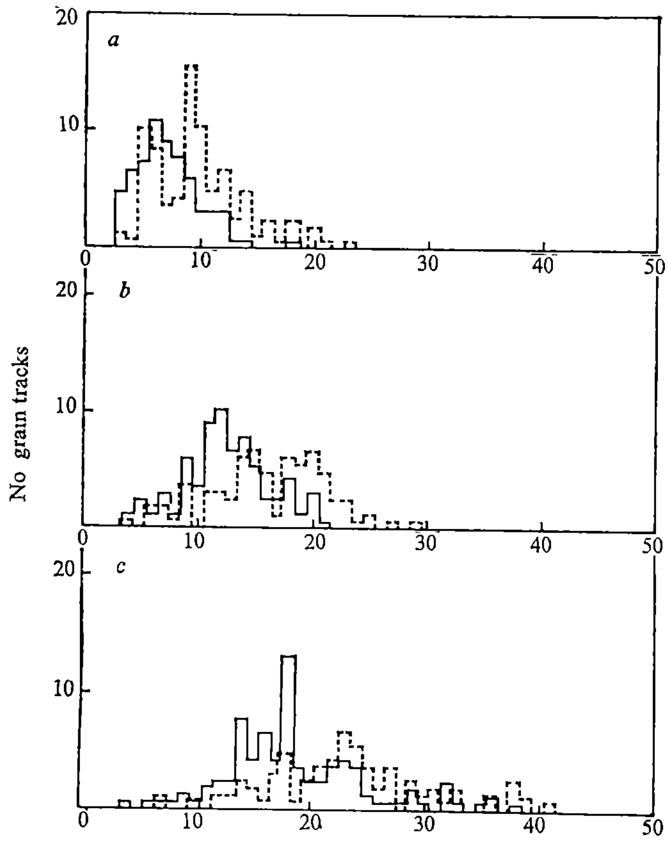

Fig 1 Histograms of lengths of labelled segments of DNA from senescent and non senescent cultures. Methods for labelling the DNA and fibre autoradiography followed procedures of Lark *et al*[11] and Huberman and Tsai[16] with minor modifications. Cultures of MRC-5 (passage 58 and passage 16 cells previously tested for mycoplasma contamination) were seeded before labelling into 50 mm plastic Petri dishes containing 10 ml of Eagle's basal medium (BME), supplemented with 10% foetal calf serum, nonessential amino acids, and penicillin (100 units ml^{-1}), streptomycin (100 μg ml^{-1}). Approximately 10^5 cells were labelled in 2 ml of the above medium containing 200 μCi of ^{3}H-thymidine (56 Ci $mmol^{-1}$, Amersham) for various pulse times (10, 20, 30 min, 1 h or 3 h). All pulses were done at 37° C. The pulses were terminated by washing with cold isotonic saline containing fluorodeoxyuridine (0.1 μg ml^{-1}) and the cells removed by trypsin (0.125% with 0.1 μg ml^{-1} fluorodeoxyuridine) treatment at 37° C for 15 min (ref 16). The DNA from approximately 5,000 cells was spread on glass slides[11,16]. The slides were rinsed with 5% trichloroacetic acid and ethanol[11,16] and covered with Kodak AR-10 stripping film[10]. Exposure time was 3–4 months. Track lengths were measured with an ocular micrometer. Slides were coded before measurements to exclude the possibility of bias in scoring. ——, Passage 58, -----, passage 16. *a*, 10 min pulse, *b*, 20 min pulse, *c*, 30 min pulse.

for the 20 min pulse, 12 μm and 16 μm, and for the 30 min pulse, 19 μm and 23 μm. The tracks labelled in 1 h and 3 h labelling periods were very long, often exceeding 100 μm in length, in autoradiographs from both passage 58 and passage 16 cultures. These were not further characterised.

The length of grain tracks produced during a pulse time which is short relative to the time necessary to complete replication of a replicating unit is primarily a function of the rate of chain elongation of DNA (ref 10). The results, therefore, suggest that DNA chain elongation is slower in senescent cells. It is unlikely that the difference in track lengths represents differential stretching of DNA during preparation of autradiography since the grain density of autoradiographs from passage 58 and passage 16 cells was not significantly different. It is also unlikely that the difference in track lengths represents a difference in the time required for equilibration of precursor pools. No measurable gradients of grain density were observed in grain tracks from either passage 58 or passage 16 cells. The difference in track lengths probably does not reflect an age-independent difference in the rate of DNA synthesis of different sublines of cells. Independent experiments with different sublines of senescent (passage 60) and nonsenescent (passage 20) cells showed the same difference in the rate of DNA chain elongation (T.D.P., unpublished). It should be pointed out that a 25% reduction in the rate of DNA chain elongation in senescent cells does not necessarily imply that the period of DNA synthesis (the S period) is 25% longer in senescent cells. Preliminary measurements of the length of the S period (R.A.F., G.M.T., T.D.P., unpublished) have indicated no difference between senescent and nonsenescent cells.

The rate of chain elongation as estimated by the length of grain tracks produced in a pulse-labelling experiment is only an approximation of the true rate of synthesis[10,12]. Initiation of DNA synthesis, termination of DNA synthesis and fusion of neighbouring replication units during the pulse are possible sources of error. Nevertheless, the calculation of the replication rate from the 10 min pulse experiment suggests that the rate of DNA chain elongation in nonsenescent human diploid fibroblasts, 0.5 μm min^{-1}, is similar to the rate of DNA synthesis in other mammalian systems[9,10,13]. For this calculation, it was assumed that DNA synthesis in human diploid fibroblasts is bidirectional from each initiation site as in other eukaryotic systems[10,12].

The distance between initiation sites along the chromosome was measured by determining the centre-to-centre distance between adjacent tracks within a tandem array of tracks[10]. There was no significant difference in the spacing of these sites in passage 58 and passage 16 cells (Fig 2). Most of the centre-to-centre distances were between 15 μm and 60 μm. Similar distances have been found in Chinese hamster ovary cells[10].

One possible reason for the slower rate of DNA elongation is that a proportion of the enzyme molecules in enzymes required for DNA replication is defective in senescent cells. Holliday and Tarrant[7] reported that senescent cultures of MRC-5 contained as much as 25% heat labile glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase and suggested that the heat lability was the result of misincorporation of amino acids during protein synthesis. If such misincorporation occurs in DNA polymerase, then even a small proportion of altered molecules could have a significant effect on the rate of chain elongation. One molecule of DNA polymerase at the replication fork may synthesise a small stretch of DNA (ref 14) (for example, one Okazaki fragment). An occasional defective

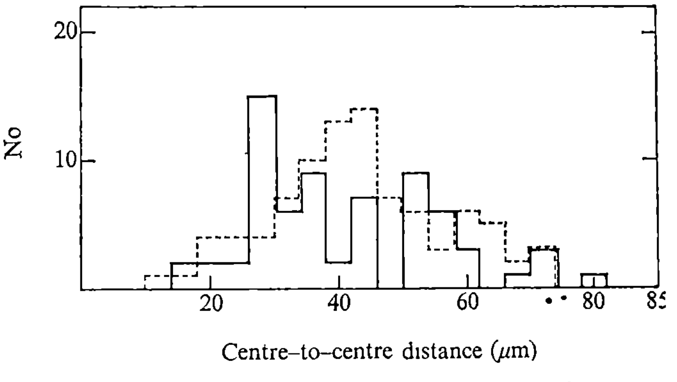

Fig 2 Histogram of the centre-to-centre distances between adjacent tracks in a tandem array. The autoradiographs were from the experiment described in the legend to Fig 1. The centre to-centre distances did not differ in the 20 min and 30 min pulses and the data from these experiments were pooled. ——, Passage 58, -----, passage 16.

polymerase molecule which binds normally may block replication for a significant length of time before being replaced by a normal molecule Faulty DNA polymerase molecules would also be expected to have 'mutator' activity[7], errors in replication would accumulate irreversibly and may be a major cause of cell death

The slower rate of chain elongation in senecent cells is not necessarily the result of defective DNA polymerase molecules It might also reflect smaller pools of DNA precursors or energy limitations Slow DNA replication as a consequence of limited precursor pools could be detrimental to the cell, since it has been observed that thymine-requiring strains of *B subtilis* grown in limiting concentrations of thymine have a mutation rate several orders of magnitude higher than the background rate[15] Slow DNA synthesis may also be a more general factor in cell death For example, completion of synthesis of certain replicons may be required to trigger other essential events in the cell cycle Slowing the rate of DNA synthesis could disrupt these control mechanisms

Control of translation of globin mRNA in embryonic cells

WHEN mouse or rabbit globin mRNA is injected into oocytes of *Xenopus laevis* both α and β mRNAs are translated but only about one fifth as much α globin is synthesised as β globin[1–3] On the other hand, the same message sample results in about equal amounts of α and β globin synthesis in a reticulocyte cell-free system and is believed to contain roughly equal amounts of α and β globin mRNA Giglioni *et al*[3] have shown that if haemin is injected into oocytes at the same time as globin mRNA, there is an equal ratio of α β globin synthesis, and their experiments strongly suggest that this is achieved by increasing the efficiency of translation of α globin mRNA These experiments thus identified a factor which has a different effect on two kinds of mRNA, and further demonstrated that the microinjection of living cells can reveal regulatory effects not readily seen in the cell-free systems used so far The experiments reported here were also carried out by injecting mRNA into frog cells They show that during development a component is formed that alters the ratio of α β rabbit globin synthesis, a change not seen when mouse globin mRNA is injected This is therefore a second example of a translational factor revealed by a living cell assay system This component shows an even higher degree of selectivity in its action than haemin

Rabbit or mouse globin mRNA is translated into globin when injected into fertilised frog eggs[4–6], which differ in several respects from oocytes Mouse mRNA yields a low, although somewhat variable, ratio of α to β globin synthesis in eggs and embryos of all stages (Table 1), as it does in oocytes (Fig 1) There is no proof that the extremely low mouse α β ratios seen in eggs and morulae are significantly different from the low ratios seen in other stages Rabbit globin mRNA also yields a low ratio of α β globin when translated in unfertilised or newly fertilised eggs, on the other hand, this ratio changes progressively, in the absence of injected haemin, to an almost equal synthesis of α and β globin as the embryos develop (Table 1) The ratio of α β globin synthesis approaches one, when tested in embryos at

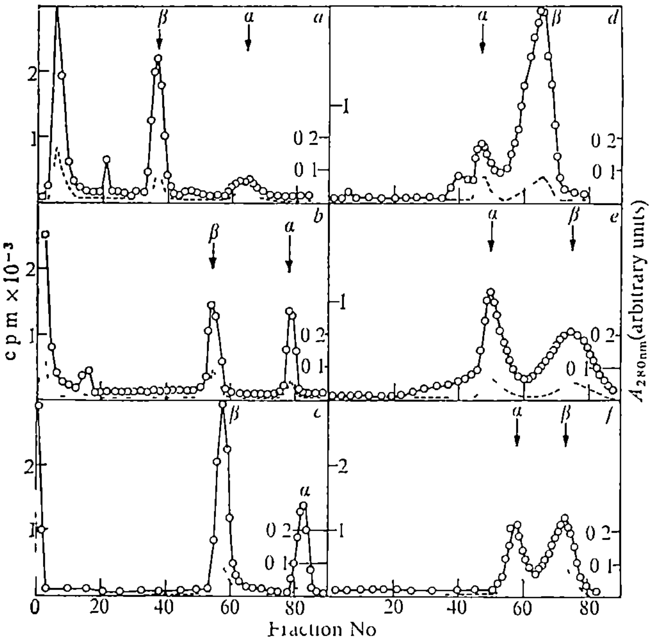

Fig 1 Effect of haemin on globin synthesis in oocytes injected with saturating and subsaturating amounts of rabbit and mouse globin messengers A stock of 16 mM haemin was prepared by the method of Zucker and Schulman[10] except that the final solution contained 90% (v/v) ethylene glycol Oocytes were injected with mRNA dissolved in saline[1], the latter containing haemin (1 6 mM) where indicated the intracellular concentration of haemin would have been about 80 μM Globin was prepared from whole oocytes and was fractionated by carboxymethyl cellulose chromatography[2] O——O, c p m per fraction, - - - -, absorbance at 280 nm of added marker α and β globin chains *a*, globin synthesis (α $\beta=17\%$) in oocytes injected with mouse mRNA (12 ng per cell), *b*, the effect of haemin (α $\beta=84\%$) on synthesis directed by such subsaturating amounts of mouse mRNA, *c*, the effect (α $\beta=46\%$) of haemin on saturating amounts (95 ng per cell) of mouse mRNA, *d* (α $\beta=12\%$) and *e* (α $\beta=84\%$) (+haemin) show analogous experiments with subsaturating rabbit mRNA (24 ng per cell), while *f* shows globin synthesis (α $\beta=55\%$) with saturating rabbit mRNA (48 ng per cell) plus haemin The α β globin synthesis ratio (α $\beta=20\%$) in oocytes injected with saturating messenger and no haemin is similar to that seen in oocytes injected with subsaturating mRNA Oocytes injected with buffer containing no RNA synthesise, no globin like species

Table 1 Ratio of α β-globin synthesis in mRNA-injected oocytes and eggs

Hours after fertilisation	Oocyte (ovarian)	Oocyte (matured)	Unfertilised egg 0	Morula 4	Blastula 8	Gastula 14	Neurula 20	Post-neurula 26	Early tail bud 44	Tail bud 50	Heart beat 54	Swimming tadpole 72	Stage 45 180
Mouse globin mRNA	20	—	3	5	24	10	10	20	14	15	11	11	—
Rabbit globin mRNA	17	20	19	22	67	59	60	68	66	—	—	54	54

Figures show ^{3}H-α-globin radioactivity as a percentage of ^{3}H-β-globin synthesis Oocytes and eggs were injected with mouse (12 ng per cell) or rabbit (7–20 ng per cell) globin mRNA[1 5] After the appropriate time, cells were labelled with ^{3}H-histidine by incubation (oocytes) or injection (embryos) Embryo homogenates were treated with acid acetone, and the resulting globin was chromatographed on a carboxymethylcellulose column[2] Matured oocytes were obtained by progesterone treatment (10 μg ml^{-1}) of immature oocytes

and beyond the neurula stage (20 h after fertilisation, Table 1)

Haemin can restore the efficient translation of rabbit and mouse α-globin mRNA in oocytes, but unlike the *Xenopus* embryo factor, it is equally effective with mouse and rabbit globin mRNA (Fig 1) For this reason the *Xenopus* factor is probably not itself haemin, though it may operate by part of the same mechanism since haemin and the embryo factor seem not to have an additive effect on rabbit globin synthesis in neurulae

Some information is available as to why less α globin is made than β globin For example this effect does not result from differential breakdown of completed α chains because α and β peptides are present in the usual 1 5 ratio in the polysomes of mRNA-injected oocytes[7] It also cannot be explained in a simple way by destruction of α rather than β mRNA because haemin increases the level of α-globin synthesis even when injected as long as 48 h after the mRNA (Table 2) It seems likely therefore that the effect is a result of a true translation control phenomenon

Two explanations of the haemin effect seem plausible One is that haemin raises the efficiency of initiation of α but not β-globin mRNA Alternatively haemin might remove some restriction to ribosome transit[7] located about half way along the α-globin mRNP particle Neither model necessitates a requirement for specific factors in the translation of specific messages and both models can be used to describe the agent enhancing rabbit α-globin synthesis during development Since haemin and the developmental factor differ in their effects on mouse globin synthesis, however, their mechanism of action cannot be identical The significance of these two regulatory phenomena is not clear In man, genetic deficiencies in haem synthesis are commonly associated with low globin synthesis and a low (0 71) ratio of α β-globin synthesis[8 9] Haem may therefore be involved in α-globin mRNA translation in normal reticulocytes The principal importance of the embryo factor, whose developmental significance is unknown, is that it indicates the possible existence in cells of a wide range of natural substances which may have very selective effects on message translation, the purification of those may help to reveal the kinds of mechanism by which translation can be controlled

Table 2 Effect of haemin when supplied after the initial injection of globin mRNA

Haemin injection (h after message)	Period of labelling (h after message)	α β (as a %)
No haemin	1–16	17
0 15	1–16	93
Simultaneous	1–16	84
No haemin	48–64	25
Simultaneous	48–64	83
48	48–64	57

Oocytes were injected with mouse globin mRNA (12 ng per cell) and were then injected with saline[1] or haemin The cells were labelled with ^{3}H-histidine Globin was prepared and fractionated[2] A further experiment was carried out by labelling oocytes for 5–18 h, with similar results to the 48–64 h experiments shown, except in the case of 'no haemin' samples About 30 ml of a 1 6 mM solution of haemin was injected per oocyte so as to give an intracellular concentration of about 80 mM

Distinct haematological disorder with deletion of long arm of No. 5 chromosome

So far, the only specific chromosome abnormality in haematological disorders is the Ph1-chromosome Chromosome abnormalities have been described in so-called idiopathic sideroblastic or refractory anaemias[1] but a constant cytogenetic abnormality associated with a defined clinical syndrome has not been reported

Out of a series of patients with refractory anaemia or anaemia of-ill determined origin, three patients, a 46-yr-old male, and two females respectively 40 and 75 yr of age, were found to present a clinically very similar haematological disorder and an apparently identical chromosomal anomaly in the bone marrow

The haematological disorder is characterised by longstanding aregenerative slightly macrocytic anaemia with haemoglobin values ranging between 6 5 and 10 g dl, low to normal leukocyte count (3,000–4,000) and normal to elevated platelets (300,000–500,000) The bone marrow showed erythrocytic hypoplasia with evidence of disordered maturation and dyserythropoiesis, normal myeloid series but nevertheless moderate excess of blast cells (up to 15%), and absence of lobulation of the megakaryocytic nucleus Patients with a similar haematological syndrome have been described in the past[2] but no cytogenetic investigation was performed

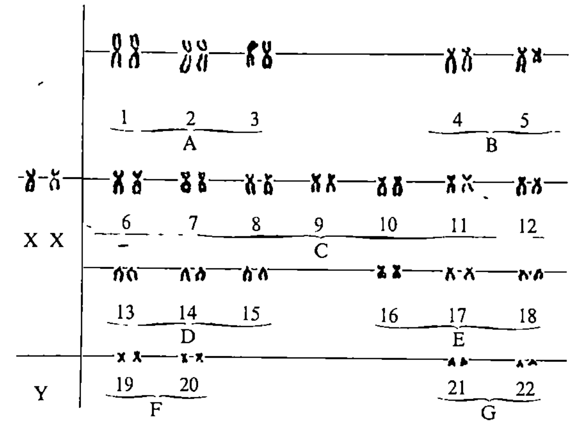

Fig 1 Routine karyotype (orceine) from a 48-h bone marrow culture of one of the patients

The chromosomal anomaly is a deletion of approximately two-thirds of the long arm of a chromosome No 5, without translocation of the deleted segment (Figs 1 and 2), present in 75–90% of the bone marrow cells cultured without PHA for 24–48 h No single abnormal cell has so far been found in peripheral blood cultured with PHA and in skin fibroblasts (Table 1), no metaphases were obtained from lymphocyte cultures without PHA The deletion seems to be interstitial and the following bands may be involved 5q 12–5, 5q 21–3 The association of this chromosomal anomaly with a defined haematological disorder may represent a newly recognised syndrome To our knowledge one case has been reported with similar clinical course and chromosome anomaly, but the B chromosome involved was not identified[3]

The absence of the deleted chromosome in the lymphocytes of the peripheral blood cultured with PHA, and in skin fibroblasts of our phenotypically normal patients indicates that the anomaly is an acquired one, occurring originally in a bone marrow stem cell, followed by clonal evolution and gradual replacement of an important part of the bone marrow

As far as can be concluded from the cytogenetic investigations, the abnormal cells are confined to the bone marrow It is possible that the stem cell with the abnormal chromosome is capable of erythroid, myeloid and megakaryocytic differentiation, but at present only morphological arguments can be found in favour of this hypothesis an erythroid hypoplasia, megakaryocytic nuclear anomaly, and a slightly reduced number of granulocytes with moderate blast excess in the marrow This situation could be very similar to that found in Ph1-positive disease Here also the chromosomally abnormal stem cell is capable of myelocytic, erythroid or megakaryocytic differentiation, and the extent of abnormal proliferation may be different for each cell line, for example, although the myeloid series is most often affected, polycythemia or thrombocytosis as well as anaemia or thrombopaenia can be the predominant haematological features So far there is no explanation for the variation in the haematological features of the Ph1-positive conditions Examination of a larger group of patients presenting with the 5q syndrome will be required before the extent of possible variability in the haematological features of this syndrome can be assessed

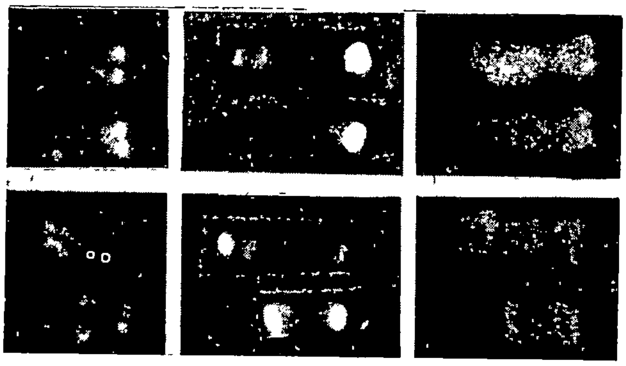

Fig 2 The B chromosomes of the three patients (T banding) showing that the chromosome involved is a No 5, of which most of the long arm is missing

Table 1 Summary of the cytogenetic investigations

Patients and tissues examined		No of cells with deletion 5q (46 cells only) Present	Absent	Undertermined
M G	(1) Marrow 48 h 1971	5	—	13
(♀ 40 yr)	(2) Marrow 48 h January, 1974	17	1	3
	(3) Marrow 48 h February, 1974	94	7	7
	(4) Skin Fibroblasts	—	30	—
E M	(1) Marrow 48 h September, 1973	98	18	8
(♀, 75 yr)	(2) Marrow 48 h March, 1974	87	15	15
	(3) Blood + PHA,, 72 h	—	50	—
	(4) Blood + PHA, 72 h	—	50	—
B A	(1) Marrow 48 h February, 1974	67	29	7
(♂, 46 yr)	(2) Blood + PHA, 72 h February, 1974	—	22	—

* No growth was observed in peripheral blood cultured without PHA

Finally it is to be noted that according to Price *et al*[4] one of the haemoglobin structural genes may be located on the long arm of a B chromosome If their findings are confirmed, and if the B chromosome turns out to be a No 5, a possible relationship between the deleted chromosome and the anaemia must be considered

More details about these patients will be published in a forthcoming paper H V D B , was supported by a grant from FWGO and J -J C and G D , by NFWO

Cytophotometric factors causing apparent differences between Feulgen DNA contents of different leukocyte types

A CENTRAL issue in the study of both metazoan differentiation and the control of cellular activity is the validity or otherwise of the hypothesis[1,2] that nonreplicating nuclei of a given higher organism contain a constant amount of DNA per haploid set of chromosomes Differential elimination or increase of DNA has been demonstrated in dipteran polytene chromosomes[3], and in the oocytes of *Acheta* and amphibia[4], but apart from these possibly special cases the most studied apparent exception to the constancy rule is probably provided by mammalian leukocytes[5–11] Most workers in this field have found the apparent DNA content of the relatively large nuclei of monocytes, as assessed by Feulgen cytophotometry, to be between 5% and 20% higher than that of the smaller, more darkly stained nuclei of lymphocytes and polymorphonuclear leukocytes The consensus of opinion seems to be that the measured differences are probably due to nonstoichiometry of staining rather than to genuine differences in the amounts of DNA present But work published to date has in general been performed without certain technical refinements which have recently become available, and we have now investigated the possibility that systematic cytophotometric errors may have been responsible for at least some of the reported differences between cell types

Air-dried smears of normal adult human blood were fixed in methanol–formalin–acetic acid (80 10 5) for 1 h at room temperature, washed in running tap water for 60 min, hydrolysed in 5 N HCl at 25° C for 80 min (found in pilot experiments to give maximum staining intensity), rinsed in distilled water, stained 40 min in fresh Schiff's reagent (prepared by the de Tomasi method[12]), rinsed in distilled water, dehydrated in a series of alcohols and mounted in Polymount Cytophotometry at λ_{max} was performed using a Vickers M86 scanning microdensitometer with a 1 3 NA ×100 apochromatic objective The achromatic microscope condenser was used dry at full aperture The field illuminated was limited by a field stop to reduce glare, each nucleus was measured both with and without electronic compensation[13] for the measured residual glare, which was 4% in a series of experiments with a 40 µm diameter illuminated field, and 6% in a series with a larger illuminated area Two sizes of flying spot, respectively 0 48 µm and 0 95 µm diameter in the object plane, were used to permit correction for residual distribution error[14] The monochromator entrance slit was opened as far as possible to increase the signal/noise ratio, it could be shown (methods and results to be published) that chromatic error due to the relatively wide monochromator bandwidth (about 50 nm at total cutoff) was negligible under the stated conditions At least 10 measurements, each accompanied by a blank scan of empty background, were made of each cell under each set of conditions At least eight nuclei of each cell type studied (lymphocytes, monocytes and polymorphs) were measured on a single stained slide in each of two experimental series

Both series gave essentially similar results, those of the series with 4% glare being given in Table 1 It will be seen that with glare and residual distribution error uncorrected, the mean integrated absorbance (that is, apparent Feulgen DNA content) of monocytes was significantly higher than that of lymphocytes, which was in turn significantly higher than that of polymorphs When glare but not residual distribution error was corrected the difference between monocytes and lymphocytes disappeared, but both had significantly higher apparent Feulgen DNA contents than did polymorphs With correction for residual distribution error but not glare, lymphocytes and polymorphs had similar apparent Feulgen DNA contents, which were, however, lower than that of monocytes No significant difference between the three cell types was found if glare and residual distribution error were both corrected

The results suggest that in our uncorrected measurements glare is largely responsible for lymphocytes having a lower apparent Feulgen DNA content than monocytes, and that residual distribution error together with glare accounts for the still lower apparent Feulgen DNA content of polymorphs This interpretation is consistent with the morphological features of the three types of cell nucleus, since stained lymphocyte nuclei have a higher mean absorbance than those of monocytes (and are therefore more liable to be erroneously measured in the presence of glare), while polymorph nuclei have both a high mean absorbance and a less uniform distribution of chromatin than either monocytes or lymphocytes

We believe that uncorrected glare and distribution errors account for at least some of the previously reported apparent differences in the Feulgen DNA contents of different types of leukocyte, and that there is therefore no longer any compelling reason to postulate either genuine differences in the amounts of DNA present, or nonquantitative staining of DNA by the Feulgen method

C-type viral particles in a urinary bladder neoplasm induced by *Schistosoma haematobium*

NEOPLASMS may be induced in nonhuman primates after infection with *Schistosoma haematobium* (refs 1 and 2 and unpublished results of R E K, A W Cheever, B J Myers, S W Young and J A Moore) After various times, masses develop within the urinary bladders of the hosts, ranging from hyperplasia to papillary carcinoma as determined histopathologically Although the basic mechanism of tumour induction in such cases is not known, the many factors involved could include stimulation of endogenous virus infections It is therefore interesting that we have now found C-type viral particles in one out of four papillary carcinomas of capuchin (*Cebus* sp) monkeys experimentally infected with *S haematobium* None were seen in two infected animals that developed only hyperplasia and squamous metaplasia Previous examination of normal bladder tissue has failed to demonstrate similar C-type viruses For electron microscopy and infection of the animals with *S haematobium* we used published methods[1,3,4] The bladders were taken from monkeys previously infected with *S haematobium* (Table 1) Histological evaluation based on examination of biopsy samples is also provided (Table 1)

Table 1 Histological evaluation of bladders of capuchin monkeys infected with *S haematobium*†

* +, ++, +++, Indicate few, moderate numbers, or many eggs in samples 1–3 weeks before indicated duration of infection

† Carried out by Dr A W Cheever, National Institute of Allergy and Infectious Diseases.

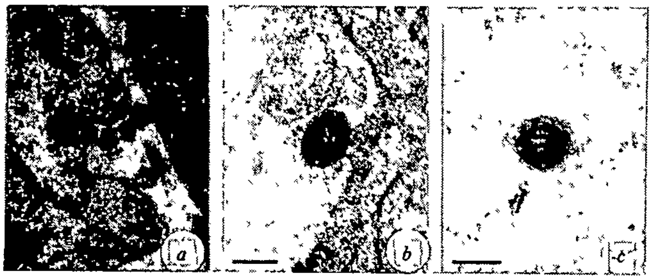

Fig. 1 *a*, Neoplastic transitional epithelium from urinary bladder of monkey No 70 with typical mature C-type viral particles in extracellular spaces *b*, C-type particle budding from plasma membrane *c*, Immature C-type particles in extracellular space (Scale 100 nm.)

Figure 1 shows electron microscopic evidence of C-type viruses at various stages of maturation associated with transitional epithelial cells in the bladder carcinoma of capuchin No 70 This tissue was the same as that examined by light microscopy Viral particles were readily observable throughout the transitional epithelial areas, but were absent in the loose connective and smooth muscle layers It should be emphasised that although one of the six monkeys examined was positive, this was the animal with moderate atypia As Table 1 shows, this animal was also passing the highest number of eggs in its urine, an indication of involvement of the bladder Control tissue, that is bladders of animals not infected with *Schistosoma* as well as those with minimal or minor involvement of the bladder, has so far failed to disclose the presence of C-type particles

No definitive conclusions concerning the aetiology of bladder cancer can be drawn from these observations, but they do offer an intriguing approach for further study Bladder cancers of nonhuman primates are extremely rare[5], and while coincidence cannot be ruled out, several other considerations must be examined It has been suggested that all primates, like some other animal species, contain endogenous C-type particles[6,7] Is the schistosome the cause or is it the triggering mechanism? On the other hand, is this tumour development due to an exogenous agent, which is carried by the parasite?

We thank Messrs Jerry A Moore and Al Bodenman for assistance This study was funded in part by the Virus Cancer Program, National Cancer Institute, the US Public Health Service, US–Japan Cooperative Medical Science Program administered by US Public Health Service and the World Health Organisation

Ethnicity is a significant factor in the epidemiology of rubella and Hodgkin's disease

SOME diseases of humans have an incidence which varies with ethnicity Epidemiologic patterns are seen for example in nasopharyngeal carcinoma[1], carcinoma of the liver[2] and Hodgkin's disease[3] There are quite marked differences in HL-A antigens between some ethnic groups, in particular, some antigens commonly found in caucasoid racial groups are infrequent in negroid groups and absent in mongoloid groups[4]

Our recent study (unpublished) of 61 caucasians (28 males) with congenital rubella revealed an increased incidence of HL-A antigens 1 and 8 (HL-A1 $\chi^2 = 9\ 57$, P corrected for 25 comparisons (P^c) $< 0\ 05$, HL-A8 $\chi^2=4\ 40$, $P^c < 0\ 89$), because of the very high occurrence of these antigens in the female subjects (HL-A1 $\chi^2 = 14\ 32$, $P^c < 0\ 003$, HL-A8 $\chi^2 = 9\ 61$, $P^c < 0\ 048$) Although the incidence of antigens 1 and 8 was not raised in the male subjects, those males who possessed these antigens were clinically more severely affected by the disease ($\chi^2 = 4\ 17$, $P < 0\ 04$)

We can now show that ethnic variations in the frequency of HL-A antigens 1 and 8 influence the epidemiology of rubella, and that striking similarities are found in the epidemiology of Hodgkin's disease These similarities support the suggestion that Hodgkin's disease has an infectious aetiological component but do not necessarily relate it to rubella

In order to determine whether the frequency of HL-A antigens 1 and 8 is relevant to rubella epidemiology throughout the world, we correlated (Fig 1) the percentage of young adults with serological evidence of previous rubella infection (that is, % seropositive) with the gene frequencies of HL-A1, HL-A8 and the mean gene frequency of HL-A1 and 8 for that ethnic composition (These were calculated from the Joint Report of the Fifth Histocompatability Workshop, 1972 (ref 4) It was sometimes necessary to calculate a mean gene frequency using the percentage of different ethnic groups in a particular population[5])

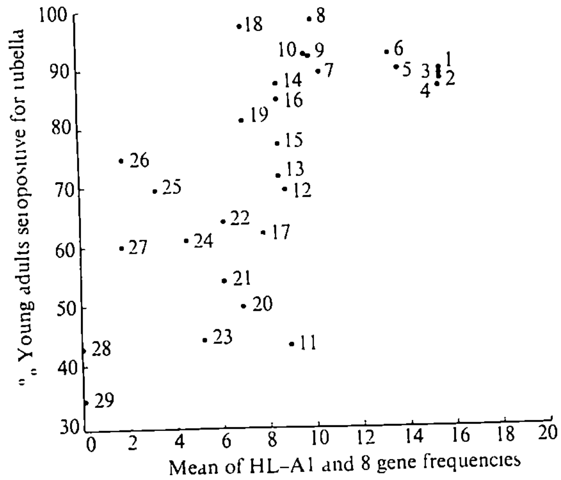

Fig 1 Geographical correlation between the mean of HL-A1 and 8 gene frequencies and seropositivity to rubella in young adults (aged approximately 20-29) HL-A gene frequencies were taken from ref 4 except for localities 4, 5, 6, 7 and 26, where refs 19, 21, 23, 25 and 34 were used respectively Correlation coefficient (r) = 0 68, t test on r (t_r) = 4 78, $P <$ 0 001 Localities indicated, together with references for the source of the rubella serology data, are as follows (1)=England[15], (2)=Australia[16], (3)=United States, Houston[17], caucasian, (4)=Sweden, Stockholm[18], (5)=Holland[20], (6)=Germany, West Berlin[22], (7)=Soviet Union, Moscow[24], (8)=Egypt[26], Arabs, (9)=Tunisia[27], (10)=Iran[28], (11)=Puerto Rico[29], (12)=Bermuda[30], (13)=Peru, caucasian[9], (14)=France, Lyons[17], (15)=Brazil, Sao Paulo[31], (16)=Argentina[9], (17)=Hawaii, all races[32], (18)=Soviet Union, Armenia[24], (19)=India[33], (20)=Panama[9], (21)=Surinam[20], (22)=Costa Rica[29], (23)=Trinidad[9,17], (24)=Jamaica[9 17], (25)=Peru, Indians and Mestizos[9], (26)=Singapore[17], (27)=Malaysia, Kuala Lumpur[7], (28)=Hawaii, Japanese[32], (29)=Japan, rural[17] In localities 9, 11, 12, 15, 16, 20, 22, 23, 26 and 27 ethnic composition was calculated from ref 5 as the exact ethnic composition of the population tested for rubella was not stated

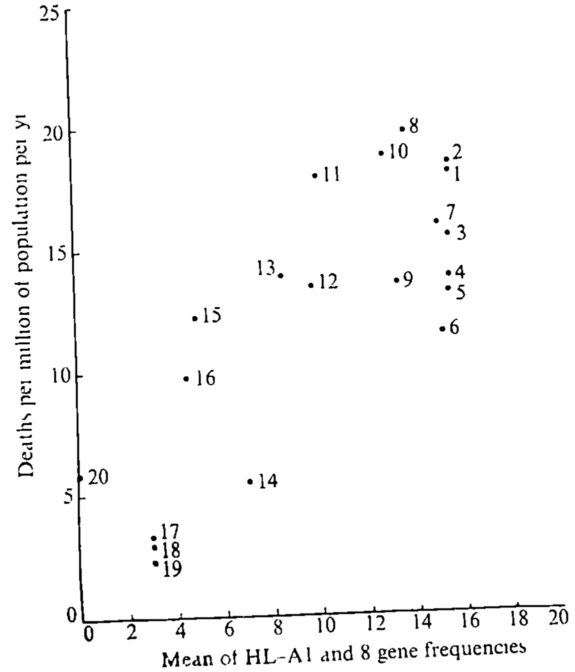

Fig 2 Geographical correlation between the mean of HL-A1 and 8 gene frequencies HL-A gene frequencies from ref 4 except where second references (19, 21, 23, 37) are cited, and deaths from Hodgkin's disease (all ages) per million of population per yr Correlation coefficient (r)=0 79, t test on r (t_r)= 5 47, $P <$ 0 001 Localities indicated in Fig 2, together with references for the source of the Hodgkin's disease data, are as follows (1)=United States, caucasian[3], (2)=England and Wales[35], (3)=Norway[3,19],(4)=Finland[3 19],(5)=Sweden[3,19],(6)=Australia[3], (7)=Canada[3], (8)=Holland[3,21], (9)=Germany[3,23], (10)=Denmark[3,19], (11)=Italy[3], (12)=India, Bombay, Parsi[35], (13)=France[3], (14)=India, Bombay, non-Parsi[35], (15)=United States, negro[36,37], (16)=Jamaica[38], (17)=Uganda[39], (18)=Kenya[40], (19)=Nigeria[41], (20)=Japan[3]

Linear regression analyses on the data for HL-A1 gave a correlation coefficient (r) of 0 72, t test on r (t_r) was 5 31 and the probability (P) was $<$ 0 001 For HL-A8, r was 0 61, t_r was 3 94, $P <$ 0 001, and for the mean gene frequency of HL-A1 and 8, r was 0 68, t_r was 4 78, $P <$ 0 001 These high positive correlations indicate that the frequencies of HL-A1 and 8 are an important factor in the worldwide epidemiology of rubella

By studying an epidemic of rubella, Hattis *et al*[6] have shown that there is a small number of infected individuals who have a high potential for spreading the virus ('spreaders') but that the majority of infected individuals have only minimal potential for spread We postulate that these spreaders who infect most susceptibles with whom they come in contact are those possessing the HL-A1, 8 haplotype The mean gene frequency of HL-A1 and 8 in a population would then be related to the number of potential spreaders, and consequently the extent and rate of transmission of virus in that population.

In the past, inexplicable differences in the mode of spread of rubella virus in various populations have been recorded. Statements concerning the spread in Hawaii[6], Malaysia[7], Taiwan[8], Jamaica and Trinidad[9], where the HL-A1 and 8 gene frequencies are low, may be related to the present hypothesis In all these areas there are fewer epidemics of rubella than expected, and in some the virus fails to become endemic in spite of high population densities This would seem to be due to the low HL-A1 and 8 gene frequencies causing sparser distribution of spreaders in a population which is genetically less susceptible to infection Although the occurrence of epidemics in these communities will also depend on the interaction of other factors such as opportunities for entry of the virus, the density of the population, and the level of herd immunity at the time of viral introduction, we propose that the most important factor is the frequency of the genes for HL-A1 and 8

Like that of rubella, the incidence of Hodgkin's disease varies in different ethnic groups, an infectious aetiological agent has been suggested, since the disease occurs in clusters[10], and a single contact can apparently give rise to multiple cases[11] Various studies in caucasians with Hodgkin's disease have revealed raised levels of several HL-A antigens[12], such as HL-A1 and 8, W5 and W18, all of which are absent from the Japanese[4], who have a later onset and slower rise of incidence of the disease[13] There is a significant increase in the incidence in Japanese moving to the United States In the United States, 71% of Japanese over the age of 50 are recent immigrants and in this older group the death rate from Hodgkin's disease rises sharply to, and even slightly above, the United States caucasian level[13] This is comparable to a group of non-immune individuals moving from a situation where an infectious disease is of low incidence and they have a low chance of contacting it, to an environment where it is more common and they have a much higher chance of contacting it, in this case the group moves from a population with low (or absent) frequencies of HL-A1 and 8 (Japan) to a population where these antigens are much more frequent (United States)

Table 1 Correlation of % mean gene frequencies of various HL-A antigens in 20 populations with deaths from Hodgkin's disease*

Antigen	*r*	t_r	*P*
HL-A1	0 79	5 47	<0 001
HL-A8	0 75	4 81	<0 001
HL-A1, 8	0 79	5 47	<0 001
HL-A3, 7	0 69	4 04	<0 001†
HL-A2, 12	0 39	1 79	Not significant
HL-A2, 7	0 54	2 72	,, ,,
W5	0 31	1 41	,, ,,
W18	0 39	1 48	,, ,,

* Deaths at all ages per million in that population per yr

† Populations which are predominantly caucasoid have high levels of HL-A antigens 3 and 7, and these antigens were more frequent (total % gene frequency 240) in our 20 test populations than HL-A antigens 1 and 8 (total % gene frequency 200) Thus the more significant association of HL-A antigens 1 and 8 ($r = 0\ 79$) with the incidence of Hodgkin's disease (compare 3, 7 $r = 0\ 69$) indicates that this relationship with HL-A1 and 8 is not simply due to a caucasoid trait not associated with HL-A

In order to determine whether HL-A1 and 8 played a part in the epidemiology of Hodgkin's disease similar to that found in rubella, data on the incidence of Hodgkin's disease in other ethnic groups were correlated with the mean gene frequency of HL-A1 and 8 (Fig 2) Linear regression analysis on the data for HL-A1 and HL-A8 produced high correlation coefficients (Table 1) The correlations with W5 and W18 were not significant We note that the high level of correlation with HL-A1 and 8 does not preclude association of Hodgkin's disease with some of the other HL-A antigens which also vary with ethnicity Populations which are predominantly caucasian have high levels of HL-A antigens 3 and 7 but the more significant association of HL-A1 and 8 with incidence of Hodgkin's disease indicated that this correlation with HL-A1, 8 was not simply due to a non-HL-A associated caucasoid trait

These similarities in the epidemiology of Hodgkin's disease and rubella support the concept that Hodgkin's disease has an infectious component, with the racial distribution of HL-A antigens controlling the degree of susceptibility of the population and the number of spreaders[11] Possibly there are other diseases of uncertain aetiology where an infectious agent has been implicated and where the incidence varies with ethnicity (for example multiple sclerosis[14]) in which there is a similar epidemiological pattern

IgD on cell membranes of human lymphoid cell lines with multiple immunoglobulin classes

IMMUNOGLOBULIN D (IgD) is present in minute amounts in the serum and the biological role of this immunoglobulin class is unknown[1]. The finding that a high proportion of lymphocytes bear IgD on their surface membrane[2] has triggered renewed interest in this molecule.

IgD constitutes only 0.2% of serum immunoglobulins, but approximately 20% of circulating 'bursal' (B) lymphocytes bear surface IgD (ref. 2). In the newborn, serum IgD is usually undetectable and IgD seems to be the predominant class of surface Ig found on B lymphocytes (approximately 60%)[3]. These findings suggest that cell-associated IgD has an important biological function. Although cell surface Ig is normally restricted to a single class, individual lymphocytes with surface IgD can bear immunoglobulins of other classes as well. Thus, IgM has been found together with IgD in the membrane of peripheral blood lymphocytes of both adults and neonates[4,5] and on cells of patients with chronic lymphocytic leukaemia[6], in patients with Sjogren's syndrome the B lymphocytes seem to have IgG, IgA, and IgM on their surfaces in addition to IgD (ref. 7). Critical to the understanding of the significance of IgD, as well as the significance of multiple Ig classes on cell membranes, is whether these immunoglobulins are produced by the cells bearing them, or whether they represent cytophilic molecules or autoantibodies.

Here we report that IgD can be found on all the cells of a relatively high proportion of established human lymphoid cell lines grown in continuous *in vitro* culture. In addition, these IgD bearing cells were found to bear IgG, IgM and IgA. These findings provide direct evidence that lymphocytes produce the IgD found on their surface membranes and that individual lymphocytes can produce as many as four different surface Ig classes.

Cell surface Ig was demonstrated by staining the membranes of living cells with specific fluorochrome conjugated antisera. Of 25 cell lines tested, six were found to bear IgD (Table 1). Cell line 689 stained very brightly for IgD and all the cells in the culture were positive. In other cell lines the staining was less intense and although all the cells had surface IgD, the intensity of staining varied. Those cell lines found to bear δ (IgD) heavy (H) chains were examined for the presence of other H-chain classes in the membrane. In each case all the cells had surface γ (IgG), μ (IgM) and α (IgA) but not ε (IgE) H chains, and only one type of light (L) chain, K or λ. Several of the IgD negative cell lines were also found to bear more than one class of surface immunoglobulin. Because of this unexpected finding, multiple staining was confirmed using independently prepared purified antibodies, and precautions were taken to rule out nonspecific staining. The Fc receptor[10,11] found on B cells could bind spontaneously aggregated γ globulin present in the fluorochrome conjugated antisera. Removal of aggregates, however, by ultracentrifugation at 100,000*g* for 2 h did not affect the staining results. Non specific binding by the Fc portion of the fluoresceinated antibody to this receptor is unlikely as some fluorescent antibodies, for example, anti-IgE, did not stain the cells. This possibility was excluded when identical staining was obtained with the $F(ab')_2$ fragment of anti-IgG antibody, which lacks Fc determinants[8].

The state of these various H chains in the membrane was investigated. Membrane surface molecules can be aggregated by cross linkage with specific divalent antibodies[12]. When stained, these can be seen as fluorescent patches which are then actively transported to one pole of the cell to form a cap. Cells of cell line 698 were stained with fluorescein conjugated antibody to K L chain, washed, and incubated at 37° C for 1–3 h to allow capping to occur. Cells were then incubated with rhodamine-conjugated antiserum with specificity for an H-chain class. This second incubation was performed at 4° C in the presence of sodium azide (0.1%), conditions which prevent capping. Capping induced by antibody to the single L-chain type caused each H-chain determinant to cap along with the L chain. That is, the antiserum directed against each H chain stained only the cap. This indicates that δ, γ, μ and α H chains are each associated with an L chain on these cells and probably exist as discrete Ig molecules. Purified antibodies directed against H chains were less effective in producing caps. Anti-μ and anti-δ reagents induced caps in approximately 30% of cells of the 698 cell line. In these instances repeat staining with antibody to the same H chain stained only the cap and antibodies directed against each of the other H chain classes stained the cell diffusely. Thus μ and δ chains each capped independently of the other three H chains. This is similar to the finding that μ and δ chains cap independently of each other on peripheral blood lymphocytes[4,5]. Antibodies to γ and α chains stained the cells less intensely and did not produce distinct cap formation.

The cell lines are grown in continuous long term culture in the absence of exogenous human immunoglobulins. It was important to rule out the possibility that the observed staining was due to a few cells in the culture secreting IgD or other immunoglobulins, which then adhered to the remaining cells because of cytophilic properties. Human lymphoid cell lines can secrete more than one Ig class, but secreted IgD has not been found[13].

Cell line 698, which had the most intense staining for each of these surface Ig classes, was tested for immunoglobulin secretion. The cells were incubated with ^{14}C-leucine and the incubation medium then analysed for newly synthesised and secreted Ig by radioimmunoelectrophoresis[14]. The cells secreted only IgG-K molecules. This result is consistent with previous reports that membrane-bound Ig and secreted Ig are regulated by separate mechanisms[15].

These findings provide direct evidence that surface IgD is synthesised by the cell that bears it and is not merely adherent because of cytophilic properties[4,6]. Furthermore, it seems that individual lymphocytes have the capacity to produce four different surface Ig classes (IgD, IgG, IgA and IgM). The evidence of Litwin *et al.*[16] that lymphoid cell lines have both μ and γ chains on their surfaces is consistent with these findings. The significance of multiple Ig classes on single lymphocytes is not clear. Although it is tempting to speculate that a switch of surface $\delta \rightarrow \mu \rightarrow \gamma \rightarrow \alpha$ L chains occurs during the ontogeny of the lymphocyte[4], similar to the switch occurring fro μ to γ with secreted immunoglobulins[17], the distribution of multiple H chains found in these cell lines does not support such a hypothesis. No cells lines were found to bear δ or evenδ plus μ chains exclusively. Indeed, all the δ bearing lines also bore μ, γ and α chain. We expect that these different Ig classes will have identical L chains and will share identical H chain variable regions as reported for myelomas secreting two different Ig classes[17]. Each class may be involved in triggering a specific lymphocyte function. The predominance of IgD bearing cells in the neonatal period suggests that this class of molecules may be involved in the induction of immunologic tolerance[4]. The existence of cell lines in which every lymphocyte bears both IgD and multiple other Ig classes provides a powerful tool for the *in vitro* investigation of these questions.

In the normal adult, differentiation has resulted in restricted expression of surface Ig classes. Multiple H chain determinants, however, have been found on individual lymphocytes in some patients with chronic lymphatic leukaemia[18–20] and also in patients with Sjogren's syndrome, an autoimmune disease in which there is a spectrum of benign to malignant lymphoproliferation[7]. These abnormali-

The cells in these cultures grow in suspension and are fed twice weekly with RPMI 1640 medium (NIH Media Unit) supplemented with 10% foetal calf serum (FCS) (Grand Island Biological NY) These cell lines have undergone a minimum of sixty subcultures Monospecific antiserums to IgG, IgA and IgM were prepared as previously described[2,7] using insoluble immunoabsorbents Special precautions were taken to ensure specificity of anti-IgD (refs 2 and 7) The antiserum was sequentially absorbed with Sepharose coupled to IgG, IgA, IgM, free L chains, and serum from a subject with low IgD levels No blocking occurred when the cells preincubated with non-fluorescein labelled anti-IgM or anti-IgG were tested for staining with fluorescein-conjugated anti-IgD When an antiserum specific for IgD (obtained by immunisation of a goat with IgD-λ myeloma protein) was absorbed with a different IgD preparation (IgD-κ) coupled to Sepharose, or with Sepharose-IgA-κ, only the IgD absorbed preparation had a markedly diminished staining capacity For capping experiments, purified antibody to IgD was prepared by absorption and elution from purified IgD-Sepharose[1] Antibody to κ chains was prepared using Sepharose-IgG-κ and antibody to λ chains prepared using Sepharose-IgE-λ Multiple H-chain staining was confirmed using independently prepared purified antibodies The antisera or antibodies were conjugated with fluorescein or tetra-methyl-rhodamine isothiocyanate[9] The fluorescein or rhodamine to protein (F/P) molar ratio of the reagents used ranged from 1 1 to 2 8 1 Viable cells were centrifuged and the pellet containing 2×10^6 cells incubated with 0 1 ml of undiluted fluorescein or rhodamine conjugated antiserum at 4° C for 30 min Sodium azide was added when it was necessary to prevent capping The cells were washed and suspended in medium (RPMI 1640 medium containing 5% FCS) on sides with vaseline-sealed coverslips The cells were examined by means of a Leitz Ortholux microscope with an Osram HBO 200 mercury arc lamp and a Leitz vertical illuminator

* Infectious mononucleosis, Hypogammaglobulinaemia, Xeroderma pigmentosum IgD bearing cell lines were tested for surface IgE and were found to be negative, nt, not tested

ties may represent dedifferentiation of the malignant or abnormal cells which permits the expression of multiple Ig classes in the membrane in a manner similar to that seen in human lymphoid cell lines On the basis of the findings in this report cytophilic molecules or autoantibodies need not be invoked to explain the finding of multiple Ig classes in lymphocyte membranes in these clinical states

We thank Dr Henry Metzger for advice and comments We also thank Dr G Klein (Stockholm) for providing many of the cell lines used in this study Purified rabbit antibodies to IgM and IgA and sheep antibody to IgE and the F(ab')$_2$ fraction of anti-IgG antibody[8] were provided by Dr H Metzger

Marrow environment not required for differentiation of B lymphocytes

In birds, B lymphocytes differentiate from primitive progenitors in the Bursa of Fabricius, which is thought to provide a unique inductive stimulus, as the thymus in both birds and mammals is thought to provide a stimulus for the differentiation of T lymphocytes A bursal equivalent has not, however, been identified in mammals Two proposed sites are the bone marrow[1] and the gut-associated lymphoid tissue[2] We now have evidence, however, that the bone marrow is not an essential site for the differentiation of B lymphocytes in mammals

B lymphocytes differentiate from pluripotent stem cells in the bone marrow[3 4] These cells are probably identical or closely related to haemopoietic stem cells Specificity-restricted precursors of B cells (PB cells) are also found in bone marrow and seem to represent a stage intermediate between stem cells and functional B lymphocytes[5 7] PB cells have immunoglobulin (Ig) receptors but cannot initiate immune responses without further differentiation Thus, the differentiation pathway of B lymphocytes can be subdivided into at least two stages the differentiation of PB cells from stem cells, and the production of B cells from PB cells We have investigated the relative role of the bone marrow environment on these two stages

Table 1 CFU-S survival in femur from ^{89}Sr-treated donors

Time at 4° C (h)	Donor	Cells per femur (×10^5)	CFU-S per femur*	% Survival*
0	Control	180	3,700±530	13±6 0
	^{89}Sr-treated	110	490±210	
24	Control	220	1,800±550	10±3 4
	^{89}Sr-treated	130	180± 29	
48	Control	180	1,500±200	0 80±0 16
	^{89}Sr-treated	68	12± 1 7	

Mice (F_1 hybrids between C57BL/6 and C3H) received an intraperitoneal injection of 50 μCi ^{89}Sr Twenty-four hours later the femurs were removed from fifteen of these mice and from fifteen normal mice These femurs were placed in a Petri dish on filter paper moistened with phosphate-buffered saline and stored at 4° C At the times indicated ten femurs were taken from each group and used to prepare marrow cell suspensions Aliquots were injected into irradiated (950 rad) recipients to measure CFU-S

* Mean values ± one s e m

It is possible by injection of radioactive strontium (^{89}Sr), to make the marrow a hostile environment for differentiation[8,9] This isotope is taken up exclusively by bone When ^{89}Sr decays, it emits 1 5 MeV electrons and irradiates the bone marrow cavity with doses of radiation that inhibit proliferating cells[8] Because the energy of the radiation is insufficient to penetrate bone and irradiate other organs in the animal, it is possible by this means to irradiate specifically and continuously the entire bone marrow of an animal without affecting the integrity of other organs

We first estimated how rapidly cells in bone marrow were inactivated by an intraperitoneal injection of ^{89}Sr Twenty-four hours after injection, the intact femurs were taken from these mice and from normal mice and stored at 4° C After various times, the marrow was collected from these femurs and the number of haemopoietic stem cells per femur was determined by injection of the cells into irradiated recipients These stem cells form easily detectable colonies in the spleens of irradiated mice, and enumeration of the number of spleen colony-forming units (CFU-S) provides a quantitative estimate of the number of surviving haemopoietic stem cells[10,11] Because the radiation sensitivity of CFU-S and B cells is similar[12], the survival of CFU-S in ^{89}Sr-treated recipients should be similar to that of B cells and their precursors located in marrow These measurements (Table 1) suggest that CFU-S are killed exponentially with time and have a halflife of approximately 10 h in a marrow environment irradiated by ^{89}Sr In four other experiments in which CFU-S survival was measured 4 d after ^{89}Sr treatment, survival was always about 1% relative to untreated controls

On the basis of this short halflife for a known stem cell in ^{89}Sr-treated recipients, we attempted to measure the function of mature B cells, PB cells and lymphoid stem cells in mice with defective marrow Recipient mice received intraperitoneal injections of 50 μCi of ^{89}Sr Four days later, both these mice and untreated controls received whole body irradiation from a ^{137}Cs irradiator with doses ranging from 750 to 950 rad and were used to measure B cell, PB cell or stem cell activity as indicated below

To test for loss of B cell activity, each recipient received 2×10^7 spleen cells from normal donors, together with 5×10^8 sheep red blood cells (SRBC) Eight days later, they were killed and antibody-producing cells were counted per spleen using the Jerne plaque-forming cell (PFC) assay[13], to give a measure of B-cell activity in these recipients Table 2 shows that in three experiments, B-cell activity was not affected by pretreatment of recipients with ^{89}Sr, if anything, the response was greater in pretreated recipients than in controls

Table 2 Function of lymphoid and haemopoietic cells in ^{89}Sr-treated mice

Assay	Experiment no	Response in†		$\frac{^{89}\text{Sr-treated}}{\text{control}}\times 100$‡
		Control recipient	^{89}Sr-treated recipient	
B cell	1	703 PFC per spleen	987 PFC per spleen	140 (112–176)
	2	629 PFC per spleen	1,803 PFC per spleen	286 (185–442)
	3	1,504 PFC per spleen	1,196 PFC per spleen	79 (51–122)
PB cell	1	1,278 PFC per spleen	730 PFC per spleen	57 (34– 96)
	2	1,606 PFC per spleen	899 PFC per spleen	56 (31–102)
	3	6,792 PFC per spleen	1,993 PFC per spleen	29 (20–42)
Stem cell	1 (25)*	22,600 PFC per spleen	14,600 PFC per spleen	65 (38–109)
	2 (24)	25,300 PFC per spleen	11,100 PFC per spleen	44 (35–55)
	3 (33)	26,000 PFC per spleen	15,600 PFC per spleen	60 (41–88)
CFU-S in marrow	1 (25)	636 CFU-S per femur	35 CFU-S per femur	5 5 (4 8–6 2)
	2 (24)	860 CFU-S per femur	16 CFU-S per femur	1 9 (1 3–2 5)
	3 (33)	1,206 CFU-S per femur	52 CFU-S per femur	4 3 (2 8–5 8)
CFU-S in spleen	1 (25)	783 CFU-S per spleen	1,933 CFU-S per spleen	247 (197–297)
	2 (24)	1,500 CFU-S per spleen	2,800 CFU-S per spleen	187 (159–215)
	3 (33)	1,512 CFU-S per spleen	2,889 CFU-S per spleen	191 (149–233)

In experiments 1 and 2 the primary recipients received 750 rad whole body irradiation, in experiment 3, 900 rad

* The numbers in parentheses are the days after transplantation, that is, in experiment 1, the stem cell and CFU-S assays were done 25 d after transplantation of cells into the irradiated (950 rad) recipients

† The PFC responses are geometric means of the responses measured in individual spleens The CFU data are arithmetic means

‡ The values in parentheses are one standard error above and below the mean

To measure PB cell activity, bone marrow was separated by velocity sedimentation as described previously[5,14] Those cells sedimenting between 4 5 and 8 0 mm h^{-1} were pooled to provide a suspension enriched for PB cells and stem cells but nearly free of B cells[6] and 3×10^6 cells from the pool were injected, together with 5×10^7 thymus cells, into recipient mice prepared as above Seven days later the recipients were immunised with an intraperitoneal injection of 5×10^8 SRBC Eight days after immunisation, the PFC per spleen were measured for each mouse Lafleur *et al*[5] showed that under these conditions the PFC response is derived primarily from PB cells Table 2 shows that the differentiation of PB cells is not markedly suppressed in ^{89}Sr-treated recipients

The differentiation of B lymphocytes from cells more primitive than PB cells was also studied according to the method of Lafleur *et al*[6] Cells were separated and injected into recipients as described above Approximately 4 weeks later, recipients were given an intravenous injection of 5×10^7 thymus cells (to ensure that there was no defect in T cell function) and 5×10^8 SRBC Six days later, at the time of peak response, the PFC response was determined As with PB cells, there was a slight suppression in the PFC response in ^{89}Sr-treated recipients (Table 2)

Radioactive strontium has a halflife of 54 d and should therefore have suppressed the activity of cells in marrow throughout the time period of our experiments This suppression was confirmed by measurements of CFU-S in the femurs and spleens of the ^{89}Sr-treated recipients When mice were killed for measurement of PFC for the stem cell assay, their spleen and marrow cells were also injected into normal irradiated recipients to count the CFU-S CFU-S content in the femurs of ^{89}Sr-treated recipients was suppressed markedly compared with the control (Table 2) Also, as reported before[8], the spleens of such recipients had increased numbers of CFU-S These results show that cells such as CFU-S, which must proliferate to function, do not survive in the marrow during the time required for experiments such as ours

The CFU-S data clearly show that pretreatment of mice with ^{89}Sr effectively destroyed the bone marrow environment as a site for normal differentiation Nevertheless, the differentiation of PB and stem cells in such recipients was only slightly suppressed If this differentiation had to occur by proliferation of stem cells in the bone marrow environment, the suppression of activity should have been of the same order as seen for CFU-S in the marrow That such suppression was not observed is evidence that the marrow environment is not essential for the development of B lymphocytes

There are several possible explanations for the small suppression observed for the PB cells and stem cells assayed in ^{89}Sr-treated recipients Perhaps the most likely is that it is a result of the ability of many B cells to circulate through the lymphoid system[15] Because of this property, it is reasonable to expect that some B cells will be inactivated as they migrate through the bone marrow In support of this suggestion is our observation that the B cell activity in spleen decreases to approximately 30% of normal within 4 d after injection of 50 μCi of ^{89}Sr (unpublished data of R A P)

An alternative explanation of the suppression of PB and stem cell activity is that the differentiation of functional B cells requires a transient exposure to elements in bone marrow If the radiation sensitivity of B cell precursors is the same as for B cells and CFU-S, a suppression of 50% would be consistent with a 10-h exposure to the marrow environment This 10-h estimate is an upper limit and the data are consistent with there being no required residence time in marrow

Oestrogen receptors and antagonism of steroid hormone action

NON-STEROIDAL anti-oestrogens antagonise the effects of oestrogen on uterine growth, vaginal cornification and ovulation[1], and their mechanism of action has been suggested to reside in their ability to compete for cytoplasmic oestrogen binding sites, or receptors, thereby reducing the formation of receptor oestrogen complexes[2–4] Since the formation of these complexes in oestrogen target tissues, with subsequent translocation to nuclear sites, is considered the primary event in oestrogen action[5,6], the reduction in their number would lead to decreased physiological responses to oestrogen This implies that the receptor antagonist complex should have a lower intrinsic biological activity than that of the receptor oestradiol complex, that is, the ability of the receptor antagonist complex to stimulate oestrogenic responses would be less than that of the receptor oestradiol complex Based on these assumptions, oestrogen antagonism should be observed after a single injection of oestrogen and antagonists, we have now found that this is not the case Thus, non-steroidal anti-oestrogens could not be acting as antagonists by competing initially for oestrogen receptors

Immature rats, 21–22 d old, were injected with 2 5 μg oestradiol, 100 μg nafoxidine hydrochloride (Upjohn 11,100A 1-(2-[P-(3,4-dihydro-6-methoxy-2-phenyl-1-naphthyl)phenoxy] pyrrolidine hydrochloride) or a combination of the two, and uterine dry weights were determined 24–48 h later The increases in uterine dry weight after a single injection of oestradiol, nafoxidine or oestradiol plus nafoxidine were identical 24 h after injection By 48 h nafoxidine or oestradiol plus nafoxidine was more effective than with oestradiol alone in stimulating uterine growth (Fig 1) Therefore, after

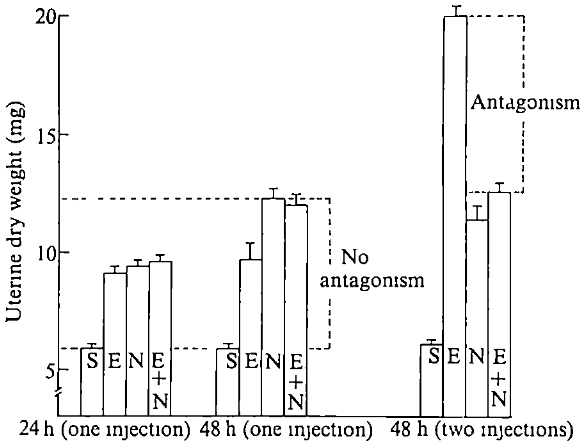

Fig 1 Agonistic and antagonistic effects of nafoxidine on uterine growth Immature female rats were injected with saline (S), 2 5 μg of oestradiol (E), 100 μg of nafoxidine (N) or oestradiol plus nafoxidine (E + N) according to the following design Two groups received one injection and uterine weights were determined 24 or 48 h later A third group received two injections 24 h apart and uterine weights were determined 24 h after the second injection Each value represents the mean ± s e m for three or four determinations with five or six animals per determination

a single injection of oestradiol plus nafoxidine there was no antagonism, indeed, nafoxidine clearly acted as an oestrogen The antagonistic properties of nafoxidine could be observed, however, when the compounds were administered at 24 h intervals and the uterine weights were determined after 48 h (Fig 1) Serial injections (between three and eight) at 24 h intervals have often been used routinely and it is well established that oestrogen antagonism can be observed under these conditions (refs 1 and 7–9 and Fig 1, two injections) Such routine methodology has resulted in the failure to detect a lack of antagonism after a single injection It should be noted that we have since used much smaller doses of antagonists than were injected in the work described with similar results, that is, smaller doses, 1–10 μg have both agonistic and antagonistic properties (to be published elsewhere)

We have proposed that anti-oestrogens antagonise oestrogen-induced uterine growth as a result of their failure to stimulate the replenishment of the cytoplasmic oestrogen receptor[10] That is, after cytoplasmic binding and nuclear translocation of receptor antagonist complexes, no additional receptor is provided to the cytoplasmic pool This failure to stimulate the replenishment of cytoplasmic receptor renders the uterus insensitive to subsequent injection of oestrogen and therefore antagonism can be observed

To test this hypothesis further and to establish the general nature of this phenomenon, we have examined the effects of two other oestrogen antagonists, CI-628 and (α-[4-pyrrolidineothoxy]phenyl-4-methoxy-α-nitrostilbene) and clomiphene (Triecthylamine, 2-(P-[-chloro-1,2diphenyvinyl]-phenoxy)-citrate) These compounds, as well as nafoxidine, were administered either alone or in combination with oestradiol, and the uterine weight and cytoplasmic oestrogen receptor content were determined The concentration of cytoplasmic receptor was determined by the ^{3}H-oestradiol exchange–charcoal adsorption method[10 11] which facilitates evaluation of total cytoplasmic receptor and avoids complications arising from assays that measure only free or unfilled receptor sites[12] Bound nafoxidine, CI-628 and clomiphene (our unpublished results) are freely exchangeable with ^{3}H-oestradiol in this assay procedure[10,11]

As Table 1 shows, all oestrogen antagonists examined were clearly uterotrophic and not antagonistic when given in combination with oestrogen Thus, CI-628 and clomiphene are similar to nafoxidine in this regard In addition, all three antagonists, alone or in combination with oestradiol, reduced the quantity of cytoplasmic receptor 24 h after treatment (Fig 2) Thus none of these antagonists could stimulate the replenishment of the cytoplasmic receptor, whereas oestradiol treatment resulted in a significant increase in receptors (Fig 2) Therefore, the ability of the uterus to respond to oestradiol 24 h after treatment with an antagonist would have been greatly reduced This was clearly the case with nafoxidine, after which subsequent oestradiol treatment induced no uterine growth (Fig 1) In contrast, the quantity of cytoplasmic receptor in animals pretreated with oestradiol was twice that of the controls and the uterus was very responsive to a second injection of oestrogen (Fig 2)[10] Thus these compounds are both agonistic and antagonistic The anti-oestrogens are agonists because they stimulate the metabolic and regulatory pathways that cause uterine growth They are also antagonists, however, because they fail to stimulate the replenishment of the cytoplasmic receptor and thus leave the uterus insensitive to oestrogen

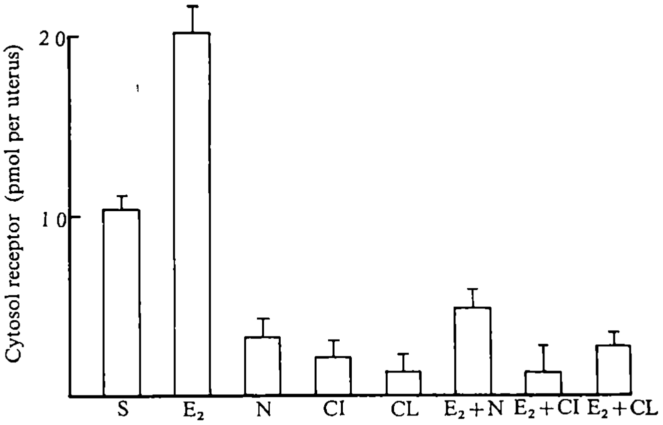

Fig 2 Effect of oestradiol and oestrogen antagonists on the quantity of cytoplasmic receptor 24 h after treatment Immature female rats were injected with 2 5 μg of oestradiol (E), 100 μg of nafoxidine (N), 0 5 mg of CI-628 (CI), 10 0 mg of clomiphene (CL) or a combination of oestradiol plus the antagonists The quantity of total cytoplasmic receptor was determined 24 h after treatment by the ^{3}H-oestradiol exchange–charcoal adsorption procedure (see text) Each value represents the mean of three or four experiments with five or six animals per experiment

Table 1 The effect of oestradiol and oestrogen antagonists on uterine growth after a single injection

Treatment	Uterine wet weight (mg) 24 h	Uterine wet weight (mg) 48 h
Saline	36 8 ± 1 5	40 5 ± 2 3
Oestradiol (2 5 μg)	53 4 ± 1 0	60 8 ± 2 7
Nafoxidine (100 μg)	54 2 ± 2 0	60 3 ± 4 2
CI-628 (500 μg)	51 2 ± 2 1	62 0 ± 3 6
Clomiphene (10 mg)	50 1 ± 2 8	69 0 ± 4 5
Oestradiol + nafoxidine (2 5 + 100 μg)	54 5 ± 1 9	63 2 ± 3 9
Oestradiol + CI-628 (2 5 + 500 μg)	52 9 ± 2 3	72 3 ± 5 7
Oestradiol + clomiphene (2 5 + 10 mg)	50 3 ± 2 8	74 0 ± 6 8

Immature female rats were injected with the compounds indicated and the wet weight of their uteri was determined 24 or 48 h later All values represent the mean ± the s e m

A further factor that might contribute to oestrogen antagonism is that anti-oestrogens might stimulate cellular hypertrophy, thereby increasing uterine weight, but fail to stimulate uterine hyperplasia In such a case the number of cells able to respond to subsequent oestrogen treatment would be reduced and this reduction would result in diminished utertrophic responses than when oestrogen alone was used To examine this possibility and to characterise further the growth induced by the anti-oestrogens, we have measured the quantity of DNA and protein in the uterus at various times after the administration of hormone or antagonist Both oestradiol and nafoxidine increased DNA content within 48 h, thus there was no apparent difference in their capacity to elicit uterine hyperplasia (Fig 3) Increased mitotic activity has also been observed to occur with either compound (unpublished results) The obvious difference between the uterotrophic responses elicited by the two compounds was the sustained stimulation of protein synthesis observed with nafoxidine (Fig 3) Apparently the long term uterotrophic effects of nafoxidine arise from the ability of the receptor antagonist complex to stimulate cellular hypertrophy These experiments indicate that oestrogen antagonism is not due to an inability of nafoxidine to stimulate cell growth In fact, it was more effective than oestradiol when uterotrophic responses were compared 72 h after treatment (Fig 3)

These studies are not sufficient to determine whether receptor replenishment is the only uterotrophic response not stimulated by oestrogen antagonists We feel, however, that most response pathways are stimulated since the increases in uterine protein, DNA and weight induced by the antagonists are equal to those induced by oestradiol Our findings are important in the interpretation of experiments in which oestrogen antagonists have been used to block ovulation, implantation and other oestrogen-stimulated responses In these systems oestrogen antagonists may stimulate oestrogenic responses just as in the uterus and, in a similar fashion, may not stimulate the replenishment of cytoplasmic receptor If this is true, the agonistic nature of the anti-oestrogens as well as their inability to promote the replenishment of the cytoplasmic receptor, and its subsequent binding and interaction with oestrogen, would become important considerations in the interpretation of such systems

Our investigation has important implications with respect to the mechanism of action of non-steroidal antagonists of oestrogenic hormones Theories and model systems designed to describe the action of oestrogen antagonists must include more than a simple competition for steroid binding sites It has been assumed that the dissociation constant, K_d, for the binding of antagonist to steroid receptors is related directly to its capacity to block steroid activity, that is, the K_d is that concentration of antagonists that will block or antagonise 50% of the maximal (physiological) biological response Assays for the action of oestrogen antagonists, however, usually have involved serial injections The marked depletion of cytoplasmic receptor under such conditions would invalidate the model because implicit in it is the assumption that receptor is present at normal levels during each period of treatment

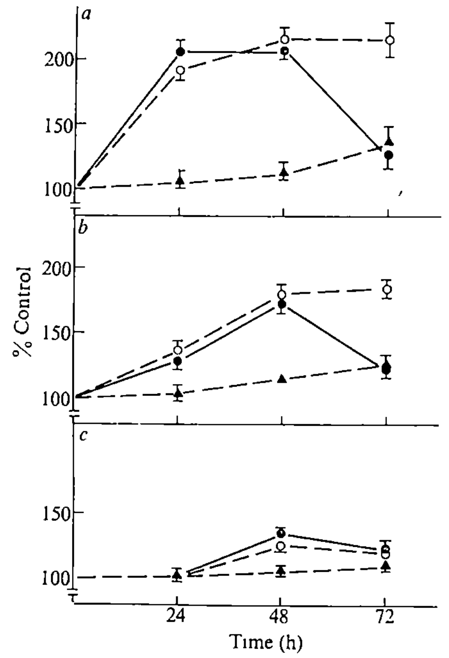

Fig 3 Effect of oestradiol and nafoxidine on uterine protein and DNA after a single injection Immature rats were injected with 2 5 µg oestradiol (●), 100 µg of nafoxidine (○) or saline (▲) and the wet weight, protein[13] and DNA[14] were determined 24, 48 and 72 h later The control values at the beginning of the experiment were wet weight, 32 5 ± 3 1 mg per uterus, protein, 4 5 ± 0 2 mg per uterus, DNA, 360 ± 12 µg per uterus Each value represents the mean of five or six determinations with three to six animals per determination *a*, Wet weight, *b*, protein, *c*, DNA

In conclusion, we believe that non-steroidal anti-oestrogens are antagonists not because they compete for cytoplasmic oestrogen receptor to produce a complex which is a poor stimulator of growth, but because they fail to stimulate the replenishment of the receptor Thus the uterus of the antagonist-treated animal contains relatively few cytoplasmic receptors and is insensitive to oestrogen, whereas the uterus of the oestrogen-treated animal contains many cytoplasmic receptors and is highly sensitive to oestrogen

The Mound People By P V Glob Pp 184+75 plates (Faber and Faber London, May 1974) £4 25

BARRY CUNLIFFE

ONCE more Professor Glob puts us in his debt Five years ago his best seller *The Bog People* was published in English, now we are presented with its sequel—*The Mound People*—a lively and enthralling account of the inhabitants of Denmark at one of the peaks of the country's cultural development in the second millennium BC In the first part of the book the author sets out to describe a selection of the remarkably preserved burials by which the Bronze Age inhabitants are known Having thus introduced them to us, down to the last detail of their clothing, he proceeds to reconstruct something of the social economic and religious background of the times

That so much is known is because of a combination of factors The bodies were buried, fully clothed, in coffins made from split oak logs which were hollowed out, and buried beneath high mounds of turf and soil—the barrows which still today dominate the skylines in many parts of Denmark Gradually the rain water percolated through the mound, and laden with tannin leached out of the oak, penetrated the coffins and thus preserved clothing as well as human skin, hair and sometimes brain tissue

Early discoveries, dating back to the beginning of the nineteenth century, were not particularly well observed and conservation techniques were unable to cope with such delicate material But more recently there have been several notable successes the most fascinating is undoubtedly the discovery in 1929 of a young girl of 20 or so from Egtved, whose midriff-exposing tunic and see-through cord skirt were greeted with shocked incredulity by certain members of the Danish academic world until it was pointed out that several contemporary bronze figures were shown clad in similar skirts

There can be very little doubt, from the surplus energy which must have been expended in constructing the great mounds, and from the richness of the personal equipment buried with the dead, that the coffin burials represent the aristocratic class of bronze age society Glob estimates that the turf required for a single barrow mound would have stripped between two and four acres of pasture of its soil cover When it is remembered that many thousands of these barrows were built in a comparatively short period, something of the devastation of the land can be appreciated

The conspicuous consumption of labour for constructing the mounds and the wealth of the objects of gold and bronze buried within them, metals which incidentally would have had to be imported into Denmark from further south, is a firm reminder of the stability of the native economy, based on the export of local products such as amber, cattle, furs and perhaps slaves, and of the strength of the military hierarchy All this is discussed in great detail in the final chapters, which bring together a wealth of archaeological facts moulded into a cohesive story of a people and their lives, with Glob's customary mixture of insight and intelligent speculation

Professor Glob evidently enjoys his archaeology In this attractively written and beautifully illustrated book he offers us the chance to share his enjoyment The opportunity is irresistible

Necessity for DDT

Chlorinated Insecticides Vol 1 Technology and Application By G T Brooks Pp 249 (CRC Press Cleveland, Ohio, 1974) $30 00

THE number of books on pesticides must by now be big enough to construct a largish pulpit from which to continue the environmental argument over such chemicals in general, and over the chlorinated insecticides, long since cast as the villains of the piece, in particular To those of us involved in agriculture, particularly tropical agriculture, and public health, the banning of these particular chemicals would constitute a disaster, with world food production the victim, the oil crisis may indeed yet cause such a shortage of pesticides as to bring about an unfortunate involuntary demonstration of their beneficial effects to mankind

It is therefore a pity that the various prefaces and introductions to this new series on the chemistry of pesticides seem somewhat apologetic and vague as to the reason why it has been launched "at a time that seems to mark the twilight of the chlorinated insecticides" If men are wise, this twilight will be a long one, because the much heralded "third generation insecticides" will not be a practical economic proposition for many years during which many more million mouths will need filling But during that time we need to re-appraise the potential and refine the deployment of chlorinated pesticides and for this a knowledge of their chemistry will be vital This is adequately and clearly covered in this volume, built up from a very extensive bibliography, included in the account of each group which comprise the DDT group, the diene group, HCH and Toxaphene, is a comprehensive summary of its syntheses and properties and the principles of analysis

The weakest parts of the book are the sections dealing with application, which are mainly a rehash of information already published in such standard texts as A W A Browne and J R Busvine This orthodoxy underrates the vital and increasing importance of correct formulation in application, particularly for the chlorinated insecticides, which can increase their efficiency and reduce their environmental danger, and which must be based on a detailed knowledge of their chemistry

It is difficult to assess the value of the entire book without reference to volume 2, which will deal with biological and environmental effects, but this volume is competent and covers the ground adequately and will be a useful reference work in pesticide laboratories

P T HASKELL

Energy in historical context

Discovery of the Conservation of Energy By Yehuda Elkana Pp x+213 (Hutchinson London, 1974) £4 00

THIS book attempts far more than a straightforward review of the historical development of the concept of energy and of the theory of its conservation Dr Elkana writes in his preface that "the fundamental idea behind [the book] is the essential unity of all aspects of the intellectual enterprise" Thus he discusses not only the internal issues (which in the case of the energy concept are wide-ranging, extending through all branches of science and over a number of centuries) but also the external issues of personality, social climate, metaphysical background and national influence The task he sets himself is a valuable one, I B Cohen, in his foreword, describes him as breaking new ground in trying to resolve the internalist–externalist debate, and certainly if a synthetic view of the historical development of science is ever to be achieved, such a resolution is essential

Despite his somewhat grandiose undertaking, Dr Elkana's book is not a long one, and at the end of it the reader is left feeling a little breathless Many lengthy discussions are curtailed by recourse to the assumption that the reader already has a thorough background knowledge of the extensive literature available, and any aspect of the subject which the author feels has already been adequately covered he omits, giving instead only a very brief critique of secondary sources This seems well justified in a study of this nature, but unfortunately creates some artificial imbalances for the unwary reader Thus, for example, Humphrey Davy is allotted as much space as Faraday or Joule, who traditionally play a greater part

Hermann von Helmholtz is, not surprisingly, the central figure in the book Dr Elkana puts forward the thesis that the very vagueness of the energy concept prior to Helmholtz's work—a vagueness he illustrates elaborately by examples of the confusions centred on words such as 'energy', 'kraft' and 'force'—was an essential element, which, combined with a metaphysical belief in the conservation of some undefined entity, eventually enabled Helmholtz to reach a formal mathematical statement of a general conservation of energy law in the 1840s This then allowed the concept of energy itself to be clarified He emphatically rejects any claims made that Newton, Carnot, Faraday or even Joule had an implicit awareness of the general law before Helmholtz's statement of it He rejects too some of the factors which have traditionally been considered important in the history of the law, such as the search for a perpetual motion machine and the development of the steam engine

The author's tendency to expound his aims and general historical method occasionally becomes distracting, especially since this is not confined to his introduction, but sometimes insinuates itself into discussions of a less general nature Hence interwoven, sometimes irritatingly, with his thesis about the concept of energy is a second, general thesis on how such concepts ought to be studied Occasionally, too, he introduces sweeping historical assumptions which take the reader a little by surprise Nevertheless his approach is very refreshing, and he raises numerous exciting and stimulating questions On every page there are suggestions for further research—indeed the author leaves almost too many avenues unexplored The book should certainly provide an excellent general scheme within which further study of the history of the energy concept can be placed

It is to be regretted that the paper republished as an appendix could not have been incorporated into the main body of the book—or at least printed in type of the same size as that used in the rest of the text

LAURA TILLING

Logic in plant chemistry

Chemotaxonomy of Flowering Plants By R Darnley Gibbs Vol 1 Constituents pp xx+1,680, vol 2 families, pp 681+1,274, vol 3 orders pp 1,275–1,980, vol 4 bibliography, index pp 1,981–2,372 (McGill Queens University Montreal and London, June 1974) $135 per set

Chemistry in Botanical Classification Edited by G Bendz and J Santesson (Proceedings of the 25th Nobel Symposium, August 1973) Pp 320 (Academic Press New York and London, July 1974) $27 50, £13 20

DR GIBBS is the doyen of English-speaking chemotaxonomists, and it is gratifying to receive the four large volumes which he has now produced

After a rather lengthy introduction, the author settles down in volume 1 to 800 pages of chemical plant constituents, arranged alphabetically under headings ranging from acetylenic compounds at one end to waxes at the other, complete with diagrams of structural formulae For the botanist, at least, this provides a very useful dictionary, and it continues to the middle of volume 2, when there is a switch to a second dictionary (of 280 pages), this time of the families of the dicotyledons and monocotyledons, also arranged alphabetically Each family, old or new, is given a paragraph with nomenclatural details and references, and there is an attempt to define the position of the family in the orders in which leading taxonomists during the last 150 years have placed it I found these paragraphs too compressed, often confusing, and of limited value

Dr Gibbs then proceeds to put the chemical and taxonomic information together, to see if it is possible in this way to define more effectively the orders of flowering plants The twelfth edition of Engler's syllabus is used as a basis for the treatment, which extends over the next 800 pages, to the end of volume 3 Orders which are minor or not generally recognised are dealt with briefly, but under each major order the relevant chemical data are given, together with the author's conclusions as to their bearing on the composition and limits of the order Thus, under the Tubiflorae, 26 families are described chemically in 40 pages of text and five tables, and this is summed up in a couple of pages of discussion

The chemical evidence is based partly on published work, and partly on the author's personal tests, which cover a wide range of species The discussions are usually critical and sometimes illuminating, but it is not always easy for the reader to evaluate for himself the great mass of data presented or to follow the author in his reasoning Essentially, he is trying to make sense of the patterns of distribution of chemical compounds among large taxa, and without advanced statistical treatment (and with so many gaps in the information) he cannot get very far But the book will be of value as a storehouse of data and as a record of the author's experience The fourth volume contains the bibliography, the valuable index and some addenda

The book of the Nobel symposium is an excellent piece of work In it, some 30 distinguished specialists present papers on a series of topics, particularly the role of special classes of compounds in the systematics of plant groups of various kinds and sizes, together with critical consideration of the discipline of chemotaxonomy

The papers are all short and to the point, presenting the special data or individual views of the author concerned, and often controversial, and each is followed by a page or so of discussion There are also a general discussion and a summing up The symposium must have been most stimulating to the participants, and this sense of stimulation is communicated in the volume, which is highly recommended

D H VALENTINE

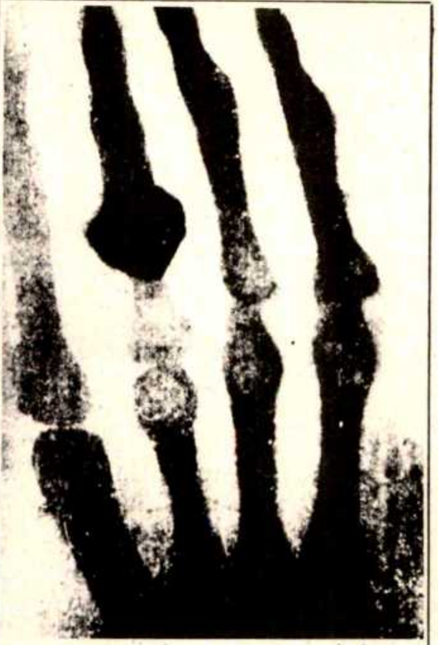
Medical meeting

Medical Research Systems in Europe. Edited by E. P. Woodford. (A joint Wellcome Trust-Ciba Foundation Symposium held in London in March 1973. Ciba Foundation Symposium 21, New Series.) Pp. viii+335. (Elsevier, North-Holland: Amsterdam, London and New York, 1973.) Dfl. 43; $17.20.

WITH all the turmoil in research circles following the British government's acceptance of the Rothschild "customer/contractor" principle of research funding and organisation, this meeting was very timely. Twenty-two speakers from all the major countries in western and eastern Europe except for the Soviet Union circulated in advance papers describing the situation in their countries. This was a wise step, for though the papers are very useful sources of information, a repetition of the various types of support and organisation would have been tedious. The main purpose of the symposium was discussion, and this comprises some 80 pages of fascinating reading, indicating a real exchange of ideas.

Although the meeting was ostensibly about research, it also dealt fully with medical education and administration, and with the ways in which students could be channelled in to research careers. The most obvious differences between the different countries stemmed from their admission policies to medical schools. Most countries, both western and communist, now restrict their student entry to numbers near to those which the teachers think reasonable—the so-called *"numerus clausus"*. Even so there were complaints of overcrowding and difficulties in communication. In Lisbon, where entry is unrestricted, a first-year entry of more than 2,000, with a 50% drop out, was found to be prejudicial to both research and teaching. Several speakers spoke of the danger to the community of the disappointed drop-outs, though this seemed more serious to western than eastern participants. There was acceptance of high numbers of students by C. H. Nachev of Bulgaria, though the proportion receiving maintenance grants there is only 40% of that in Britain.

Nobody was entirely satisfied with the existing situation. Everybody deplored the lack of interest in research by many of the abler students, which seemed more serious than any shortage of funds. In all countries there was some division between work done in universities and separate institutes—where student numbers were high, institutes seemed to play the greatest part. Though the need to cooperate with scientists without clinical qualifications was realised, P. J. Hjort of Norway suggested, not entirely in fun, that, perhaps, "these invaders should be driven back, under the slogan 'medicine for the doctors' ". This sounded somewhat outdated to the ears of those from Britain, where the most eminent of the directors of our most prestigious medical research institutes have been, from a medical viewpoint, laymen. Clinicians and others regretted the difficulties of obtaining the cooperation of patients, though H. Berndt said that in East Germany "patients are well educated and understand the value of clinical research, so they are cooperative".



An early X-ray photograph of "the bones in the fingers of a living human hand. The third finger has a ring upon it." Described by W. C. Rontgen, writing on "a new kind of rays," in *Nature* in 1896. Reproduced in *Patterns in Physics*. By W. Bolton. Pp. vii+448. (McGraw-Hill: Maidenhead, March 1974.) £3.95.

The one thing missing from the symposium was any objective assessment of the success of any particular system of education and research. Experience elsewhere has indicated that there is little correlation between research productivity and available facilities. There was little which suggested that any political system was less—or more—likely to make research particularly productive. R. Saracci of Italy did indeed defend the principle of commissioned research, quoting Peter Medawar's point that painters and musicians in the past produced commissioned masterpieces, so "why shouldn't scientists react similarly?" This book was perhaps of greatest value in providing the background information for a survey of research efficiency, something which has still not been made, even by those who are responsible for the recent drastic changes in research organisation in Britain and elsewhere.

KENNETH MELLANBY

Introduction to superfluids

Superfluidity and Superconductivity. By D. R. and J. Tilley. Pp. viii+262. (Modern University Physics Series.) (Van Nostrand-Reinhold: New York and London, July 1974.) £9.50 cloth; £4.95 paper.

IT has long been recognised that the phenomenon of superfluidity in helium four has much in common with that of superconductivity in metals, each being marked by the macroscopic flow of material particles without dissipation of energy. A major defect of all previous introductory texts has been that although the similarities were in many cases commented upon, a genuinely integrated treatment was not attempted: it is this deficiency which the Drs Tilley have set out to rectify.

They start with brief descriptions of the observed properties of superfluid helium and of superconductors. The macroscopic wave function is then introduced on page 32; and it is around this unifying concept that the rest of the book is built, with chapters discussing the two-fluid model of HeII, electrodynamics and tunnelling in superconductors, vortex states, Josephson effects, Ginzburg–Landau theory, and the possibility of superfluidity in other systems.

The level assumes no more than an undergraduate knowledge of statistical mechanics, electricity and magnetism, and solid state physics, and the mathematical demands on the reader are remarkably modest. It is astonishing how much material the authors have managed to cram into the 248 pages of main text: I suspect that the large concentration of conceptual challenges, while highly stimulating to the beginning Ph.D. student, may prove rather strong meat for the majority of M.Sc. students.

A book of this scope is bound to attract minor quibbles from almost every reader whose particular research interest lies among the topics discussed. It does, however, seem rather a pity that, after a lucid exposition of Landau's famous explanation of superfluidity in terms of the elementary excitation spectrum, the authors fail to mention the one and only physical situation where this approach leads to an accurate numerical value of the critical velocity, namely, the passage of negative ions through pressurised HeII. On the other hand, I very much like the chapter on vortex states, a topic which lends itself particularly well to a unified treatment; and the section which presents a point by point comparison of vortices in superconductors with those in superfluid helium, emphasising the differences as well as the similarities, will be especially useful to novitiates.

A measure of the continuing vigour of research in this field is given by the extent to which the book has been overtaken by important new discoveries during its writing. The most significant of these came with the observation in 1972 of two new and apparently superfluid phases of liquid helium three below 3 mK thus, at a stroke, doubling the number of superfluids known in nature. The authors are to be commended for having managed to slip a page on this topic into the last chapter but, even so, the pace of advance has been such that already the passage strikes one as being principally of historical interest.

Vigorously and concisely written, the volume is lavishly adorned with diagrams and graphs of relevant experimental results, many of which will look comfortably familiar to workers in the field, but a significant number of which have not previously appeared within the pages of any textbook. There is a selection of problems at the end of each chapter except the last. In addition to references at the conclusion of each chapter, there is a select bibliography at the end of the book listing most of the standard texts and laced with descriptive comments, a number of which are amusingly barbed.

Thus in spite of one or two deficiencies, there is so much to be said on the positive side that I, for one, will strongly be recommending my graduate students and, indeed, some of my colleagues to read this book.

P. V. E. McClintock

Analysis of rocks

Laboratory Handbook of Petrographic Techniques. By Charles S. Hutchinson. Pp. xxvii+527. (Wiley: New York and London, 1974.) £10.60.

The title implies a rather unexciting prospect for the reader. Petrography is a vital part of petrology, and few scientists concerned with the genesis of rock complexes can afford to neglect the textures and mineral associations within a rock sample. Even so, it is the petrological analogue of anatomy in medicine, and has recently been in danger of neglect during the race by earth scientists to embrace geophysics and geochemistry as providing the main information for understanding the evolution of the Earth. Petrographic analysis is not essential for all geological studies, but there are few in which it does not demand an important role.

Some petrographic techniques have remained essentially unchanged throughout this century, such as polarised-light microscopy, mineral separation, and determination of specific gravity and refractive index. There have, however, been advances in method and this book presents an up-to-date survey of the whole field. The real advance made here, compared with earlier books on the subject, is the inclusion of sections on X-ray diffraction, differential thermal analysis and thermoluminescence measurements, and the expansion of the concept of petrography by including geochemical analysis by X-ray fluorescence, atomic absorption, and other techniques for components that cannot be analysed by physical methods. An excellent chapter on "Display of Data" deals rigorously with norm calculations, variation diagrams for rocks and minerals, and the statistical analysis of data.

The book is designed as a laboratory manual, and step-by-step instructions are given for all the techniques, ranging from photomicrography to the determination of feldspar structural state, matrix corrections in XRF spectrometry, or the calculation of mineral formulae. The subjects are well illustrated, and the book makes interesting reading. The author has, in fact, been remarkably sucessful in bringing new life to an old subject, probably because he conveys the impression that each technique has been subjected to his critical usage, and because he makes lively quantitative recommendations that are difficult to fault.

There is some overlap with *Physical Methods in Determinative Mineralogy* (edit. by J. Zussman) and *Methods in Geochemistry* (edit. by A. A. Smales and L. R. Wager), although surprisingly he does not refer to the latter. Nevertheless, the emphasis of this book is different and there is no real equivalent for a research student or advanced-level undergraduate specialising in petrology. It will save supervisors and tutors many hours of routine instruction, and may extend the life expectancy of much laboratory equipment.

My major criticism of this otherwise excellent book is the inclusion of 68 pages on X-ray fluorescence spectrometry which, like electron probe analysis, is dealt with in specialist texts. The author omitted electron probe techniques partly for that reason, whereas I would view them as vital to petrographic analysis. In contrast, the section on reflected-light microscopy is absurdly brief (about 6 pages) despite its vital role in petrography and the difficulties encountered by students.

Other notable omissions, in the context of the author's aims, are single-crystal X-ray diffraction (for example anorthite structural state), petrofabric analysis, factor analysis, electron microscopy and Mössbauer spectroscopy. Some attention to problems of zoned crystals (refractive index section) and modal analysis (for example use of reflected light), and to mineral examples (eight pages for garnets versus one third of a page for clinopyroxeies, under X-ray diffraction) are also needed, in any revised edition.

G. M. Brown

Please take note

Effective Technical Writing and Speaking. By Barry T. Turner. Pp. xi+206. (Business Books: London, 1974.) £4.75.

The Professor of Industrial Management at the University of Newcastle has aimed his book at engineers and scientists in industry; there are chapters on how to write specifications, sales literature, contracts, patents and handbooks. But the sections on writing articles and reports, on organising meetings, on giving talks and how best to illustrate them, will interest academics as well.

Professor Turner's advice on all these topics is sensible and helpful. Some of it might even seem obvious, were it not for the incomprehensible handbooks, the turgid and jargon-filled articles, and the ill-prepared lectures with illegible slides, that we are all unhappily familiar with.

We are urged to avoid technical jargon in our writing; to use short sentences and short Anglo-Saxon words; and to approximate to conversational speech. It helps, we are told, to "write in haste, polish at leisure". A few false grammatical idols are toppled: " . . . grammar is common speech formulated—usage is the only test" (Somerset Maugham). The Professor disapproves of foreign phrases, which is unfortunate because "*le mot juste*" appears on page 2—professorial licence perhaps.

There are a few misprints in the book, some of which are amusing: ("The medium is the massage"; MacLuhan). More serious is an error in a table on SI units, in which kilo, mega and giga imply factors of 10^6, 10^9, and 10^{12}, respectively. Recommended reference books do not include a dictionary of quotations, which is perhaps why George Eliot is misquoted. And in a book devoted to better writing the use of "disinterested" to mean "uninterested" is regrettable.

In general, however, Professor Turner's book makes useful reading for anyone speaking or writing on technical subjects. It would be a profitable addition to any library.

John Walker

Revolution in physics

The History of Quantum Theory. By Friedrich Hund. Translated by Gordon Reece. Pp. 260. (Harrap: London, March 1974.) £6.10.

THE main part of this book is a blow-by-blow account of the development of quantum theory in about the first 28 years of the present century, from Planck's introduction of light quanta through the 'old quantum theory' up to the formulation of quantum mechanics and wave mechanics culminating in Dirac's relativistic equation for the electron. The whole of existing basic quantum theory may be said to have been produced in about the three years 1925-8. The school of Max Born in Göttingen, including Heisenberg, Jordan and Pauli played a leading part at that time and Professor Hund was himself a prominent member. So here we have a first-hand account of all that was achieved in those heroic times of phenomenal activity, as well as the story of what had led up to this. It would be almost impossible for anyone ever again to provide such a survey, and the history of science will owe a great deal to Professor Hund for giving it.

The important thing is that this account has been written. It would, however, have been interesting to know more about the history of the history. The brief foreword is undated and there are no bibliographical particulars whatever of the original German publication save for its title: *Geschichte der Quantentheorie*. There are a few references to relevant items in the literature after about 1930 up to the present, but the text could have been written any time in that interval.

Within its set design, the history is comprehensive and exceedingly well digested. It is clear and it is also very terse. Its value as a historical document is all the greater for these reasons. But they almost inevitably eliminate the excitement and romance. Before the first World War there were tremendously revolutionary ideas about atoms, photons, space and time. After that there was an interlude when all kinds of things about atomic spectra—transition rules, line intensities and the like—were got with extreme ingenuity by using a wierd combination of classical and quantum physics with astonishing elaboration and success but with no new basic idea. Then suddenly quantum mechanics in its several varieties came into bloom and fruition; its doing so seemed curiously inevitable though the forms were wholly unexpected. The facts are all here on permanent record; however, there has never been a time like that in the history of physical thought and one doubts whether the reader in a different epoch will be able to re-create from the bare facts the stimulus of living through it.

Also I am convinced that no historian has yet explained how there came to be such a rush of discovery by so many scientists in so many places all at the same time. All previous fundamental advances seem to have been largely the work of one outstanding individual at a time—one may think of Newton, Maxwell, Rutherford, Einstein, Bohr as examples—but in 1925-8 fundamental contributions came from maybe 20 individuals of comparable stature (no doubt some more comparable than others), several of them only half the age of the others, working in some 10 or so different institutions. Hund does indeed indicate these aspects in a brief note on "Centres of Research" at the end of his book; it contains a most interesting diagram on page 251 showing the times when a number of the leading workers made their contributions, but this is presented without explanation or comment. Possibly someone else, working from all this material so ably marshalled by Professor Hund, will some day succeed in revealing the underlying historical causes of the phenomenon.

The book is expensive for its number of pages, but perhaps not for the concentration of information they convey. Gordon Reece's translation is outstanding. W. H. MCREA

Some useful ammunition for worried ornithologists

The Seabirds of Britain and Ireland. By Stanley Cramp, W. R. P. Bourne and David Saunders. Pp. 287. (Collins: London, 1974.) £3.50.

HERE is a classic for the last-page-first reader since the final appendix clearly illustrates both the origins and the uses of this book. In this appendix figures are given which demonstrate the fate of puffins at various breeding colonies in Britain and Ireland during the last 100 years or so. The immense colonies on so many of Britain's islands at the turn of the century are all seriously depleted or even deserted; the 20,000 birds on Puffin Island, County Kerry in 1965 had declined to 3,700 five years later. Not that all is gloom with Britain's seabirds. As this book shows, gannet, kittiwakes and fulmars have all had population expansions, even explosions, in recent decades. Not only are the causes of these fluctuations unclear but all too often their extent is little more than guesswork. In order to build a sound basis for assessing future fluctuations, the Seabird Group, founded in 1965, took upon itself the onerous task of making as full as possible a census of the breeding seabirds of Great Britain and Ireland. After a pilot study in the year of the Torrey Canyon disaster, the full survey was carried out in 1969–70. "Operation Seafarer" as it was known, yielded several volumes of detailed results. The essence of these forms the basis of this book.

Twenty-four regularly breeding species are considered under the title of seabirds although such thoroughly maritime birds as the eider duck and the oyster catcher are arbitrarily excluded. The bulk of the text is composed of a section devoted to each species and covering their identification, breeding, world distribution and past and present status in the areas surveyed, together with a note on the census method used for each species except, inexplicably, any of the gulls. These sections are sound and well referenced. Only the identification details, even in conjunction with the rather mean drawings and photographs, leave something to be desired; but they are probably superfluous anyway.

The rest of the book consists of three chapters on seabirds—dealing with their biology, the threats to their existence and their present numbers and changing fortunes. These make informative, if not always elegant, reading. At the back of the book are placed a series of maps and tables. The former, one per species, show the locality, number and size of the breeding colonies discovered in Operation Seafarer. Crispin Fisher is to be congratulated on presenting in them a large deal of information in a masterly way. The tables are an inconsistent set, sometimes supplementing the data in the maps, sometimes duplicating it.

Much of the information in the book is unique, all will be valuable. It is perhaps a pity that room could not be found for a more general chapter on bird population changes covering at least Europe and including inland as well as seabirds. It would also have been fascinating to know more about the organisation and logistics of the survey. We are told something about the census methods, which ranged from the smelling out of storm petrels' nesting sites to aerial photography of gannet colonies. But exactly how the hundreds of intrepid observers worked we never find out.

Despite some deficiencies this book should appeal to all who have more than just a passing interest in birds. As the sides line up for forthcoming battles over North Sea oil landing sites and other coastal attacks, it will be a source of much useful ammunition.

PETER NEWMARK

Culture and cognition

The Cultural Context of Learning and Thinking: An Exploration in Experimental Anthropology. By M. Cole, J. Gay, J. A. Glick and D. W. Sharp. Pp. xx+304. (Tavistock: London, June 1974.) £1.50.

THIS book is an important attack on the problem of the relation between culture and cognition. Too often in the past psychologists have travelled the world with a kit of psychometric tests, showing that on most tests "primitive" people obtain very low scores. They have concluded either that these people are innately less intelligent than those in western society, or that aspects of their environment have hindered their intellectual development. In both cases, what is posited is an intellectual deficit, a failure to develop the most powerful cognitive structures. Recently, however, a number of psychologists have argued that cognitive skills of the same order develop in all human groups; what differs between groups is the contexts in which these skills are applied. In order to assess the skills of another culture it is necessary to understand the tasks it imposes on its members. This book describes an interdisciplinary study by anthropologists, linguists and psychologists of cognitive skills in one African society.

The authors started with an educational problem; the Kpelle children in Liberia experience great difficulty with western type mathematics. Yet in their daily lives the Kpelle use quantitative operations and argue skilfully and with logic. In order to resolve this paradox the authors developed a series of experiments that would throw light on the Kpelle concept system and their methods of learning and problem solving. They first attempted to describe the Kpelle classificatory categories, and then used them in their investigations of learning, remembering, and concept formation with groups of non-literate children and adults, and primary and secondary school children.

A brief account of one investigation will give the flavour of the work. Kpelle schoolchildren seem to learn by rote, without grasping the principle involved. The authors confirmed this observation experimentally; in classical learning tests the initial recall of the Kpelle was poor, and increases with practice were negligible. These deficits seemed to be related to their failure to impose any order or structure on the material to be learned. Performance was no better when objects were substituted for words. The authors sought ways of evoking efficient performance. Attempts to improve motivation by a variety of rewards were unsuccessful: however, when the task was structured, either by indicating the categories involved, or by embedding the words in a story, recall dramatically improved. Only the high school students could impose structure on the learning material themselves.

From these and many other experiments, and from a study of Kpelle society, the authors conclude that the non-educated Kpelle is capable of concept-based learning, inference and logical thought, but that the situations in which he applies these skills are different and more restricted than those of his high school age mate. The findings raise many questions—for example, what learning experiences are crucial in order to develop transferability of skills—and this important book should stimulate more work by educationalists and psychologists.

BARBARA TIZARD

A theoretical view of life

Molecules and Life: An Introduction to Molecular Biology. By Mikhail V. Vol'kenshtein. Translated from the Russian by Serge N. Timasheff. Pp. xiii +513. (Plenum: New York and London, 1974.) $9.55.

MOLECULAR biologists at work may be compared to industrial archaeologists: pieces of the machinery are carefully retrieved, dusted and measured and parts of the mechanism are put together in the test tube and made to work. This sort of activity has been in full swing for fifteen years or more and has led to an impressive, though far from complete, understanding of what makes living things tick. In the background of this activity have hovered physicists and theoreticians who have been crucial in inventing and applying new methods of gathering information and, more peripherally, who have attempted to explain the properties of interesting biological components in terms of fundamental physical theory. The latter have often impressed and sometimes enlightened the less sophisticated biochemist but I would guess that they have rarely blazed pathways for molecular biology.

Academician Volkenshtein has made important contributions to our understanding of polymers and several other fields and has in recent years turned his interest to biology. One of the fruits of the latter interest is this volume—first published in the Soviet Union in 1965 and now available in revised form in English in a paperback edition. As the author says in his preface the book deals principally with the structure and function of nucleic acids and proteins but, throughout, the quest of the theoretician for regularities and generalisations is apparent. This is first manifest in the first chapter which is devoted to grand concepts such as statistical mechanics, irreversible thermodynamics and information theory. These notions and their application to biology are explained with admirable clarity but one is left with the feeling that they are not of immediate relevance to the working molecular biologist in that they tend to disappear into abstraction. To take one example, an argument is presented in refutation of the hypothesis of the inheritance of acquired traits in terms of the proposition that no flow of information from somatic to sex cells has been detected. I am sure he is right but an experimental fact or so might have been more convincing. In similar vein, the text which is otherwise descriptive breaks into mathematical derivation and matcrices and their Eigen values loom up from the pages. These may deter the biologist and it would be better to have a degree in physics or chemistry with some mathematical experience before embarking seriously on this book. But this is not meant as a criticism and more experienced workers will find much to interest and enlighten them in this book for topics not covered in similar works are given space; simple treatments of helix coil transition theory are hard to find and the sections on the genetic code and on polymer conformation are especially interesting.

Nevertheless, the graduate student entering the field for the first time and to whom I hesitate to recommend this book should beware of several errors and misleading passages. One of the more serious occurs in the chapter on protein structure. There, the idea is presented that the success that Perutz achieved in the X-ray crystallography of haemoglobin by using heavy atom derivatives had something to do with making the diffraction spots sharper and revealing the location of the hydrogen atoms, rather than being the crucial method of overcoming the phase problem that it was. In the chapter devoted to a cytological description of the living cell, no prominence is given to the distinction between prokaryotes and eurkaryotes and the significance of the single sentence that says that bacteria do not have a visible nucleus is unclear.

Again, as is to be expected in a book first published in 1965, much recent work is not mentioned and hence there is little on ribosome structure, protein synthesis or the structure of tRNA, to mention just a few topics. In fact there are few references dated later than 1965 so to read this book in isolation would give a somewhat antiquated picture of the state of molecular biology. One would question the wisdom of issuing a paperback edition of a book first published nine years previously were it not for the distinctive flavour of the approach and the light it may throw on thinking on molecular biology in the Soviet Union.

E. G. RICHARDS

Doing something for the centre

THERE is something distinctly unnerving about writing about the British General Election before it happens yet being published only after it is all over. The one thing that the last two elections have clearly indicated is that it would be the height of folly to assume even two days before the event that any particular party had won. The most recent opinion polls unanimously point to a Labour victory with 42% of the vote compared with the Conservatives' 35% and the Liberals' 19% and if this pattern persisted until polling day a Labour government would be returned with a majority of at least fifty over all other parties. Certainly the pattern has shown a stability over the past few weeks which reflects the inability of any political party to make a major impact on the uncommitted, but there is a feeling that there is still all to fight for.

The issues before the electorate are more serious than they have been at any time in the recent past, and the party positions are probably as clear-cut and distinguishable as they have ever been. And yet it is this very clearness of division which has made the choice for anyone who gives some thought to his decision an extremely difficult one to make this time. For separation on the issues, particularly on how to handle inflation and on how to fortify British industry, inevitably means bringing out that perennial skeleton in the cupboard—class warfare. Both Labour and Conservatives have, of course, their mechanisms for moderation; the Labour party's social contract with the unions looking at present deservedly more like an election-winner than the Conservative pledge to create a government of national unity. And yet the social contract, a sort of Swedish arrangement with the unions to work for more equality in exchange for moderation in wage claims is not universally enthused over by the unions, particularly those which represent the more-than-equal at present. And if anything there is more socially divisive electioneering from Labour than there was in February, and there have even been threats of industrial chaos this winter if Labour does not win.

Not that the Conservative party has actually been proposing policies which seem to be aimed at picking up the floating voter who might be disturbed by the threatening noises from the left, but fears that old-style Conservatives would get the country back into confrontation politics between government and unions. There is as yet no sign that old-style Toryism is being replaced by something more of the centre.

And yet it is pursuit of the centre which both of the present major political parties ought to be engaged in at a time of deep crisis if they seek electoral success; surely the McGovern experience ought to have taught moderates the world over that lesson. In any country with a less perverse electoral system it would be ridiculous that the support of 42% of the populace should give an unfettered mandate to a party, and it is high time that if the two major parties do not move to the middle ground, life should be made easier for the Liberals—who have been occupying it without success for so long.

The dilemma for the voter contemplating the Liberals has always been the taunt that a vote for them was a vote wasted, and yet even against this they have made steady progress until this election. It is unlikely that they will make much more headway now for rather obvious reasons. Their policies are widely regarded as attractive, sensible and likely to unite the country but their abilities are bound to be suspect whilst they have a mere handful in parliament but an army of untried hopefuls outside. There are many able politicians of the centre at present in the two main parties who, one suspects, would happily defect to the Liberals given some job prospects. The party finds itself in the bind of having amassed the support of a fifth of the electorate, the potential for more and yet, without being given some sort of break, it probably will be incapable of going above the critical size (at about 28% support the party would probably have a hundred or so members in parliament).

The case for letting some fresh air in to the British parliament is strong and it is only just that a party of the centre with a broad support should provide much of this fresh air and help towards realigning British party politics in a more healthy way. But this is unlikely to occur in the near future unless electoral reform is taken seriously by one of the two main parties. The question of which is the best of many systems of representatives tried elsewhere should not be allowed to bog down the central issue of the need for reform. And if in the next few years neither party comes to terms with electoral reform, it will be incumbent on the more thoughtful and moderate to lobby intelligently for social justice at the very place which claims to dispense social justice.

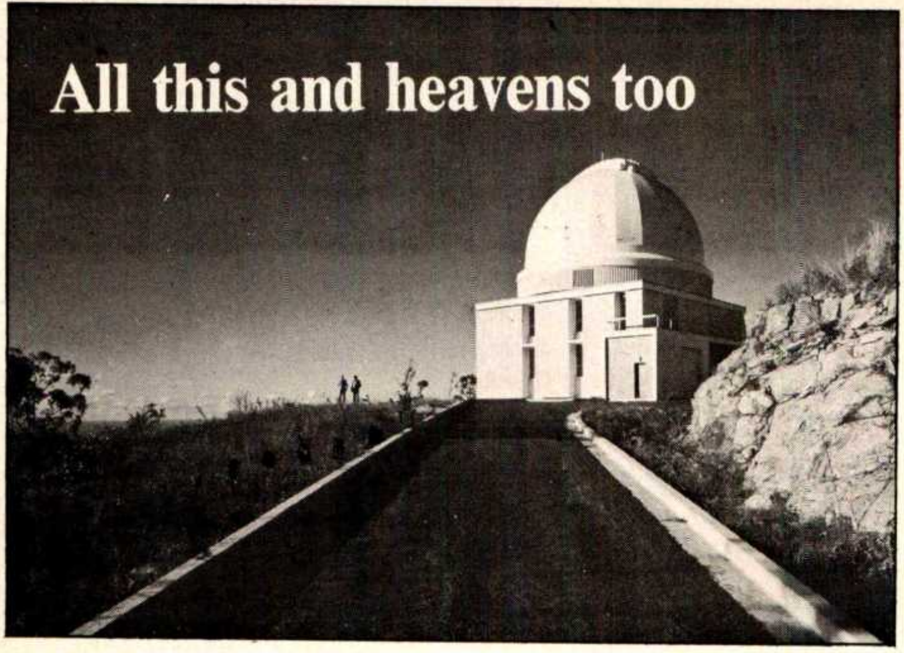
From *Nature*, **10**, 480, October 15, 1874.

All this and heavens too



On October 16 the Anglo-Australian 150-inch telescope is being inaugurated at Siding Spring in New South Wales. Together with the recent announcement of plans for an infrared flux collector in Hawaii, the imminent retirement of the Director of the Royal Greenwich Observatory and of the Astronomer Royal for Scotland, and with the concept of a Northern Hemisphere Observatory very much alive we are clearly at the beginning of a new era in British astronomy. John Gribbin has been talking to Dr Alan Hunter and Professor F. G. Smith, of the RGO, and Dr V. C. Reddish, of the Royal Observatory Edinburgh, about future prospects in the light of these developments. Picture: dome of UK 48-inch Schmidt telescope at Siding Spring.

IN terms of optical astronomy, Britain has been behind the United States since the beginning of this century. The 60-inch telescope completed some 70 years ago and other telescopes on good sites within the home territory of the United States made this inevitable; and modern astrophysics needs big telescopes. Only 130 years ago, of course, the biggest telescope in the world was in Ireland. But that was no consolation to the bright youngsters in Britain who were interested in astronomy in the 1920s and later. The natural reaction of such people was to move into theoretical work, where thanks to Eddington and others Britain became as pre-eminent as the United States was in observational work.

And that, of course, led to a still more lopsided growth of the subject in Britain. The next generation followed where these pioneers had led and achieved fame, and what could have been a very unhealthy situation was saved only by the advent of radioastronomy.

In recent years there have sometimes been bitter attacks on the administrators of British science for failing to prevent Britain slipping behind in terms of optical telescopes. But much of this criticism, made only now with the benefit of hindsight, seems a little harsh when we recall the conditions which prevailed, say, 30 years ago. Dr Alan Hunter, who retires as Director of the Royal Greenwich Observatory (RGO) next year recalls that in 1947 it was still something of an adventure to travel to South America to view a solar eclipse. In those days, the aircraft still flew south on the first leg of the journey, in order to cross the Atlantic at its narrowest point. Yet the decision to build the Isaac Newton Telescope (INT) in Sussex was taken in 1946; could the planners really have been expected then to appreciate how jet travel would revolutionise astronomy, opening up the prospect of British telescopes being run effectively even when built in Australia or Hawaii?

The experience now being gained with the Anglo-Australian Telescope (AAT) and the UK Schmidt camera on the same site illustrates how rapidly things have changed over the past decade. Dr V. C. Reddish, of the Royal Observatory Edinburgh (ROE) has been closely associated with both projects, and is at present on the management committee of the AAT. The Schmidt camera has now been operating for a year, and he says that the first papers reporting observations made with the instrument will be published soon. The importance of this camera, and the reason for siting it with the AAT, is that it produces a wide angle view of the sky, covering twelve times the Moon's diameter on one plate. Essentially, such a camera is used for survey work while the more powerful but narrower angle optics of the 150-inch will be used to investigate interesting sources revealed by the survey. The Schmidt plates are also of great interest to radioastronomers who wish to identify the sources they have found.

In the northern hemisphere, the Palomar Sky Survey (obtained with a 48-inch Schmidt camera) has provided the basic sky atlas for astronomers over twenty years or so. But there has never been a comparable survey of the southern sky.

This is being rectified by the UK Schmidt and by a similar instrument at the European Southern Observatory in Chile (ESO). Each camera is taking a set of plates covering the whole southern sky, but at two different wavelengths. Together, these plates make up an atlas which enables astronomers to pick out many interesting objects—such as possible QSOs—from their relative brightness at two frequencies. Reddish says that the operation of the joint survey with ESO has been "co-operative, pleasant and efficient". ESO plate copying facilities in Geneva are being used for both ESO and UK Schmidt plates, and this specific area of collaboration typifies the way astronomy has developed as an international science.

The UK Schmidt has given British astronomers experience of both international cooperation and of the building and running of a really big telescope. Of 800 plates produced in the first year of operation, more than 100 have been accepted for the southern sky survey. This reflects a wish to maintain high standards, since plates once accepted for the survey will be used by many people for many years, together with a reluctance to seek perfection, which would make the task impossibly long.

Even so, thanks to the advances made since the Palomar Sky Survey was carried out in the north, the new Schmidt is producing plates which are a distinct improvement in quality over any previous survey. Thanks partly to the use of a new photographic emulsion (known as IIIaJ) and a new technique for treating plates before exposure by soaking them in oxygen-free environment (*Nature*, **249**, 22; 1974), the plates record all celestial objects down to magnitude 23 with an exposure of 40 minutes. This means that twice as many radio sources can be identified as on comparable Palomar Sky Survey plates, and that radioastronomers can even tell what type of galaxy their sources are associated with at magnitudes which would not even be recorded on Palomar plates.

There is no direct association between the building of the Schmidt and of the AAT, but inevitably some expertise must rub off from one committee to another, since some people, like Reddish, have been involved in both projects. Reddish points out that although the AAT will be the third biggest telescope in the world it has "superb" optics and that, together with the improvement of instrumentation over the past 30 years, means that it could well be even more powerful in practice than the 200-inch, just as the 48-inch UK Schmidt is more powerful than its older counterpart at Palomar. Already there is great demand for time on the AAT, and even some very good projects will inevitably fail to receive an allocation.

The attitude of the Science Research Council (SRC) certainly seems more realistic than they have sometimes been given credit for. Accepting that a capital investment of £1 million must be used efficiently, they are prepared to fly people out to Australia to work with the new telescope two or three times a year. And there may well be more large capital investment in the offing, again at sites far from Britain.

Already the decision has been made to go ahead with construction of a 3.8-m infrared flux collector in Hawaii (*Nature*, **250**, 617; 1974), and a decision will be taken in the new year on whether to build a UK Northern Hemisphere Observatory (NHO). This idea has been in the wind for several years, but should now receive the go ahead. France, Germany and Italy are all planning their own large telescopes, and although this activity might seem to run counter to the spirit of international cooperation in astronomy that is not really the case.

According to Dr Reddish, it is not efficient to share construction of telescopes and observatories too widely—the technology of interfaces are difficult enough to cope with without the worry of international management interfaces. But it does make sense to share sites, services and overheads. Through that kind of sharing joint use of the instruments will inevitably follow.

All that, together with the infrared telescope decision, must make Hawaii one of the favourite contenders for the site of the NHO. That site is really a little too high, since it becomes difficult to breathe on top of the Hawaiian mountains. But otherwise it seems ideal, with a US observatory already there and obvious possibilities of sharing the running expenses. With such an observatory—in Hawaii or elsewhere—Britain could well, in fact, lead the world in observational astronomy for the rest of this century.

That would certainly be a remarkable development. But it reflects the growing awareness that astrophysics is rapidly becoming the big science of the present day. Both Reddish and Professor F. G. Smith, who has just left the University of Manchester to go to the RGO as Deputy Director, and eventually to succeed Dr Hunter as Director, commented on the high standard of people entering astronomy today. There is no evidence of a drift away from the sciences here; in fact, the very best students now are of a higher calibre than ever before.

This is understandable. It is now clear that the next great advances to be made in physical science are likely to centre on problems of high energy and the study of gravitation. And these problems cannot be tackled in the laboratory. Nuclear astrophysics, cosmic ray studies, and information about energetic sources obtained at all parts of the spectrum are the 'laboratory' sciences of the immediate future. It is no wonder, then, that the first class physical scientists today are attracted primarily to astronomy.

Indeed, Smith's move from Manchester to the RGO is one symptom of how astronomy's face is changing. Smith emphasises that he is an observer, not a theorist, but that there are no barriers between different astronomical observers any more. With modern instrumentation, whatever kind of 'electromagnetic radiation bucket' is used to collect signals, the job of the observer is really one of analysing electric impulses. So it is misleading to talk about 'radio', 'optical' or 'infrared' astronomers; as Smith says, "we are all just 'astronomers' now".

Even so, there must be a good reason for Smith to move to the RGO at the present time, and it seems that the lure of the NHO has played a large part in this. The RGO has the job of creating and operating the NHO (assuming it receives the go ahead), and could well become the most important astronomical centre not just in Europe but in the world—indeed, the way science is progressing at present, one might well envisage the RGO becoming the key scientific centre in the world. It is small wonder that Smith should be attracted by the challenging job of acting as Director of the RGO for the exciting years ahead.

Both the RGO and the ROE have university links, the ROE a long established relationship with the University of Edinburgh and the RGO a more recently established but important link with the University of Sussex. The RGO also provides summer schools in astronomy for university students from all over Britain, and these are so popular that only one applicant in five can be accommodated. In Edinburgh, when a job on the UK Schmidt was advertised recently there were ten applicants, nine of whom had first class degrees and were short listed. This is unprecedented in Reddish's experience; astrophysics is now getting the pick of the research students in the same way that nuclear physics did 50 years ago. Looking at the progress made in nuclear physics since the 1920s, that simple statistic, as much as anything else, points to an exciting time for British astronomy in the next 25 years.

international news

“*Nature* published two replies (June 14, July 5) to the letter from Dr Gerschenfeld and his colleagues (March 29) dealing with the dramatic conditions of the Chilean academic community. These replies support the military junta, minimise the abrogation of civil liberties and democratic government in Chile, and suggest that Dr Gerschenfeld and his colleagues were not properly informed. Coming from supposedly well-informed Chileans, they leave the impression that the situation there has indeed been over-dramatised. In fact both replies are studded with misleading and tendentious statements we feel obliged to correct. Most of us worked and lived in Chile under the government of Dr Salvador Allende and during the military coup of September 11. We feel qualified to write about conditions in the Chilean academic community at least as much as Admiral Swett, who had no relation with academic life before his appointment as rector of the Catholic University, or Professor Eyzaguirre who has lived for the past 17 years in the United States.

Admiral Swett admits in his letter that he was nominated rector by the military junta, which is extralegal. To minimise this abuse of power he adds that he was confirmed by the head of the Catholic Church. However, the Catholic bishops of Chile in a collective declaration of April 1974 entitled "The reconciliation in Chile" have publicly stated their concern for ". . . arbitrary arrests or imprisonment by ideological motives . . ." and declared that Chileans are "living in a climate of insecurity and fear". We believe that the head of the church had no alternative to accepting the nomination of Admiral Swett. Professor Eyzaguirre repeated this and other remarks, but in a very different style. He spent half of his letter discrediting the Allende government and justifying the military coup, expounding the official statements of the military junta. This is a general polemic, and irrelevant to the specific charges presented in the Dr Gerschenfeld's letter and under International News in *Nature*, May 3. Few factual statements were challenged in the two "replies from Chile". We wish to comment on those few challenges since they definitely distort the reality.

"Students at some universities had to reregister. Students who did not qualify as such in the traditional sense (. . .) were dismissed. This weeded out the purely political 'students,' . . .". In fact, all students at five out of six universities had to reregister. 20,000 students were dismissed. Since more than a thousand lacked a few credits or a final examination to obtain their degrees and had entered the university two to four years before Allende was elected president, it is difficult to see them as purely political "students".

In reply to recent letters in Nature from supporters of the Chilean junta, twenty-six Chilean scientists have signed this joint statement on the condition of academics in the country. Their names have been supplied to the Editor.

"The Faculty went through the same screening procedure. Those who did not qualify for lack of degrees or for being exclusively political activists were dismissed," wrote Professor Eyzaguirre. More than 60% of the Faculty of the Technical University, almost the whole Faculty of the schools of Anthropology, Psychology, Sociology and Economics at the University of Chile, Concepcion and others, and most of the members of the prestigious Department of Public Health of the School of Medicine at the University of Chile would then be exclusively political activists. Admiral Swett said "They were dismissed because they simply abandoned their jobs. . .". Many of us were indeed dismissed for abandonment of our jobs but it should be known that we were absent because of imprisonment.

"Very few fell either immediately after or during the coup because, allegedly, they were caught either shooting at soldiers, carrying arms or actively participating in the organisation of revolutionary activities." We and almost every colleague know that professors Mario Ramirez, Jorge Pena and Enrique Paris neither shot at soldiers nor carried arms; we must infer that they were executed because of "organisation of revolutionary activities"; a very broad charge since the government of Allende was categorised as revolutionary.

"There are charges against some of these people and if they return they will face legal prosecution. But prosecution is one thing and persecution another." It is general knowledge that legal procedures have been suspended in this instance. Dr Edgardo Enriquez, minister of education and former rector of the University of Concepcion; Mr Enrique Kirberg, rector of the Technical University; Mr Galo Gomez, president of CONICYT; Mr Raul Iriarte, secretary of CONICYT, and many other less known members of the academic community have been imprisoned from September 1973 with no formal charges and no trial date.

"Some academicians have had trouble with the police because of denunciation by neighbours or colleagues. These people have been investigated . . . " Investigation consisted in arrest and interrogation usually with physical mistreatment. Many of us experienced this and it was clear to us that this was purely political persecution.

"The appointments . . . (of retired senior armed forces officers as rectors) . . . would not be too far from practices that are not unknown in the United States." The appropriate parallel to the Chilean situation would be the appointment of military presidents in every American university, by the Pentagon.

"Chaotic finances which prevented normal university activities and the payment of adequate personnel salaries" (during Allende's government). There were indeed some financial problems for adequate scientific research but during this time the universities received their largest share in the history of the national budget. This policy should be compared with that of the junta which ordered every university to finance itself with no funds from the government by January 1976 while the share of the armed forces has been increased from under 10 to 40% of the national budget.

With regard to Chilean scientists remaining in Chile, we agree that they are not fascist (nothing close to that is said in Dr Gerschenfeld's letter) but people sincerely devoted in pursuing their research under very difficult circumstances. We believe, however, that the letters of Admiral Swett and Professor Eyzaguirre do not help them and are in fact unfair since these colleagues are not in a position to disagree. Chilean scientists remaining in Chile as well as those who will return are better helped by encouraging the return of at least academic freedom.”

● THE COURT of inquiry into the explosion which killed 28 people and caused £70m damage at the Nypro chemical works in Flixborough, Lincolnshire, has been told that a temporary by-pass system in the cyclohexane unit was not tested at an appropriate pressure. According to counsel for the company (owned jointly by Dutch State Mines and the National Coal Board) it is now clear that the by-pass system was installed without an adequate design study, and that if such a study had been carried out, a different system would have been used. Most of the technical evidence has yet to be presented, and a recess is expected to allow for a consensus of expert specialist opinion. Reaching the consensus, however, will be difficult because of the quantity and complexity of the technical information likely to be available.

But there is no doubt that the findings of the inquiry will have profound implications for the chemical industry in Britain and elsewhere because of the fundamental safety issues which have been raised. The complexity of chemical plants and the huge reserves of stored energy they contain seem to have completely outrun the rather Victorian arrangements of the Factories Inspectorate—the 1974 Health and Safety at Work Act notwithstanding. The safety officer at the Flixborough site told the court that nothing on the scale of the explosion had ever been conceived or considered and that the rule book governing the safety of chemical plants needed rewriting in the light of events there.

The Health and Safety Commission now being set up is bound to look carefully at the results of the findings of the Flixborough Inquiry. As an independent commission it will bring together the existing government inspectorates covering nuclear installations, explosives, alkali works, mines, quarries and factories. The commission was proposed before the events at Flixborough but it comes at a time when a lead to industry is desperately needed. Already some large petrochemical companies have approached the Atomic Energy Authority Safety Commission for consultation on safety problems and there is a growing feeling, not least amongst the companies themselves, that the chemical industry should be governed by regulations at least as stringent as those of the Nuclear Installations Inspectorate.

Round Britain

● IN SPITE of recent inflammatory news reports, vaccination is still the best means of ensuring overall community protection from infectious diseases. This was the outcome of a report on vaccination published by the Office of Health Economics (OHE) last week.

While diseases such as polio, diphtheria, tetanus and measles still present significant health hazards, OHE maintains that in some areas of the UK, only two-thirds or less of all children are adequately immunised. Thus to maintain public trust in vaccines available from the National Health Service, withdrawal of controversial vaccines such as whooping cough (pertussis) may become necessary in the near future. It has been claimed that pertussis vaccine has caused brain damage in a small number of young infants, although there are no published figures to substantiate such an accusation. The OHE, however, recognises that an element of risk is associated with vaccination, but takes the view that provided the benefits far outweigh the risk then it is acceptable.

The study suggests that only a very small proportion (probably a few hundred) of the 50,000 to 60,000 severely mentally handicapped children in Britain owe their condition to immunisation by pertussis vaccine. But this small proportion has become of increased relative significance because of the fall in risks from other factors, such as infectious diseases. In an ideal national health care service, argues OHE, special provisions for the compensation of those damaged by vaccines should not have to be made because services for all the handicapped should be adequate. However, state compensation for vaccine-damaged people and their families may well draw attention to the poor provisions for the majority of brain-damaged people.

Improved living conditions, environmental health measures, new medicines and vaccination programmes, says the report, have reduced health risks in Britain from all known infectious diseases. In fact over the past 30 years, the number of child deaths from infectious diseases has dropped from about 10,000 to virtually none. Thus withdrawal of vaccination programmes which have outlived their usefulness should be considered.

Worldwide progress in smallpox immunisation has been so effective that in this country the risks associated with 'protection' outweigh the dangers of smallpox infection. The withdrawal of routine smallpox immunisation in 1971 by the NHS is supported by the OHE, although here again there has been much criticism of this action mainly because of the occasional reappearance of the disease.

All the same there appears to be strong evidence to indicate that there is a positive benefit to be derived from all the vaccines currently in use by the NHS, the only possible exceptions being BCG and pertussis vaccines.

The attention which pertussis vaccine has received was criticised by OHE as being over dramatised, particularly since the figures are not backed up with any definite evidence. The report says that there is no firm evidence to show that this vaccine's use causes more distress than benefit to the community as a whole.

OHE suggests that in view of the publicly voiced doubts as to the safety of pertussis vaccination priority should be given to a relatively swift action designed to restore confidence before other forms of immunisation are affected. An obvious option would be the temporary withdrawal of routine pertussis vaccine by the NHS, although this is not a recommendation of OHE. Recently the Department of Health and Social Security decided to continue pertussis vaccination while data necessary to make a critical review could be collected. The Institute of Biology endorsed this view when they submitted their views to the Royal Commission on Civil Liability and Compensation for Personal Injury.

Although it is unlikely that any major changes in vaccine policy will be made in the next few years the proposal to withdraw routine BCG vaccination is under discussion.

● AN idea for using the energy in the waves of the sea as a source of safe non-polluting power, developed by Dr Stephen Salter of Edinburgh University has attracted a Department of Trade grant of £60,000. As described by Dr Salter in an article in *Nature's* Energy Review earlier this year (*Nature*, **249**, 720; 1974) his system incorporates large steel vanes which harness the rolling motion of the waves, more efficiently than the up and down movement utilised by previous systems.

Apart from the Department of Trade, the Central Electricity Generating Board and a leading British concrete fabricator, Cementation Ltd., are also interested.

Also, Sir Christopher Cockerell, the inventor of the hovercraft, is a partner in a newly formed company, Wavepower Ltd, which is interested in the commercial application development of wavepower.

Astronautics in Amsterdam

from Angela Croome

Dr Kraft A. Ehricke belongs to the same generation of German-born space engineers and prophets as Werner von Braun and similarly helped to lay the foundations of the American space programme. It is not therefore too surprising that he retains an almost apocalyptic faith in man-in-space as bringer of solar energy (to supplement dwindling Earth resources) and grower of super crystals. That there are no limits to growth for life on this planet—only changes in pace and direction—was the theme of his keynote address to the 25th International Astronautical Congress, the annual rendezvous of the leading figures in the field, in Amsterdam last week. He urged growth and expansion in astronautics as a way of obtaining additional resources and accelerating the imperatives of international cooperation.

The note was not really in harmony, however, with the main tenor of the meeting. Programme scientists and project leaders today must have hard-headed arguments in justification of even low-cost automatic satellites. An all-day symposium on cost reduction in space operations is now a regular feature of the Congress, in fact. Dr Ehricke's industrial suburbs in orbit were not included in the programme.

The principal way of reducing the costs of space operations, of course, is to share them. The degree to which NASA has embraced this policy was heavily underlined at the Amsterdam gathering. Detente has certainly eased the way for American-Soviet space cooperation (where only a few years ago the 'space race' was an extension of the cold war) but the sight of Tom Stafford, captain of the American crew for next summer's Apollo-Soyuz rendezvous and docking project, and Alexei Leonov, the Russian crew leader giving a joint briefing on progress without interpreters gave credibility to the plan that has hitherto been lacking. Officially each country is contributing 50/50 to development, the 5 joint experiments, project management, even the command during the 2 days when the two capsules will become one; unofficially one learns that the exchange of information is all 'one way' and in particular the American space medicine experts responsible for crew fitness are unhappy at the lack of Soviet data.

There is only one American-Soviet flight scheduled at present and nothing definitely planned beyond. Next spring the two sets of senior negotiators (which includes the President of the Academy of Sciences on the Russian side) will consider possible further joint ventures, and Soviet participation in the reusable Shuttle programme for the 80s has been mentioned. Meantime Europe through ESRO is firmly committed to designing and building the Spacelab element of the shuttle programme which will substantially share the burden of the civilian sector of the programme with NASA. What is now being equally stressed is the virtue of having an integral European contribution to some of the promising planetary programmes of the next 10 years. A system of multiple spacecraft to collect and recover some soil samples from the surface of Mars would be substantially aided by having, for example, Europe build and operate one of the Mars descent vehicles. Similar arguments apply for a 1978 Venus probe in two parts and ESRO is studying a Jupiter mission for the 80s which would be on a joint contribution basis.

A note of caution was struck in the law sessions. The problems of liability in the case of a failure or an accident where several nationals are taking part in a common spacecraft will be formidable and there is no really adequate international court to decide possible space disputes.

Maltese conference cross over Caracas

from Wendy Barnaby, Malta

"It is", said Lord Ritchie-Calder, "the biggest smash-and-grab since the European powers at the Berlin Conference of 1885 carved up Black Africa." And his view of the Caracas United Nations Law of the Sea Conference was echoed by many of his fellow participants at Pacem in Maribus. The fifth meeting of this group, which can claim to be the most influential non-governmental organisation considering matters relating to the oceans, was held in Malta from September 9–13. Attracted to this discussion on the results of the Caracas proceedings were 64 people from 18 nations, the World Bank, the United Nations Environment Programme, the Commonwealth Secretariat and a number of non-governmental organisations. The statement which summarised the meeting's discussion was highly critical of Law of the Sea developments.

It was generally thought that the concept of a twelve nautical mile territorial sea plus a 200 nautical mile exclusive economic zone would eventually be accepted by the U.N. conference, possibly at its next session at Geneva in March 1975. Dr. Arvid Pardo, the original initiator of the U.N. Conference, argued that these concepts will not provide the necessary precision on the scope of national jurisdiction because rules determining the drawing of baselines, from which each zone will be measured, have not been agreed upon. Nor are they likely to be. Neither has agreement been reached on the relationship of the continental shelf to the economic zone. What will happen to those parts of the shelf which extend beyond 200 miles from the baseline?

As present technology makes exercise by states of their rights to expore and exploit the resources in the economic zone easy to the depth of 200 metres, it would be possible to imagine those states with extensive continental shelves taking advantage of the imprecision of baselines to push their economic zones out to the limits of their shelves. The inequalities this would entail seem too blatant to be borne.

This question of the inequalities built into the proposed system let loose another shower of criticism, this time from Dr. Sidney Holt, the Director of the International Ocean Institute in Malta. He pointed out that although the underdeveloped countries may benefit in the short term from the economic zone concept (on the argument that, even if it will make the rich richer, it will at least give the poor more than they have at the moment), there is no guarantee that their long-term benefit will be great. This is because the potential yield from the living resources within the economic zone is limited to double the present catch, while the potential of living resources much further out is one or two magnitudes greater. This mid-water life, which includes pelagic squid and the shrimp-like krill of the Antarctic ocean, needs special technology to harvest it. It is a reasonable bet that the developed countries will perfect this before the underdeveloped ones. If the latter are not to miss out in the future they should be pressing for international arrangements to enable co-operation with the developed countries in the utilisation of these resources.

A more immediate deficiency in the Caracas machinery was the inconsistency in terms of reference between the Conference's three committees. The second and third committees dealt with the ocean space including the water column, but the first committee was limited to the seabed. The result is that "the authority" which each committee was trying to set up within its own terms of reference will have ambiguous jurisdiction. Clearly this ought to be sorted out quickly at Geneva. And, just as clearly, the Conference should adopt the solution favoured by Pacem in Maribus: jurisdiction that will cover the ocean not just the seabed. The seabed cannot be dissociated from the water column in the sort of issues that will face the world community in its attempt to draw up a law of the seas.

ACCORDING to a remark often attributed to Mark Twain, "everybody talks about the weather, but nobody does anything about it". In the United States, where the federal government spends about $20 million a year on weather modification research (the actual amount depends on how you define the enterprise) and where the Department of Defense has recently admitted conducting a massive cloud seeding programme in South east Asia, Twain's remark is demonstrably untrue. Nevertheless, nine separate reports in as many years have all said that nobody is doing enough.

The latest in this series, a study conducted by the General Accounting Office (GAO), is no exception for it suggests that weather modification research is financially undernourished, badly coordinated and poorly focused. Such complaints have, of course, been made before for virtually every branch of science but in this case they merit some attention since for one thing the GAO has no axe to grind, and for another they are couched in language which, for the GAO, is uncharacteristically blunt.

A science born in 1946 when Vincent Schaefer and Irving Langmuir seeded rainclouds with pellets of solid carbon dioxide, weather modification moved briskly into commercial application—as much as 10% of the United States was under commercial cloud seeding operations in the 1950s—but it is still full of uncertainties. Even the Pentagon's rainmaking activities in Vietnam, for example, are generally regarded as having had only a marginal effect on rainfall there, and most weather modification experiments conducted in the United States have had mixed results.

Nevertheless, a number of organisations including the National Academy of Sciences and a Presidential advisory committee have argued during the past decade that a variety of weather modification techniques show sufficient promise for the federal government to initiate a centrally directed, adequately funded research programme.

But weather modification activities are now spread among some seven federal agencies, and the GAO has found that "an effective overall national weather modification program has not been established". Attempts to coordinate weather modification research, GAO continues, "have been somewhat disappointing", and the fragmentation of effort "has made it extremely difficult for agencies to conduct effective field research".

The GAO identified some $17.4 million in the federal budget for the 1974 fiscal year (which ended on June 30) for weather modification experiments, a level which falls dismally short of all the recommendations during the past decade. The National Academy of Sciences, for example, recommended as long ago as 1966 that $30 million a year could be wisely spent.

But the GAO's chief complaint (and, indeed, that of everybody else who has reported on the matter) is that no agency has been given the power to coordinate and manage an overall weather modification programme.

As an example, GAO singles out the National Hail Research Experiment, a $16.5 million project begun in 1972 which is designed to test various methods for eliminating or mitigating the effects of hail storms. Six different departments and agencies are taking part, with the National Science Foundation in a leading role.

Après moi . . .

Although GAO is quick to point out that the experiment has already yielded some promising results, it lists a number of cases in which agencies failed to meet their obligations, presumably because they accorded the project a low priority. The Department of Commerce, for example, failed to furnish radars and aircraft for the experiment in the first year, the Department of Defense did not supply helicopters as planned, and the National Science Foundation had to put up funds for a part of the project carried out by the Department of Agriculture.

Such problems, GAO reckons, would not have arisen if a national research programme were established and a single federal agency were given responsibility for implementing it.

● THE supplementary agenda of the current session of the United Nations contains a resolution, proposed by the Soviet Union (in a letter of August 7, 1974), urging "The prohibition of action to influence the environment and climate for military and other purposes incompatible with the maintenance of international security, human wellbeing, and health." Not surprisingly, this resolution is receiving much favourable publicity in the Soviet press. While one must applaud the laudable sentiments of this resolution, a certain doubt nevertheless arises; since the Soviet Union is one of the chief exponents of climatic manipulation (for peaceful purposes, be it understood), is there not perhaps the danger that such projects, however beneficial to the country concerned, may result in the deprivation of others, that one nation's plenitude may result in another nation's deprivation.

Apart from grandiose schemes for climatic manipulation in the distant future, such as their longstanding scheme to divert southwards those rivers which at present discharge uselessly into the Arctic Ocean and the creation of artificial glaciers in the deserts of Soviet Central Asia, alarming scheme are proposed in an imaginative survey *Life in the Twenty-First Century*, compiled in 1957. These include the damming of the Bering Straits and the pumping of warm water from the Pacific to the Arctic Ocean, so as to change the climate of Kamchatka, North-East Siberia and the Arctic Basin. Similarly, it is proposed to join Sakhalin Island to the Soviet mainland, and, by pumping warm water from the Kuro-Siwa current through the dam into the Tartar Strait, to warm the Sea of Okhotsk. Naturally, in this panegyric, undesirable side-effects are minimised—there is no more than a joking reference to the Japanese skiing enthusiasts who no longer (in AD 2007) have any snow.

At present, the principal efforts of the Soviet Union are aimed at what *Pravda* calls "hail-prevention" — in reality, hail-making. Research in this field was begun in the late 1960's at the Institute of Alpine Geophysics at Nalchik in the North Caucausus. Potential hail clouds are observed by radar, and then seeded by lead iodide from a rocket fired into the cloud's centre. Although the method appears to be reasonably successful—provided that the hail cloud is spotted in time—it does result in heavy hail falls in surrounding areas. By 1971, the technique was considered sufficiently reliable to form part of the Soviet aid programmes to Argentina, the Lebanon, Hungary and Yugoslavia.

EPA firm on pesticides ban

from Colin Norman, Washington

RUSSELL TRAIN, Administrator of the Environmental Protection Agency, last week held firm on his decision to halt production of the widely used pesticides aldrin and dieldrin, pending the outcome of public hearings on charges that the chemicals may be carcinogenic to man.

The decision is an attempt to establish an important concept in the regulation of environmental chemicals—that possibly dangerous substances should be removed from the market until they are found to be safe, rather than being kept in use until they are definitely found to be hazardous.

That concept is already well established in the regulation of food additives in the United States, thanks to a legal requirement that chemicals cannot be added to food if they are found to increase the incidence of cancer in test animals, but attempts to apply it to the regulation of other environmental chemicals have so far met with mixed success. Moves against aldrin and dieldrin were made by the EPA as long ago as 1971, when the agency issued an order to cancel the pesticides' registration—which was tantamount to banning their use. That order was based on findings that the pesticides increase the incidence of liver tumours in mice when fed to them in relatively high doses. But the Shell Chemical Corporation, sole manufacturers of aldrin and dieldrin, appealed against the order, and the appeal has been making glacial progress through the courts and EPA's administrative machinery ever since.

Meanwhile, evidence has accumulated that aldrin and dieldrin raise a variety of tumours in at least five strains of mice and possibly rats as well. Their residues can be found in the tissues of virtually every man, woman and child in the United States, and a survey conducted last year by the Food and Drug Administration found the pesticides in 83% all dairy products, 88% of garden fruits, and 96% of meat, poultry and fish.

On the basis of that evidence, EPA privately asked Shell to stop producing aldrin and dieldrin, at least until the appeals process on the cancellation order has been exhausted. But Shell refused, and announced that it would produce about 10 million pounds of the pesticides this Autumn for use in 1975, knowing full well that if EPA's cancellation order is upheld next year it would be virtually impossible to call in the pesticides which had already been sold. Train therefore exercised emergency authority in July to order Shell to stop making the pesticides. Shell appealed against that ruling, however, and demanded a public hearing on the matter. The hearing took place in August and early September before Administrative Law Judge Herbert L. Perlman, who upheld Train's order on September 20, as a result of which Train last week refused to reconsider his decision. Shell officials immediately announced that they will take their case to the federal courts.

There is no dispute over the fact that aldrin and dieldrin increase the incidence of liver tumours in mice—in fact, Shell representatives even conceded that point during the public hearings—but there is a dispute over the relevance of that fact for humans.

According to Dr Don Stevenson, Director of Shell's Tunstall Laboratory, for example, five separate criteria must be met before there is sufficient evidence of human carcinogenicity. There must be a higher incidence of tumours in exposed animals, tumours should develop in more than one species, there is adequate proof that the development of the tumours is related to the test compound, the animal has proved to be an adequate model for extrapolating to man, and that there is proof of at least one incidence of cancer in man related to the test compound.

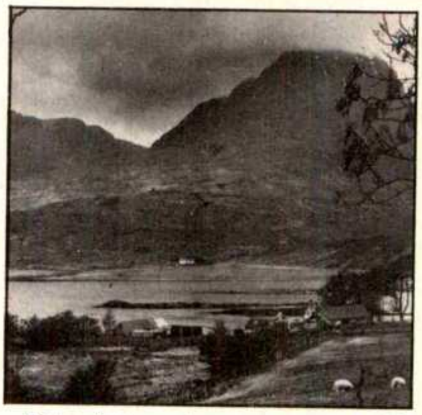
As Train pointed out last week, such criteria would be impossible to meet since cancer in man often takes several decades to develop after the initial exposure. Both Perlman and Train therefore concluded that there is already sufficient evidence of carcinogenicity in mice to suggest that aldrin and dieldrin pose a high risk to man.

Meanwhile, the appeals process for EPA's original cancellation order against the pesticides grinds on. Public hearings have been dragging on since August 1973, and according to Train, they will continue into the "indefinite future". It is worth noting, however, that although the production ban in theory does not prejudge the cancellation issue, Perlman is sitting as hearing examiner for the cancellation hearings as well as for the hearings into the production ban. His 109-page opinion on EPA's production ban represents such a severe indictment of the pesticides that it seems unlikely that he will ultimately give them a clean bill of health.

AFTER the good news about Drumbuie, the bad news about Kishorn. The Secretary of State for Scotland, Mr William Ross, has approved an application by the Howard/Doris partnership to build concrete gravity-type oil production platforms at the Loch (pictured). On the face of it the Kishorn site seems to satisfy none of Mr Ross's criteria for a suitable site; that it must have access to existing facilities, that it can draw on existing labour sources and that it can make use of existing infrastructure.

By giving this decision Mr Ross has brought down on himself a hail of criticism, not only from those who successfully opposed the development at Drumbuie, but also from those who felt that Drumbuie would be the lesser of two evils. As the site is even more remote than Drumbuie from existing rail and road services, all materials and supplies are to be shipped across the loch from the nearest rail link, which will involve an additional development at this point.

But giving his reasons for the decision, Mr Ross emphasised that the very remoteness of the site was a point in its favour. Also, the site will employ a smaller workforce than that proposed at Drumbuie. Obviously a major factor in the differing decisions is the National Trust land involved at Drumbuie, and the fact that far fewer local residents were likely to be affected.



But what must worry many people is the fear that this is only the beginning. This decision has been made despite the recent publication of the Scottish Development Department's Coastal Planning guidelines which designate the West Highlands coast as a conservation zone. Mowlem/Taylor Woodrow who lost the site at Drumbuie, are unlikely to rest under this decision and will no doubt look for a site nearby. As necessary infrastructure is developed, the economic advantages of allowing more sites to use it will no doubt be cited.

A few crumbs of comfort may be gathered in the appendices to the Secretary of State's memorandum. Twelve years from now, the site must be cleared completely of all buildings, and restored to its original condition, with replanting if necessary. Optimists can book their holiday now.

Genetic engineering with viruses

A SIGNIFICANT development in the field of genetic engineering is described in an article by Drs Noreen and Ken Murray in this week's issue of *Nature* (page 476) They have been able to isolate a mutant of bacteriophage λ which can replace the normally used plasmid in experiments designed to construct new hybrid DNA molecules

These experiments are very simple in principle and (in brief) involve mixing together in a test tube the donor DNA molecule (the gene to be studied), the receptor (the plasmid) and a 'DNA cutting' enzyme, the restriction enzyme *Eco*RI The cutting enzyme breaks the circular double stranded plasmid at a single point converting it into a linear molecule But it does more than this The enzyme cuts DNA slightly asymmetrically leaving four nucleotides projecting at each end These 'sticky ends' can pair up by forming Watson–Crick base pairs with similar sticky ends formed on the donor DNA molecule by the cutting enzyme. Thus a linear hybrid plasmid is formed which can circularise To stabilise the new hybrid plasmid another enzyme, DNA ligase (a 'joining' enzyme), is added to reform the covalent bonds broken by the restriction enzyme The success of such experiments, which have now been carried out using staphylococcal DNA, *Xenopus laevis* ribosomal genes and *Drosophila* DNA as donor, depends on there being a single site for the restriction enzyme on the plasmid The problem in phage λ is that there are five sites

The Murrays' work involves a brilliant series of genetic and biochemical manipulations to construct a mutant phage λ with one or two sites for the restriction enzyme *Eco*RI Then, in subsequent experiments, restriction fragments of these various mutant phage λs were joined together *in vitro* to form hybrid molecules with a deletion in a non-essential part of the phage These new molecules were isolated as biologically active phage λ after infection of *Escherichia coli* By this means the single-site mutant was converted to a bacteriophage with a gap in it leaving room for an incoming piece of DNA The authors were able to insert the genes specifying the biosynthesis of tryptophan in *E coli* (the *trp D* and *E* genes) into this receptor phage λ They imply that they hope to extend this work to study the expression of the *trp* genes, for which phage λ is an ideal host (and has significant advantages over a plasmid host), as well as to study the insertion of DNA from higher organisms

Many readers of *Nature* will know that there is some controversy among scientists about the ethics of performing genetic engineering experiments (see *Nature*, **250**, 279, 1974) Part of the concern is about the nature of the particular *E coli* plasmid used in these experiments which confers on the *E coli* resistance to the antibiotic tetracycline Clearly, if one wishes to introduce foreign, and possibly hazardous DNA, it is advantageous to use microorganisms susceptible to antibiotics Dr K Murray, in a recent lecture to the Biochemical Society, has pointed out that phage λ is much safer than the plasmid It is sensitive to antibiotics and only infects some strains of *E coli* There is also evidence that the laboratory strains for which λ is infective do not establish themselves in the human gut It is thus improbable that hybrid molecules (of whatever type) could be pathogenic

G G BROWNLEE

Some myths about heritability and IQ

THINGS have gone too far Estimates of the heritability of IQ reported in *Nature* have assumed a distinctly bimodal distribution First, Eaves and Jinks[1] decried my data on the heritability of scholastic aptitudes[2] as a failure to detect the high heritability of IQ In a sample of urban school-age twins, I found that black and economically disadvantaged children from both races seemed to have lower heritabilities for verbal and quantitative aptitudes than white and middle-class children In some cases heritabilities were not calculable, because the correlations of opposite-sex twins were slightly larger than those of same-sex twins Now, Schwartz and Schwartz[3] proclaim zero heritability for IQ as the obvious conclusion to be drawn from the same study and from Kamin's iconoclastic efforts (Invited Address, Eastern Psychological Association, Washington DC, March 1973) I beg to differ with both extremes and to argue against any simple conclusions on the issue

The notion that there is a single answer to the question "What is the heritability of IQ?" is patently false Heritability estimates vary according to what skills are measured as intelligence, by how they are tested, by the age at which abilities are measured, and by the genetic and environmental composition of the population tested To claim that there is a single estimate for the genetic contribution to human abilities is to deny, first, half a century of evidence on differential abilities Some aspects of intelligence, such as vocabulary, have consistently higher heritability estimates than, say, numerical reasoning Even if one concluded, with Burt, that general intelligence (*g*) is more important than specific abilities, different tests of *g* will still yield different heritability estimates[5]

Differences in heritability estimates across abilities and tests are exceeded only by differences across age groups and populations Bayley Infant Intelligence Test scores for the first two years have been found to have generally lower heritabilities than later scores Even early heritabilities vary enormously from 0 2 to 0 4 for siblings (McCall, American Psychological Association, Honolulu, September 1972), 0 75 for some twins (Nichols and Broman, preliminary report of the Collaborative Perinatal Study, 1973); and 0 3 for other twins[6] Across populations, Nichols[7] reported a significantly lower correlation for black than white siblings on the Stanford–Binet test at age 4 Another twin study (Scarr-Salapatek, Katz, and Barker, *Black and White Twins*, in preparation) found lower heritabilities for adolescent black and white twin pairs on each of four tests of cognitive abilities and for the first principal component from the four tests These data are presented in Table 1 Not only are

Table 1 Heritability estimates for four tests of cognitive abilities in two adolescent twin populations

Test	Black h^2* ($N=160$ pairs)	White h^2 ($N=211$ pairs)
Raven Standard Progressive Matrices	0.59	0.87
Peabody Picture Vocabulary Test	0.28	0.49
Columbia Test of Mental Maturity	0.42	0.58
Revised Test of Figural Memory	0.61	0.71
First Principal Component	0.48	0.63

*$h^2=2\,(r_{i\mathrm{MZ}}-r_{i\mathrm{DZ}})$, where $r_{i\mathrm{MZ}}$ is the intraclass correlation for monozygotic twins and $r_{i\mathrm{DZ}}$ for dizygotic twins.

heritabilities lower for black children on all four measures, the heritabilities are not uniformly 0.80 or 0.00 in either group.

If one observes an array of data from studies of related and unrelated people, the IQ scores of those more closely related generally correlate more highly than those more distantly related. This is undeniable. The view from afar reveals important regularities in the results. If the proponents of a uniformly high heritability would look more closely, however, at the constellation of human differences, they would find important inconsistencies as well.

A recent reanalysis of data on the heritability of Stanford–Binet IQ scores questions the very high heritability estimate that Eaves and Jinks[1] propose. Jencks[8] reanalysed US family correlations and obtained heritability estimates between 0.45 and 0.60, far below the 0.8 claimed by Burt[9], Jensen[10], Eaves and Jinks[1], and Herrnstein[11]. If Burt's data are included, the heritability estimates rise, in large part because his observed (?) correlations fit genetic expectations so perfectly. As Jensen[12] has recently shown, however, there are serious inconsistencies in Burt's reports. If one relies primarily upon Burt's data, one could be grossly misled as to the proper range of heritability estimates.

A reanalysis of Jencks's reanalysis[13] suggests that the best fit to the US data is a heritability of about 0.68. But Eaves and Jinks ignore Jencks's major point: that the data from parent–child, twin, sibling, and adopted child pairs do not fit any simple model! There are sufficiently serious disagreements that forcing the data into a biometrical model is to risk a nonsense solution—however mathematically elegant.

In addition, twin data on which the proponents of high heritability rely have been shown to overestimate heritability values[14], presumably because twin environments, particularly those of monozygotic twins, have less variability (pre- and post-natally) than the environments of ordinary siblings. The variance between monozygotic co-twins is further reduced by genotype–environment covariances and interactions. There has not yet been a serious test of the magnitude of covariance and interaction effects on human intelligence. Although Jinks and Fulker[15] suggest a test for interaction (the correlation of half the sum and half the difference between IQ scores of separated monozygotic twins), their barely significant results are based on very small samples.

Further evidence on the exaggeration of heritability values comes from Morton[16]. He revived Wright's[17] reanalysis of Burks's[18] adoption study. Burks's faulty path analysis model yielded a heritability estimate for general IQ (in white California adoptees) of 0.75 to 0.80. Wright's more adequate path model resulted in a heritability of 0.50 from the same data. Morton's additional calculations for sibs and foster sibs gave a heritability solution of 0.52.

The idea of zero heritability strikes most geneticists and biologists as odd (Fuller, presidential address, Behavior Genetics Association, Minneapolis, June 1974). How can there be any biological characteristic for which genetic variability makes no contribution to phenotypic variability? As Morton[16] remarked, " the experience of biometrical genetics [is] that a trait heritable at its extremes has never been found to have zero heritability within the normal range" (page 257). Certainly IQ is affected by many single gene and chromosomal anomalies. There are four possibilities to explain a finding of zero heritability: first, the measurement of the phenotype is invalid or unreliable, second, there is no genetic variability underlying the phenotype, third, all genotypes are functionally equivalent in producing the phenotype, or fourth, other effects overwhelm genetic variability. The first two possibilities for the heritability of human abilities can be dismissed out of hand. The third is what Schwartz and Schwartz[3] want to argue. There is simply too much evidence to the contrary, however, from studies other than those that they and Kamin would dismiss. Though every human family study may be criticised on one or more methodological grounds, their flaws are varied and non-overlapping. The weight of evidence suggests that genetically related persons are more similar intellectually than unrelated persons, whether they are reared together or apart. The microscopic examination of research flaws has blinded some critics of heritability to the obvious pattern of results.

The fourth is what Henderson[19] and I[20,21] argued for some populations. Other effects can include rearing conditions, growth patterns at a particular age, the skills tested, and many unspecified conditions that will affect sources of variability. The negligible and low heritabilities reported for aptitude scores among disadvantaged, school-aged twins in Philadelphia[2] were a function of the environments sampled, the tests, the populations, and possibly the age group. The point is that genetic differences did not seem to contribute much to variability in aptitude scores in those populations. Different tests, ages, populations, and cohorts may well yield other results. Since these tests are very widely used to make life decisions for children, however, their low heritabilities have considerable implications.

There is no single answer to the question "What is the heritability of IQ?" because it is a pseudo-question. Heritability estimates range between 0.00 and 0.9 in reported research, but most values are in a middle range. An accurate view of genetic contributions of differences in IQ cannot be obtained from the proponents of extreme positions. In fact, the best view of human variability can be obtained by getting off the political platform and out there to study families. With the notable exception of Arthur Jensen, not many advocates of high or low heritability are adding to our store of knowledge about human intelligence.

Origin of metalliferous sediments

FOR reasons which are largely historical and political rather than scientific, the first specific phenomenon likely to come to mind at any general mention of ocean mineralisation is that of manganese nodules No doubt there is some justification for this emphasis, for in spite of the many unsolved problems relating to both their collection and processing, nodules will almost certainly be the first deep sea minerals to be exploited commercially But nodules are not the whole story of marine mineralisation, nor, as Bullard (*Endeavour*, **33**, 80, 1974) has pointed out, will they necessarily prove to be the most important part of it in the long run Nodules are attractive because they are discrete conglomerations of a few metals in a particularly concentrated form, but in both economic and scientific terms they are likely to be rivalled increasingly by sediments containing unusually high proportions of similar elements

The story of the discovery of metal-rich sediments begins in 1948 when Swedish workers on the research vessel Albatross discovered a region of abnormally high temperature in the Red Sea just north of latitude 21° N About 15 years later, more detailed investigations of water temperature and salinity were carried out in the same region by teams from the United States, Germany and Britain, and as a result of the discoveries made then, a further study of both water and underlying sediments was undertaken in 1966 by the research vessel Chain from the Woods Hole Oceanographic Institution These expeditions found three deep basins containing hot water with a salinity about seven times greater than that of normal Red Sea water The largest of these 'brine pools' was the Atlantis II Deep (about 15 km long by 5 km wide), although it became clear that this is not the deepest of the brine-filled basins when Backer and Schoell (*Nature phys Sci*, **240**, 153, 1972) reported the discovery of 13 more brine pools by the German ships Wando River and Valdivio

But if the water in the Red Sea deeps is remarkable, equally so are the sediments beneath them For whereas the normal sediments in the central trough of the Red Sea are light-coloured marls, those in the brine pools were found to comprise yellow, red, brown and blue layers enriched in such metals as iron, manganese, copper and zinc The enrichment seems to be high but quite variable In 1969 Bischoff (in *Hot Brines and Recent Heavy Metal Deposits in the Red Sea*, Springer-Verlag, 1969) said that the high grade sediments in the Atlantis II Deep contain an average of 3 4% Zn and 1 3% Cu after removal of salt and water But Tooms (*Endeavour*, **31**, 113, 1972) has quoted a more recent survey by a commercial company which led to average estimates over a much wider area of 6% Zn and "several per cent" Cu Even more recently, Backer and Schoell have claimed that some facies contain 50–65% iron, that the average manganese concentration in the Chain Deeps is 30–40% and that some sulphide layers in the Atlantis II Deep contain 20% zinc, although they admit that "continuously changing facies conditions" reduce the average base metal content to a few per cent

But although quoted metal concentrations differ, there is complete agreement that enrichment has taken place, and this inevitably raises the question of how and under what circumstances it occurred The Red Sea is widely believed to be an embryo ocean, and the deeps containing hot brine are closely associated with the central trough The connection between metallogenesis and seafloor spreading is thus unmistakable—but is metal enrichment a feature only of spreading in its early stages or does it occur whenever and wherever spreading takes place? The thick salt deposits covering a large part of the Red Sea depression must be the ultimate source of the salt in the brine pools, and the brine pools are closely associated with the enriched sediments beneath Does this mean that metal enrichment only takes place in relatively closed oceans conducive to the formation of salt deposits by repeated evaporation, or is the presence of abundant salt in itself an unnecessary condition?

These questions cannot yet be properly answered But there is now abundant evidence for the existence of metal-rich sediments on the East Pacific rise and other ocean ridges Such sediments were apparently known to Revelle (*Publs Carnegie Instn*, **556**; 1944) thirty years ago, although modern studies can probably be said to date from the geochemical work of Bostrom and Peterson (*Econ Geol*, **61**, 1258, 1966) following the discovery of the critical part played by ocean ridges in global tectonics In this and numerous subsequent reports, Bostrom and his colleagues and others have shown that metal enrichment (but not apparently to economic concentrations) does indeed take place along ridges in late stages of spreading, and Deep Sea Drilling Project results have indicated that such sediments are not uncommon at the base of sedimentary columns throughout the ocean basins

The general circumstances in which metalliferous sediments are likely to form are thus at least partly understood, but precisely how they form is still an unsolved problem Nevertheless, it is becoming increasingly clear that hydrothermal processes are involved in some way In the case of the Red Sea, for example, it may be presumed that the salt in the brine comes from the existing salt deposits, but the water must have acquired its temperature from the upwelling magma at the central rift It is then reasonable to suppose that, during contact with the magma, the water also acquired metallic components which later precipitated out as metallic compounds to form the observed sedimentary ores

In fact, water may well penetrate to substantial depths (possibly several kilometres) in the new oceanic crust at ridge axes, thus leaching a considerable volume of rock Both Corliss (*J geophys Res*, **76**, 8128, 1971) and Spooner and Fyfe (*Contr Mineral Petrol*, **42**, 287, 1973) have proposed models in which sedimentary metal enrichment could occur by this mechanism, and Lister (*Geophys J*, **26**, 515, 1972) has used deep hydrothermal circulation to explain the unexpectedly low average heat flow at ridge crests and the high scatter of heat flow values at ridge crests and flanks Piper (*Earth planet Sci Lett*, **19**, 75, 1973) and many others have offered geochemical evidence, and on page 473 of this issue of *Nature*, Anderson and Halunen present combined geophysical and geochemical data which give further support As Lister (*Eos*, **55**, 740, 1974) has rightly suggested, what is required now is a commitment to test the hydrothermal circulation hypothesis more directly by deep sea borehole measurements

PETER J SMITH

Cell culture pharmacology

from Mary Dawson

THE action of drugs on cultured vertebrate cells was the subject of the autumn meeting of the British Society for Cell Biology, held at the University of Strathclyde, Glasgow, on September 19 and 20, 1974 Most of the experiments described had one of four main objects—to increase knowledge of the cells being studied by using known compounds as tools, to elucidate the mode of action of drugs where this was unknown or partly known, or to design *in vitro* tests which would either provide knowledge about new drugs under development or would form a basis for choosing the best drug from a range of possibles for any one patient Of the papers presented more had been engendered by cancer research than by any other single disease area This is a fair representation of cellular pharmacology work since it is logical and practicable both to study the effects of compounds on normally and abnormally proliferating cells and to use compounds to study differences between such cells

The Searle Lecture was delivered by L J Tolmach (Washington University) who spoke of his group's work on the enhancement of radiation effects on proliferating cells by various drugs used separately or together He emphasised, as did several subsequent speakers, the relative ease of carrying out statistically satisfactory numbers of replicate experiments in cell culture, and of automating additions and removals of drugs Drug–radiation interaction was discussed also by A H W Nias (Belvidere Hospital, Glasgow) and papers on specific groups of compounds were presented by A M Creighton (Imperial Cancer Research Fund) and B J Phillips (Chester Beatty Research Institute)

The papers of R I Freshney (Beatson Institute, Glasgow) and J A Dickson (Royal Victoria Infirmary, Newcastle-upon-Tyne) dealt with the design of cell culture tests for measuring human tumour sensitivity to drugs, and the place of such tests in cancer therapy They described the uses and limitations of such tests, and factors influencing the results, pointing out that a laboratory LD_{50} end point still meant 50% of surviving cells too

A further group of four papers was on the subject of cardiac glycosides and electrophysiology experiments These were by J F Lamb (University of St Andrews) and W F Dryden *et al* (University of Strathclyde) There were two papers on anaesthetics and related compounds by L J Erkell (Goteborg) and A G Macdonald (Aberdeen) The latter paper led to comment on the validity of using non-mammalian material to investigate clinical problems, as did the paper of D Brown, M Balls and J Pryor (University of East Anglia) who chose amphibian cell cultures for their relative functional longevity The symposium title had been deliberately widened from "human" to "vertebrate" cells to generate discussion on the possibility of errors due to species difference on extrapolating from various types of *in vitro* tests to clinical situations There was indeed much discussion on choice of culture material

The action of parathyroid hormone on explanted bone rudiments was discussed by P J Gaillard (University of Leiden) in relation to hyperparathyroid conditions, and P J Hornsby and M J O'Hare (Chester Beatty Institute) described functional activity in cultured adrenal cells The extraordinary biological properties of the cytochalasins were discussed by S B Carter (Imperial Chemical Industries, Macclesfield) who indicated their value in examining cellular processes as did M de Brabander (Janssen Laboratories, Beerse)

Further areas where cell culture study was relevant to finding information about the compounds or the cells were reported in the papers on prostaglandins by M Adolphe (Institute of Pharmacology, Paris), on *in vitro* antibody production by G Harris (Kennedy Institute, London), on bacitracin by M Dawson (University of Strathclyde) and on colchicine and microtubules by D Wheatley (University of Aberdeen)

Mystery molecule in Japan

from Sydney Shall

THE Japanese have taken poly(ADP–ribose) to their heart Since much of the progress in this area of molecular biology comes from Japanese laboratories, this is understandable The occasion of the first Oji International Seminar at Tomakomai, Hokkaido, was used by Professors Osamu Hayaishi (University of Kyoto) and Takashi Sugimura (University of Tokyo) to organise the third international meeting on poly(ADP–ribose) and the ADP–ribosylation of proteins (September 10–12). This very young field has progressed steadily over the last five years, but without success so far in two major respects a simple method for measuring poly(ADP–ribose) in intact cells, and unequivocal evidence of its physiological function are both lacking

This unusual chromosomal polymer has a composition almost identical to that of poly(A) but does not have a nucleic acid structure It is made by a chromosomal enzyme for which NAD$^+$ is the sole substrate NAD$^+$ metabolism in cancer cells is unusual and poly(ADP–ribose) is thought to have some role in DNA replication and cell proliferation

The highlights of the meeting included progress in the purification (5,000 times) of the poly(ADP–ribose) polymerase by Ueda and Hayaishi (University of Kyoto) The partially purified enzyme still requires both DNA and histones and makes short chains The enzymes that degrade the polymer have been isolated and purified by L Burzio (Rockefeller University, New York) from testis, and by M Tanaka, M Miwa and T Sugimura (University of Tokyo) from liver, thymus, *Physarum polycephalum* and from tobacco cells in culture

There was considerable discussion following the paper by H Hilz (University of Hamburg) as to whether the polymer is covalently attached to chromosomal protein Hilz demonstrated that at least some of the polymer is covalently bonded to protein

The most interesting report was the description by T Kanai and T Sugimura (Tokyo) of the preparation of antibodies to poly(ADP–ribose) They showed that with these antibodies a radioimmunoassay for poly(ADP–ribose) will be possible The antibodies seem to be specific and do not cross-react with DNA, RNA or poly(A) In addition, they have detected anti-poly(ADP–ribose) antibodies in the sera of human patients with the autoimmune diseases, especially in systemic lupus erythematosus H Hilz has estimated the amount of poly(ADP–ribose) in intact animals by an extremely carefully controlled, isotope dilution technique Three important conclusions emerge the polymer exists in intact cells, the amount of polymer was estimated in adult rat liver to be 5 25±0 09 nmol of ADP–ribose residues per mg DNA, no striking difference in amount was found between adult rat liver, neonatal rat liver and Ehrlich ascites carcinoma cells But in isolated nuclei there is a substantial difference in the content of mono(ADP–ribose) residues between adult and neonatal liver

Other examples of ADP–ribosylation of proteins are very well authenticated The modification and alteration of DNA-dependent RNA polymerase by ADP–ribosylation after T4 phage infection of *Escherichia coli* was clearly demonstrated by W. Zillig (Max-Planck-Institut, Munich) and C G Goff (Medical Research Council, Cambridge) ADP–ribosylation of mammalian ribosomal elongation factor II by diphtheria toxin was dissected by C Edson, K Ueda and O Hayaishi (University of Kyoto) and E S Maxwell (National Institutes of Health, Bethesda) Both laboratories have so far failed to identify the ribosyl–protein bond in modified elongation factor But Maxwell showed the presence of an unusual amino acid in unmodified elongation factor II to which the ADP–ribose was apparently attached by the diphtheria toxin Finally, K Yoshihara (University of Nara, Japan) adduced evidence that the recently described chromatin-bound Ca^{2+}, Mg^{2+} endonuclease is itself ADP–ribosylated

The mysteries of poly(ADP–ribose) are steadily yielding to systematic attack The elucidation of its function will radically alter our picture of the biology of the cell nucleus

Fish out of phase

from Marian Dawkins

ANIMALS often need to distinguish between stimuli which arise from their environment (which includes other animals) and those which are caused by some action of the animal itself. An apparent movement of an object or a sound, for example, may require a completely different response depending on whether or not the animal has produced that movement or that sound by its own behaviour, even though the pattern of stimulation reaching the animal's sense organs may be extremely similar in the two cases.

Although the ways in which animals make this distinction are many and varied, a recently described example in a species of electric fish by Scheich (*Science*, **185**, 365; 1974) is of particular interest as it illustrates how the distinction can be made even in a situation where the animal must distinguish between two similar and simultaneous wave forms.

Scheich studied a species of fish, *Eigenmannia*, in which the electric organ has a regular wave-like discharge, enabling the fish to locate objects by detecting disturbances in the resulting field. When two *Eigenmannia* which are discharging their electric organs at similar frequencies come close enough together, they both unerringly adjust their frequencies in opposite directions so that their frequencies are no longer similar and the danger of interference to their object-detecting systems is avoided.

Conveniently for experimental study, a fish will also alter its frequency if stimulated through an electrical dipole in its tank at a frequency near its own. Within wide limits of absolute frequency, the fish will correctly alter the frequency difference between its own discharge and that of the applied stimulus to maintain a difference. In order to do this the fish must be able to detect how near its own frequency is to that of the applied stimulus and to have information on whether it is lower or higher.

A possible, although cumbersome way of doing this would be to have an array of frequency-tuned filters and for the fish to respond whenever two filters near enough in frequency were active together, provided it had some way of telling which frequency filter was responding to its own discharge. In fact, as Scheich demonstrates, the fish's solution is much simpler and his theory accounts more satisfactorily for the fish's ability to recognise the sign of the frequency difference whatever the fish's own frequency within that range.

The analysis is done by sensitivity to the beating of the two signals in the electric field—that is, the coming into and out of phase of the two waves of slightly different frequency. The frequency with which the two waves come into phase with one another (like the frequency of beat notes with two sound waves) is the difference between the two frequencies and will be independent of absolute frequency.

If the electric organs discharged sinusoidally there would be ambiguity as to which signal belonged to which fish, but the discharge is not sinusoidal: the wave shape is rich in harmonics and is clipped in one polarity. By being sensitive to the peculiarities of beat patterns produced by the interaction of two such oddly shaped waves, the fish can tell whether the interference is above or below it in frequency as well as how near in frequency. By ingenious experiments in which the fish's own output was converted artificially into a sine wave, Scheich found that under these circumstances, the fish was completely unable to distinguish the sign of the frequency difference between its own output and a sinusoidal applied stimulus. Only when its own output was allowed to resemble more closely the normal discharge was its normal behaviour restored. Scheich also found neurones in the fish's midbrain which responded to differences in frequency in such a way that they could directly provide the input into the electric organ.

Thus the fish is able to obtain information about how near its own frequency another fish is discharging and whether the other is above it or below it in frequency, not by analysing constituent frequencies, but rather by beat analysis in the time domain. It is interesting that a similar mechanism is postulated by some theories of hearing.

RNA molecules in initiation of protein biosynthesis

from Alan E. Smith

TEN years ago the main interest in protein biosynthesis was the establishment of the genetic code by translating synthetic polynucleotides of known composition or sequence in bacterial cell-free systems. Then it seemed reasonable to suppose that any ribosome can attach to almost any RNA molecule and translate it into polypeptide. This view is now known to be totally naive. The initiation of protein synthesis is a highly complex interaction between a ribosome, the initiator tRNA, and the specific ribosome-binding site on the mRNA. Several protein factors which also play a part in this process have various enzymatic functions: dissociating the ribosome into subunits, binding the initiator tRNA and binding the appropriate mRNA molecule. It now seems that in addition to the protein initiation factors, there are RNA molecules involved.

For some time, Heywood and his colleagues have been studying the specificity of mRNA translation in heterologous cell-free systems and have concluded that a specific mRNA can only be translated in a heterologous ribosome if a specific homologous initiation factor (designated IF_3) is present. Thus the synthesis of myosin on, say, erythroblast ribosomes requires initiation factors obtained from muscle ribosomes (*Biochemistry*, **11**, 2061–2066; 1972). When they further fractionated red muscle initiation factors required for the synthesis of myoglobin and myosin in a reticulocyte cell-free system, Heywood, Kennedy and Bester (*Proc. natn. Acad. Sci. U.S.A.*, **71**, 2428–2431; 1974) found that two activities are present: one specifically stimulates myoglobin synthesis and the other stimulates myosin synthesis. In addition to these two proteins, an RNA molecule was isolated from the IF_3 preparation and this seems to inhibit the initiation and translation of heterologous mRNA molecules. Bogdanovsky, Herman and Schapira (*Biochem. biophys. Res. Commun.*, **54**, 25–32; 1973) have previously shown that a similar RNA molecule of molecular weight 11,000 is present in preparations of initiation factors from rabbit reticulocytes and that the RNA is required for the synthesis of globin *in vitro*.

The presence of a small RNA initiation factor may corroborate the observations of Reichmann and Penman. They found that the base analogue 5-azacytidine inhibits protein synthesis in HeLa cells with a half life of 90 minutes (*Biochim. biophys. Acta*, **324**, 282–289; 1973). The inhibition seemed to occur at the initiation of protein synthesis and was suppressed by actinomycin D. Earlier studies had established that the half life of mammalian mRNA is very long compared with the response to aza-cytidine, and this suggested that an RNA molecule other than mRNA or rRNA, which is rapidly metabolised *in vivo*, is involved in the initiation of protein synthesis. The authors then showed (*Proc. natn. Acad. Sci. U.S.A.*, **70**, 2678–2682; 1973) that the putative RNA species accumulates in cells subjected to inhibition of protein synthesis by, for example, cycloheximide or starvation of an essential amino acid, and cell-free systems prepared from such cells show a greatly enhanced ability to initiate new polypeptide chains.

The evidence available to date indicates that the RNA species involved

Pure Che stry Library
SCIENCE COLLEGE

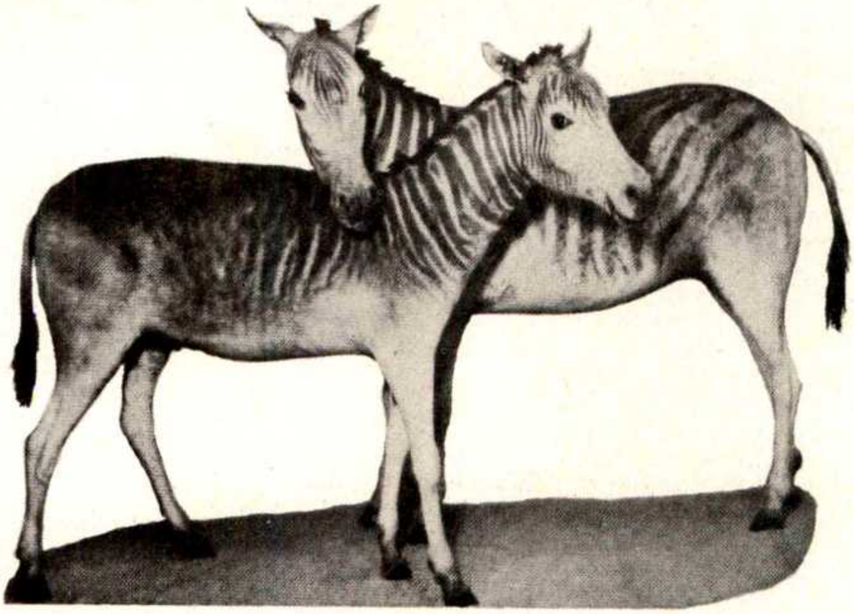
in initiation is not rRNA. Probably, therefore, the phenomenon described above is not related to the small 2S RNA species recently reported in *Drosophila* ribosomal RNA (B. R. Jordan, *FEBS Lett.*, **44**, 39–42; 1974) since this seems to be a cleavage product of 26S rRNA maturation. It is possible, however, that the mode of action of the small stimulatory RNA in eukaryotes resembles that proposed for the 3′-OH end of 16S RNA in bacteria. Shine and Dalgarno (*Proc. natn. Acad. Sci. U.S.A.*, **17**, 1342–1346; 1974) have sequenced the terminal portion of the rRNA from several bacteria and found that certain oligonucleotides near to the 3′-OH are complementary to GGAGGU—a sequence common to many of the mRNA ribosome binding sites that have so far been examined. Perhaps such a structure selects the correct site of mRNA and positions it on the ribosome. It is conceivable that the small RNA species described above has a similar function in eukaryotes.

The new RNA species not only has initiation factor activity but can also discriminate between different mRNAs. This means that a change in the specificity of initiation can be effected either by a protein (IF$_3$) factor or by an RNA species, and adds a further dimension to experiments in which changes in the specificity of initiation factors are being examined, for example, at different stages in development (Sierra, Meier and Ochoa, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 2693–2697; 1974). The presence of small RNA molecules in initiation factor preparations from uninfected cells may also suggest a function for those ribosome-associated RNA molecules that are found during viral infection but apparently do not function as mRNAs. For example during reovirus and adenovirus infections, small viral RNA molecules have been detected in excess of those required to code for viral proteins—these RNAs could alter the specificity of translation on host cell ribosomes, either by shutting off host cell synthesis or preferentially favouring viral protein synthesis.

Double-stranded RNA also has a profound effect on the initiation of protein synthesis. This was first described by Ehrenfeld and Hunt (*Proc. natn. Acad. Sci. U.S.A.*, **68**, 1075–1078; 1971) who were searching for the inhibitory agent responsible for shutting off host protein synthesis in poliovirus-infected cells. The effect on initiation was detected in rabbit reticulocyte lysates and was remarkable because of the small amounts (about 0.1 ng ml^{-1}) of ds RNA required. Celma and Ehrenfeld (*Proc. natn. Acad. Sci. U.S.A.*, **71**, 2440–2444; 1974) have now reassessed the possible role of ds RNA in the shut-off phenomenon by studying the initiation of protein synthesis in cell-free extracts of uninfected and poliovirus-infected HeLa cells. Host and viral protein synthesis are equally sensitive to ds RNA and much higher concentrations (about 5 μg ml^{-1}) of RNA are required to inhibit synthesis in the HeLa cell-free system. Since such concentrations of inhibitor are not present until late in poliovirus infection Celma and Erhenfeld suggest that ds RNA does not act directly to inhibit host cell protein synthesis. Such a conclusion is supported by experiments reported in the same issue of *Proc. natn. Acad. Sci. U.S.A.* (**71**, 2549–2553; 1974) by Thach and colleagues, who have determined by electron microscopy the structure of the purified replicative intermediate of encephalomyocarditis virus (a picornavirus closely related to polio). These authors conclude that before deproteinisation the replicating RNA contains very little ds RNA, thus the inhibitory agent detected in polio-infected cells may be an artefact caused by extraction of the viral RNA.

But three further considerations should be weighed in favour of ds RNA as the inhibitory agent before it is completely rejected. First, cell-free extracts from HeLa cells are never very active compared with whole cells; second, disrupted cells may contain an RNase III type activity which destroys much of the added ds RNA but is without such activity *in vivo* and finally even though full length ds RNA may not be present in infected cells presumably the area immediately surrounding the polymerase molecule is in a double stranded form; the effect of ds RNA in

Shades of meaning



Male quagga in Naturhistorisches Museum, Mainz on left; Burchell's zebra (type of *E. quagga paucistratus*) on right.

THE quagga, *Equus quagga quagga*, no longer roams the Cape Colony having succumbed to the hunter's gun in the nineteenth century. The last quagga died in the Amsterdam Zoo in 1883, but it is thought that this one had outlived by several years the wild quaggas in South Africa.

The striping and coloration of this close relative of the modern zebra have long been contentious subjects. There has also been controversy about whether the quagga is a true subspecies or just a geographical variant of Burchell's zebra, *E. q. burchelli*. In an attempt to sort out the confusion, Rau of the South African Museum in Cape Town, has scoured Europe for quagga remains and he now presents his revised list of what he considers true quagga material (*Ann. S. Afr. Mus.*, **65**, 41–87; 1974).

In the past, the quagga has been described variously as having black or dark stripes on a brown or fawn base with white or whitish legs and ventral surface; or being dark brown, chestnut or fawn coloured with white or whitish stripes on the antero-dorsal area of the animal. Authors writing this century have favoured a light striped animal.

After studying preserved quaggas in 27 European museums Rau concludes that there is no sharp distinction between the quagga, *E. quagga quagga* and *E. q. burchelli*. It just seems to represent, with many variations, the extreme southern limit of the trend seen in the plains zebra group: that is, in the south, the white darkens towards brown and the black lightens to a brown. This process gradually culminates in the disappearance of the stripes.

reticulocyte lysates, which lack RNase III, is so potent that this small region of poliovirus ds RNA might be sufficient to produce the inhibitory effects seen *in vivo*.

The mechanism of action of ds RNA in reticulocyte lysates is the subject of another recent paper in *Proc. natn. Acad. Sci. U.S.A.* Benzard and London (**71**, 2863–2866; 1974) have shown that the inhibitory effect can be prevented or reversed by addition of the initiation factor M_3. Preparations of initiation factors M_1 and M_2 (which are responsible for the binding of initiator tRNA) and ribosome dissociation factor are ineffective. These observations are in agreement with similar experiments by Kaempfer and Kaufman (*Proc. natn. Acad. Sci. U.S.A.*, **70**, 1222–1226; 1973) who showed that ds RNA inactivates reticulocyte initiation factor IF_3, but both reports conflict with those of Darnbrough, Hunt and Jackson (*Biochem. biophys. Res. Commun.*, **48**, 1556–1564; 1972) who found that ds RNA inhibits the formation of the complex between 40S ribosomal subunits and initiator tRNA. At present it is difficult to resolve this apparent contradiction. But it seems that very small amounts of ds RNA inhibit initiation by sequestering a catalytic site which normally recognises some structural feature in another RNA molecule. Such a structure could be present in mRNA, rRNA, initiator tRNA or perhaps even the small RNA molecule discussed earlier.

Archaeopteryx flies again

from Barry Cox

Archaeopteryx is probably the best example of an evolutionary intermediate between two major groups of animal. It is normally accepted that it is not far removed from the arboreal reptilian stock from which birds evolved. Though its skeleton is not greatly modified for flight, the elongated feathers of *Archaeopteryx* strongly suggest that flight of some kind had already evolved.

Ostrom (*Q. Rev. Biol.*, **49**, 27; 1974) has now questioned the idea that bird flight evolved in an arboreal environment. He starts from the observation that *Archaeopteryx* and the smaller cursorial dinosaurs such as *Ornitholestes* show so many characteristics in common that it would be surprising if their habits of life were totally different. He also states that the terminal phalanges of the foot of *Archaeopteryx* are relatively straight and robust, like those of cursorial birds but unlike those of perching birds, which are strongly curved.

It has long been noted that, surprisingly, the manus of *Archaeopteryx* has three long, unfused clawed fingers, and these have been interpreted as adaptations to climbing in trees. Ostrom shows that the hand, and the whole pectoral skeleton, of *Archaeopteryx* are very similar to those of such dinosaurs as *Ornitholestes*, and that the claws were long, curved and pointed—more suitable, he thinks, to a prey-grasping function that to climbing. He also notes that neither the pectoral skeleton nor the long many-feathered tail of *Archaeopteryx* suggests that it could have been an active flier.

Ostrom's view is that *Archaeopteryx* was a bipedal fast-running form which lived on "relatively small animals, most probably large insects, and perhaps small lizards and mammals". He believes that feathers evolved to aid in thermal insulation, and that their elaboration on the forelimb was originally to increase its efficiency as a prey-catching appendage, the two arms "becoming a trapping device or net with which to corral or surround small prey so that they could be more easily grasped in the mouth or hand". True flight, Ostrom believes, evolved from flapping, leaping attacks on such prey.

Long-established theories are often found to be based on deductions which are today either discarded or less certain, and it is usually worthwhile to attempt a fundamental reappraisal. Ostram's work seems certain to provoke further discussion and criticism—both of the orthodox theory and of his own views. Walker (*Nature*, **237**, 257; 1972) has already suggested that birds are more closely related to crocodiles than to theropod dinosaurs, but both Gingerich (*Nature*, **243**, 70; 1973) and Bakker and Galton (*Nature*, **248**, 168; 1974) have supported the link with dinosaurs—the latter even to the extent of including birds in a new class Dinosauria.

Some aspects of Ostrom's theories seem somewhat unlikely, at least at first glance. It is always heartening to the palaeontologist to be able to see similar adaptations in use today, but there are none such for *Archaeopteryx's* supposed insect-snaring spread of feathers. These would also have been of little use (and possibly a hindrance) in catching the small lizards and mammals that Ostrom proposes as alternative prey. His suggestion that the long, feathered tail was a braking mechanism seems equally unconvincing. Ostrom may well be right in suggesting that the ancestors of *Archaeopteryx* evolved bipedality as ground-running forms, like some modern lizards (in which bipedal and quadrupedal locomotion are not fundamentally different), and that they only evolved the extensive spread of feathers as a gliding adaptation after they had become arboreal forms. Nevertheless, the adoption of a dramatically different method of locomotion (flight) might well have followed from colonisation of a very different habitat, such as trees. The imperfection of *Archaeopteryx* as an arboreal gliding form and its retention of a grasping hand might then merely indicate a relatively recent adoption of this way of life, rather than disproving it.

Other interested parties are girding their loins for the fray, and it will be interesting to see whether *Archaeopteryx* ends up with its feet on the ground or its head in the air.

Agricultural waste to supplement oil

from D. A. H. Taylor

In 1949 Dupont opened a plant at Niagara for the production of nylon intermediates from furfural. This has long been closed down, as it could not compete with petrochemical routes, but it may now be time to reconsider the position of furfural in the light of the present oil situation.

Furfural is obtained by acidic hydrolysis of pentosans, contained in agricultural waste. Almost any plant material may be used, including straw and sawdust, with an average yield of 5–10%. Present sources include oat hulls, maize cobs, and bagasse, which is the residue after extracting sucrose from sugar cane. The potential supplies are large: it has been calculated that 2 million tons of furfural could be produced per annum in the United States from maize cobs alone (Dunlop and Peters, *The Furans*, 283, Reinhold, New York; 1953); the potential yield from sugar cane is roughly equal to that of sucrose, currently about 50 million tons yr^{-1}. This may be compared with a world production in 1970 of approximately 40 million tons of primary petrochemicals (Imhausen, *Chem. Ind.*, 1559; 1970.)

It is possible to make practically any petrochemicals one wishes from furfural, at a price. As the sources of furfural are usually of slight alternative value, the main expenses in production are plant construction, operating costs and handling and collection charges for the raw material. Its present uses are mainly as a solvent and in the synthesis of resins used to manufacture grinding wheels and brake linings. A major use is the production of resin for impregnating the glass fibre mats wrapped around steel pipelines to prevent corrosion, and currently the demand in connection with the construction of Arctic pipelines has raised the price of furfural delivered in Europe from less than £200 to more than £650 a ton. By comparison, the current price of naphtha feedstock, used for the production of petrochemicals, is of the order of £60 per ton. At this level, oil prices have still far to go before furfural could compete as a fuel for heating or power plant use. Furfural itself does not seem to have attractive properties for use as a fuel for internal combustion engines, but chemical derivatives are more promising.

Furfural derivatives usually require hydrogenation to be useful chemically which is unfortunate because hydrogen is rich in energy and hence expensive. The Dupont nylon process first decarbonylated furfural to furan by catalytic treatment, and then hydrogenated the furan to give tetrahydrofuran. This was then cleaved with hydrogen chloride to form 1, 4-dichlorobutane, which with sodium cyanide gave adiponitrile, a conventional intermediate for nylon 6/6.

Tetrahydrofuran is a valuable intermediate in other ways; one fifth of German wartime butadiene was produced by vapour phase dehydrogenation of tetrahydrofuran over a phosphate catalyst (Dunlop and Peters, *The Furans*, page 730). Although no longer used, this process would become viable again if alternative supplies of butadiene became more expensive, and gives access to a wide range of products, including the synthetic rubbers. Tetrahydrofuran has also potential as a fuel for internal combustion engines. Although its properties in this respect have not been investigated in detail it seems promising either alone or together with hydrocarbons, with which it is readily miscible.

The tetrahydrofuran process involves the loss of one carbon atom from the furfural molecule, and an alternative route which avoids this is to hydrogenate furfural to tetrahydrofurfuryl alcohol. This on heating in the gas phase gives 2, 3-dihydropyran, which may be hydrogenated to tetrahydropyran. This is also a potential fuel and chemical intermediate; analogously to tetrahydrofuran it can be converted to 1, 3-pentadiene, or to pimelonitrile and hence to nylons of the 7/7 series. Extensive development work has been done on these and other possible routes for utilisation of furfural in the chemical industry.

Hydrogenation of butadiene or pentadiene will give the saturated butane or pentane, which are in the main stream of petrochemical practice. Butane is currently used to manufacture motor fuel.

Thus increased furfural production may help to solve at least some of the present and future problems produced by the increased price and declining supply of crude oil.

Protein in two environments

from R. Colin Hughes

THE classical concept of amphipathic membrane proteins defined by Winzler, Morawiecki, Singer and their colleagues is a polypeptide containing separated domains of peptide sequences of polar or non-polar character. This seems to occur in the major erythrocyte membrane glycoprotein, a molecule in which oligosaccharide units are attached exclusively to the amino terminal half of the polypeptide. The carboxyl terminal half of the chain contains an amino acid sequence which is unusually hydrophobic and seems to be embedded in the lipid bilayer of the membrane. As Singer has pointed out, however, an amphipathic protein may consist of a linear polypeptide of more mixed character that only when folded produces the two distinct segments, one highly polar and the other highly hydrophobic, required of an integral membrane protein. Sequence analyses of more membrane proteins are obviously of great interest, and information of their three-dimensional structure cannot be too long delayed.

In the meantime, however, the field is open for speculation. In the June issue of the *Proceedings of the National Academy of Sciences* (**71**, 2396–2400; 1974) Inouye produces a particularly ingenious model for one membrane protein—the lipoprotein of the outer membrane of the *Escherichia coli* envelope.

The bacterial envelope consists of two distinct membranes: the inner or cytoplasmic membrane and the outer membrane, which are separated by a thin layer of peptidoglycan. The outer membrane contains a large amount of lipopolysaccharide and a unique lipoprotein, thoroughly characterised by Braun and his colleagues. The lipoprotein just penetrates the lipid bilayer of the outer membrane to peep out both at the bacterial external surface and at the inner surface towards the peptidoglycan, to which the lipoprotein is in part covalently linked. The sequence data of Braun show that the lipoprotein consists of 58 amino acid residues. An unusual amino acid, glycerylcysteine [S-(propane-2′, 3′-diol) 3-thio-2 amino-propanic acid] is N-terminal and linkage to the peptidoglycan involves the C-terminal lysine residue, which is linked to the carboxyl group of meso-diamino pimelic acid.

The lipoprotein has a high α-helical content and Inouye puts forward two possible arrangements in which the α helix is twisted to allow the hydrophobic amino acid residues to face in one direction whereas the hydrophilic residues face oppositely. These arrangements are of course compatible with an integral membrane protein, provided that the twisted helices are aggregated to form a superstructure in which the hydrophilic faces are in contact and the outer surface of the structure is hydrophobic. This is satisfied either by a cylindrical arrangement of six helices or by six α-helical coils arranged in a superhelix or a coiled coil, with the hydrophobic residues of each α helix pointing outwards. The height of the superhelical assembly will be about 76 Å, sufficient to penetrate through the 75 Å thick outer membrane with hydrophobic interaction between the surface of the assembly and the lipid bilayer of the outer membrane. The lipoprotein molecules may be stabilised further in the bilayer through lipid–lipid interactions involving the three fatty acids attached to the N-terminal residue (two by ester linkage and one by amide linkage). Since one or more of the individual α-helical polypeptides of the assembly may be attached covalently to the underlying peptidoglycan, the lipoprotein assembly is constrained and free diffusional motion within the outer membrane presumably is not allowed.

The function of the bacterial lipoprotein is unknown. Inouye points out an intriguing aspect of his model, however, in that the superstructure of assembled helices spanning the membrane could provide hydrophilic pores through the outer bacterial membrane. Two general classes of molecular mechanisms for protein-mediated transport involving pores may be postulated. A penetrating membrane protein could be itself porous. Alternatively, the pores could be formed by an assembly of protein molecules: the proteins are porogenic rather than porous. In the case of the bacterial lipoprotein, Inouye calculates a hydrophilic pore size of from 12.5 Å to 35.8 Å depending on an assembly of six or twelve α helices. The number of lipoprotein molecules per bacterium is about 7.5×10^5, and accordingly the calculated total number of channels per cell varies from 1.25×10^5 to 0.63×10^5. That is, about 35% to 45% of the total bacterial cell surface is occupied by the assemblies. These hydrophilic channels could accommodate the passive diffusion through the outer bacterial membrane of almost all materials required for growth, provided of course that diffusion of these substances is also allowed through the other barriers of the peptidoglycan layer and the cytoplasmic membrane

Search for pulsed X rays from 3U0833-45 (Vela pulsar)

S. Rappaport, H. Bradt, R. Doxsey, A. Levine & G. Spada*

Physics Department and Center for Space Research, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

A search for pulsed X rays from 3U0833-45 has been carried out. The Uhuru error box for this source (~8′ × 24′) contains the Vela pulsar. We obtain an upper limit of ~1/3 the intensity of 3U0833-45 for periodic pulsing with the 89-ms period of the Vela pulsar. Other evidence for X-ray emission from the Vela pulsar is reviewed.

SOME 100 radio pulsars have been discovered. The spin periods range from 33 ms (NP0532) to 3.75 s (NP0525). Only two of these pulsars have been reported to emit X radiation: the Crab pulsar (NP0532) and the Vela pulsar (PSR0833-45). In the case of NP0532, the pulsed X-ray emission is rather intense, making it the 25th brightest X-ray source in the sky. Its high energy emission covers the range from 1 keV to greater than 1 GeV (refs 1–3).

The Vela pulsar is the next most likely emitter of X rays because it has the next highest spin frequency, ~89 ms. There have been various reports of X-ray emission, and lack of emission, from it. In the 2 to 10 keV range, a source (3U0833-45) has been detected in the vicinity of the Vela pulsar by Uhuru[4]. The error box for this source is ~8′ × 24′ and contains the Vela pulsar; however, the time resolution of Uhuru is insufficient to reveal a possible 89 ms pulsing. The diffuse Vela supernova remnant has not been detected in the 2 to 10 keV energy range.

A marginally significant detection of X-ray pulsing from the Vela pulsar in the energy range 23 to 80 keV has been reported[5], but with a period 155 ms different from the radio period. In the same energy range the MIT balloon group found no pulsing (2σ confidence) at the same level of intensity[6]. In soft X rays, 0.5 to 1.5 keV, the AS&E group found pulsing with the same period as in the radio and with an intensity of ~2% of the total X-ray intensity of the Vela supernova remnant[7]. The same group also reported a non-pulsed component about twice as intense as the pulsed component[7]. These latter results are inconsistent with a recent pulsing limit set by the CalTech group[8] (<0.3% of the intensity of the Vela supernova remnant) and the detection by the Copernicus satellite of only a much weaker source within 6′ of the Vela pulsar[9]. The time resolution of the Copernicus X-ray instrumentation during the Vela observation was inadequate to detect 89 ms pulsing. The experimental results are summarised in Fig. 1.

Our data

The present experiment, which features 1 ms time resolution, was directed toward a search for periodic (89 ms) pulsed X-ray emission from 3U0833-45 in the energy range 1.5 to 10 keV. An earlier search in the same energy range[10] yielded an upper limit substantially above the intensity of 3U0833-45. The present observations were made from an Aerobee 170 sounding rocket launched from Woomera (Australia) at 1800h, November 9, 1973 (UT). The payload instrumentation consisted of a bank of 6 beryllium window proportional counters, sensitive in the energy range 1.5 to 10 keV with 900 cm² total open area. During the final 100 s of the flight, the view axis of the detectors was pointed in an intermediate direction between Vela X-1 (3U0900-40) and the Vela pulsar. Only 70 s of the Vela data were recovered because of a single 30 s loss of the telemetry signal. The instrumentation and the results of the observations of Cir X-1 (observed earlier in the flight) and Vela X-1 have been presented previously[11].

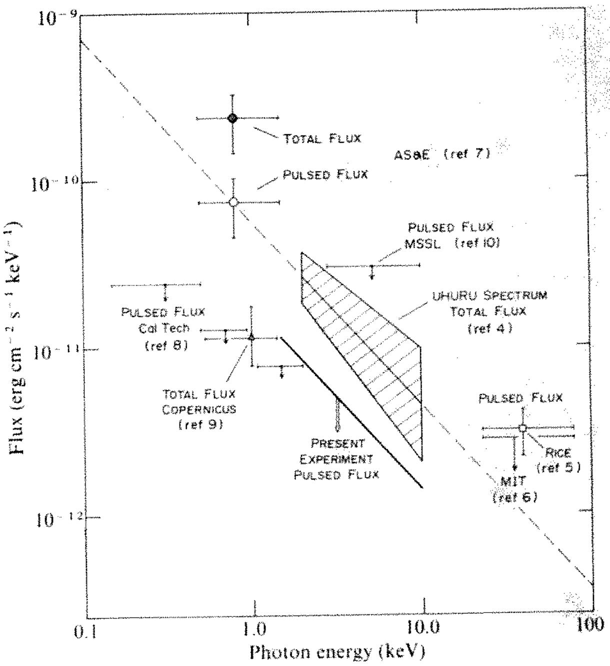

Fig. 1 Summary of X-ray data for the Vela pulsar. The pulsing limits from the present experiment (1.5 to 10 keV) are derived under the assumption of an energy spectrum with a spectral index $\alpha = 1.1$ (same as for 3U0833-45, ref. 4). For different assumed spectra, the limits set by the heavy line in the figure would rotate about a fixed point near 3 keV (5×10^{-12} erg cm^{-2} s^{-1} keV^{-1}) where the detectors are most sensitive.

The observations in the Vela region yielded about 6,500 signal counts above a background of ~38,000 counts, due mostly to the isotropic X-ray flux. We estimate that 3U0833-45 contributes about 600 of the 6,500 signal counts. We arrive at this estimate by folding the spectrum of 3U0833-45 (ref. 4: $I(E) = 5.6 \times 10^{-11} E^{-1.1}$ erg cm^{-2} s^{-1} keV^{-1}) with the response function of our detectors. The calculation indicates a total source counting rate for the present experiment of 9 counts s^{-1}. The data were folded modulo the apparent period of PSR0833-45 at the time and place of the rocket launch, $P = 0.0892230$ s

(private communication from P. Reichley). The resultant histogram (Fig. 2) shows no obvious or statistically significant features. The hatched peak superimposed on the data represents the expected appearance of the light curve if 3U0833-45 were 100% pulsed and had a light curve identical with the radio pulse profile of PSR0833-45 at 2.4 GHz (single pulse ~4 ms wide[12]).

Implications for models

So most of the signal from the Uhuru source 3U0833-45 is either pulsed with a wide duty cycle ($\gtrsim 30\%$) or is a steady non-pulsing flux. A steady X-ray flux could be synchrotron radiation from a nebular source surrounding the pulsar although there have been no reports of a compact steady non-thermal radio source[13]. The observed emission cannot be blackbody radiation from the hot neutron star surface since the required temperature, $\sim 10 \times 10^6$ K, is too large for the current age ($\sim 10^4$ yr, ref. 14) of the pulsar. Also, the X-ray flux at the Earth would be almost two orders of magnitude larger than observed, even for a minimum neutron star radius of ~5 km and a distance of ~1 kpc, which is twice that given in ref. 15.

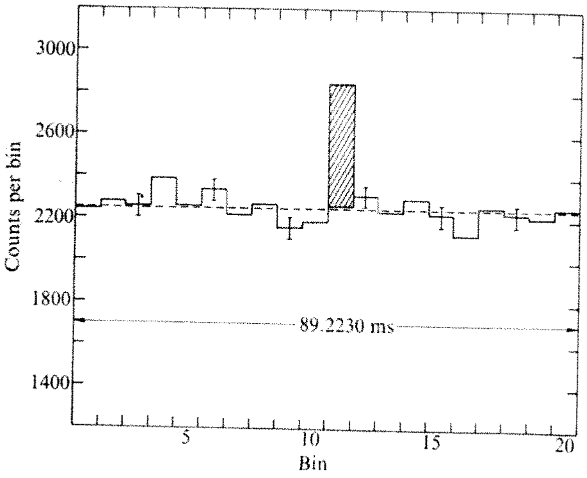

Fig. 2 X-ray data from the Vela region superimposed modulo the apparent period of PSR0833-45. The time reference for zero phase, (start of bin 1) is the launch time: 18 h 00 min 00 s, November 9, 1973 (UT). About 99% of the counts are from the isotropic X-ray background and 3U0900-40. The hatched peak represents the expected light curve if 3U0833-45 were 100% pulsed with a duty cycle similar to that of the radio pulsar. The phase of the expected peak is arbitrary since we were unable to obtain the phase of the radio pulse.

The limit (3σ) for the time averaged pulsed X-ray emission is 3×10^{-11} erg cm^{-2} s^{-1} (1.5 to 10 keV) or 5×10^{-12} erg cm^{-2} s^{-1} keV^{-1} at 3 keV for an assumed $E^{-1.1}$ energy spectrum and pulse profile similar to that of the radio pulse. In this context, we note that the X-ray and radio pulse shapes for the Crab pulsar are similar[1,16]. If the width of the X-ray pulses from PSR0833-45 is as broad as 12 ms, then the upper limit to pulsed emission which we can set is about 5×10^{-11} erg cm^{-2} s^{-1}. The time averaged X-ray luminosity then becomes

$$L_{\mathrm{Vela}}\ (1.5\ \text{to}\ 10\ \text{keV}) \leqslant 8 \times 10^{32}\ \text{erg s}^{-1}$$

for a distance of 500 pc and a 4 ms pulse produced by a broad fan beam. This compares with the X-ray luminosity of the Crab pulsar, for a distance of 2 kpc (refs 1, 17):

$$L_{\mathrm{NP0532}}\ (1.5\ \text{to}\ 10\ \text{keV}) = 9 \times 10^{35}\ \text{erg s}^{-1}$$

The Crab pulsar therefore radiates at least 1,000 times the power of the Vela pulsar in the 1.5 to 10 keV range. This ratio is still greater than 150 if the Vela pulsar is as far as 1 kpc and the Crab is as close as 1.5 kpc. If the X-ray luminosity of pulsars has a power law dependence on the spin period, P, ($L_x \propto P^{-n}$), then these ratios yield an index n which is probably greater than seven and conservatively greater than five. The value $n = 4$ is predicted for the total luminosity by the oblique rotator or unipolar inductor models[18-20]. If one further assumes that a fixed fraction of the rotational energy loss is emitted in the form of pulsed X-rays (ref. 21), then the present result is incompatible with these models. The luminosity dependence on spin period predicted by the "corpuscular model" ($L \propto P^{-7}$, ref. 22) and that predicted for incoherent synchrotron radiation close to the speed-of-light circle ($L \propto P^{-10}$, ref. 23) seem to be consistent with the present X-ray observations. The calculated X-ray luminosity for incoherent radiation from the "electron polar zones" ($L \propto P^{-17/4}$, ref. 24) is inconsistent with the present result both in its dependence on spin period and in its absolute value.

A similar comparison at optical wavelengths has been made previously. The time averaged apparent magnitude of NP0532 is $m_v = 16.5$. No detections of PSR0833-45 have been made down to limiting magnitudes $m_v \sim 24$ (refs 25, 26). This leads to a conservative upper limit to the optical luminosity ratio[25]:

$$L_{\mathrm{Vela}}/L_{\mathrm{NP0532}} < 2 \times 10^{-4}$$

which is even smaller than in the X-ray region. The index n for the optical case is then greater than ~8.5, but this holds only if there is no severe optical extinction for the Vela pulsar.

Further X-ray observations of 3U0833-45 are required to provide an improved position to confirm the identification with the pulsar and to search for lower levels of pulsed X-ray emission.

We thank E. Leverenz and R. Shafer of MIT for assistance in the data analysis. Engineering support was provided by E. Boughan and F. Miller. We also thank the staffs of the Center for Space Research at MIT, the Goddard Space Flight Center (in particular, R. Windsor, F. Lau, and P. Velgos), and the Weapons Research Establishment, Woomera, Australia.

Implications of heat flow for metallogenesis in the Bauer Deep

Roger N. Anderson & A. John Halunen jun.
Marine Physical Laboratory of the Scripps Institution of Oceanography, University of California, San Diego, La Jolla, California 92037
Hawaii Institute of Geophysics, University of Hawaii, Honolulu, Hawaii 96822

The Bauer Deep, in the south-eastern equatorial Pacific, is the only deep ocean basin so far known to be characterised by metalliferous sediments throughout the depositional column. The basin was formed when the eastern Pacific spreading centre jumped from the now fossil Galapagos Rise to the newly formed East Pacific Rise.

The distinctly bimodal distribution of heat flow in the Bauer Deep indicates that precipitation from hydrothermal fluids emanating from the oceanic crust may be the mechanism for metallogenesis in the Bauer Deep. The hydrothermal circulation may have been initiated by the emplacement, approximately ~ 6 Myr BP, *of a heat source associated with the ridge jump into that vicinity.*

THE existence of metalliferous sediments on the East Pacific Rise and other mid-ocean ridges has been known for some time[1-3]. Such deposits are a characteristic of basal sediments from Deep Sea Drilling cores throughout the ocean basins (see refs 4–6). The Bauer Deep in the south-eastern Pacific, is the only deep-ocean basin known at this time in which metalliferous sediments have been reported throughout the depositional column. Sayles and Bischoff[7] reported concentrations of Fe and Mn of up to 18% and 6.5%, respectively, and low concentrations of Al and Ti in sediments containing little or no $CaCO_3$. They also reported anomalously high concentrations of Cu, Ni, and Zn.

Extensive mapping of the regional extent of the ferriginous sediments has been an integral part of the IDOE Nazca Plate project (G. R. Heath *et al.*, unpublished). Cores from JOIDES, leg 34, site 319 (Fig. 1) have recently shown more than 100 m of metalliferous sediment in the Bauer Deep[8], with large concentrations of metalliferous components throughout the entire section. Cores from leg 34, holes 320 and 321 (Fig. 1) also revealed basal segments rich in heavy metals, although the upper sections of each were relatively free of anomalous metal concentrations.

Corliss[9] argued that metallic sediments from the mid-ocean ridge crest were precipitated from hydrothermal solutions percolating upwards from the basaltic oceanic crust. He argued that metals are mobilised by dissolution in seawater circulating in the crestal provinces of ridges, Williams *et al.*[10], Lister[11], and Sclater *et al.*[12] have presented extensive evidence, based upon a bimodal, oscillatory heat-flow pattern, for massive hydrothermal circulation in the crestal province of mid-ocean ridges. The seafloor spreading process itself thus provides the heat source, volcanism, faulting, and fracturing necessary to drive hydrothermal circulation in this environment.

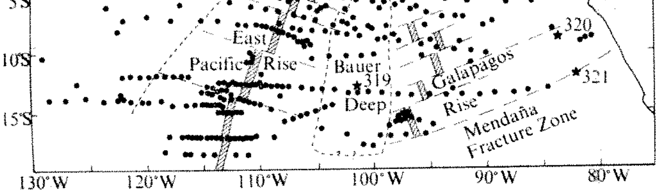

Fig. 1 Physiography of the south-eastern equatorial Pacific Ocean. Solid circles, locations of heat-flow stations plotted in Fig. 2 (sources from refs 20, 27–31, and R. N. Anderson *et al.*, unpublished); hatching, active and inactive spreading centres; light dashed lines, fracture zones; stars, JOIDES, Leg 34, hole locations[8].

Sediments from the Bauer Deep are chemically similar to sediments from the East Pacific Rise in that both have high transition metal: aluminium ratios[13-15], with sulphur, uranium, and O_2 isotopic compositions consistent with formation from seawater[13,14], strontium isotopic compositions suggesting equilibrium with seawater[14,15], rare-earth patterns like that of seawater[9,13], and lead isotopic compositions which are similar to mid-ocean ridge tholeiites[15]. The mineralogies of the two areas are, however, quite distinct —the ridge crestal metals are found as oxides and the Bauer Deep metals are found as silicates[7]—and the mode of formation is by no means settled.

The origin of these metalliferous sediments and, in general, iron–manganese deposits throughout the oceans is still an unsolved problem. Bonatti *et al.*[16] suggested four different mechanisms of origin. First, hydrogenous, that is, slow precipitation from seawater in oxidised environments. These deposits are found as microparticles dispersed in sediments, nodules and concretions on abyssal plains, and solid pavements on topographic highs. Second, hydrothermal, that is, precipitation from hydrothermal solutions in areas of volcanism and/or high heat flow. These deposits are found along active oceanic ridges and rifts and are associated with submarine volcanism. Third, halmyrolytic, that is, manganese supplied by submarine weathering of basaltic debris. Fourth, diagenetic, that is, precipitation resulting from diagenetic remobilisation of manganese in the sediment column.

There are at least three major hypotheses for the occurrence of metallogenesis in the Bauer Deep. Metals may be precipitated from hydrothermal solutions actively circulating there today[15]. Alternatively, they may be hydrogenous and may have nothing whatsoever to do with hydrothermal circulation in the basin. Excessively slow sedimentation rates could produce the large concentrations of metallic components; or some metals may be released into the water column at mid-ocean ridges by hydrothermal circulation and others may be hydrogenously deposited in the Bauer Deep[13]. Little geophysical evidence has so far been brought to bear on this problem.

We present a compilation of heat-flow measurements in the area and draw upon the anomalous nature of the thermal structure of this basin to propose that extensive emanation of hydrothermal fluids[15] can account for both the observed metalliferous sediments and the heat-flow distribution in the Bauer Deep. A qualitative model is presented, associating both with the emplacement of a new heat source into old oceanic crust during the jumping of the major north–south seafloor spreading centre in the eastern Pacific from the Galapagos Rise to the East Pacific Rise.

---

*Present address: Lamont-Doherty Geological Observatory of Columbia University, Palisades, New York 10964.

Physiography

The Bauer Deep is bounded on the west by the East Pacific Rise, on the north by the Galapagos Spreading Centre (both are active seafloor spreading mid-ocean ridges), on the east by the Galapagos Rise, a fossil spreading centre, and extends to the south to at least the Mendaña fracture zone at 16° S on the Nazca Plate (Fig. 1). The basin was formed by the westward jumping, about 6 Myr ago, of the spreading centre from the Galapagos Rise[17,18], 800 km to the west to form the East Pacific Rise in crust which was at least 10 Myr old at the time of the jump[17,19].

The Bauer Deep has a marked topographic step bordering the basin on the west, and a relatively smooth slope up to the Galapagos Rise on the east (Fig. 2). The elevation offset across this western step indicates an age discontinuity from crust which is about 6 Myr old, and which was generated at the crest of the East Pacific Rise to the crust of the Bauer Deep which is about 10–16 Myr old and which was generated at the Galapagos Rise.

The western boundary of the basin is also marked by extremely rough topography. These ridges are probably not primary topographic features emplaced at the spreading axis, but are either uplifted basement[8] or extrusive ridges emplaced at the time of the ridge jump. Basement at site 319 (Fig. 1) is extremely fresh compared with other drilled basalts recovered just below basal sediments of the same age (~ 15 Myr) and the composition of basalts is more alkaline than tholeiites from the ridge crest[8]. Therefore, the basement could be 'off-ridge extrusions' younger than the basal sediments[8].

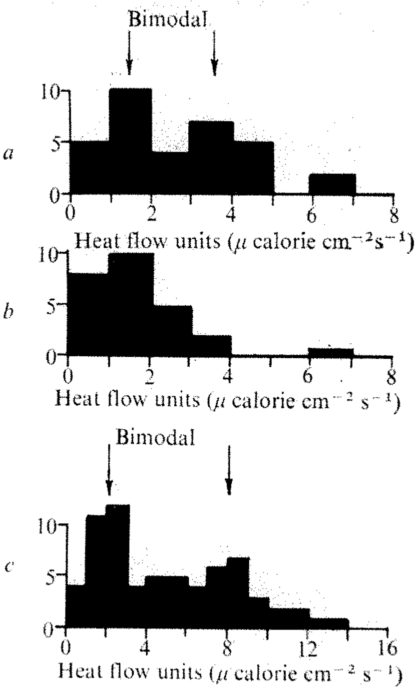

Fig. 3 Histogram of heat-flow values in *a*, the Bauer Deep—$n=33$—(crustal ages 10–16 Myr BP, from Fig. 2); b, the eastern Pacific—$n=26$—(ages 10–16 Myr BP, from Fig. 6 of ref. 20); *c*, the Galapagos Spreading Centre—$n=67$–(0–1 Myr BP, from ref. 10).

Heat flow distribution

Our heat-flow compilation is part of an extensive discussion of the heat-flow distribution on the Nazca Plate (R. N. Anderson *et al.*, unpublished). A heat flow against age plot for the eastern Pacific shows that the Bauer Deep is characterised by high, but variable heat flow (Fig. 2). The variability of heat flow commonly decreases as the average heat flux decreases with age away from mid-ocean ridges[20]. The mean and standard deviation of heat-flow values from the Bauer Deep are twice as large as values for oceanic crust of the same age in other ocean basins (see ref. 20). The observed mean heat flow departs significantly from the heat flux predicted by an empirical relationship between heat flow and age compiled for the entire eastern Pacific[20] in one area only—the Bauer Deep (Fig. 2). High heat flow and large scatter in values are evident around the crests of the East Pacific Rise and the Galapagos Rise, as well as in the Bauer Deep. This is a characteristic of mid-ocean ridge heat flow patterns in general (see ref. 10). For crust 10–16 Myr old (the age of the Bauer Deep) the empirical heat flow against age relationship[20] was determined from 26 heat flow measurements in areas of the eastern Pacific away from ridge jumps and fossil ridges. These 26 measurements do not show the bimodal heat flow pattern characterised by the Bauer Deep values (Fig. 3). Rather, they show a normal distribution about their mean, of 1.4 μcalorie cm^{-2} s^{-1} (~60 mW m^{-2}), (Fig. 3). A comparison of crust 10–16 Myr old, east and west of the Galapagos Rise (Fig. 2), again shows the anomalous nature of the thermal structure of the Bauer Deep. Such variability is characteristic of conductive heat flow measurements in areas dominated by convective heat transfer which is associated with hydrothermal circulation[10–12]. Heat flow values from the Bauer Deep (Fig. 3) show a distinct bimodal distribution characteristic of hydrothermal circulation areas such as the Galapagos Spreading Centre (Fig. 3). The heat-flow pattern at the crest of that mid-ocean ridge shows a 5 km wavelength oscillation of heat flow away from the ridge. Variations from 0.1 μcalorie cm^{-2} s^{-1} (4.1 mW m^{-2}) to >33 μcalorie cm^{-2} s^{-1} (>790 mW m^{-2}) were measured over a 4 km distance. This variability, the systematic oscillation, and observed water temperature anomalies which indicate hot spring activity led Williams *et al.*[10] to comment that there was conclusive evidence for widespread circulation of seawater into the oceanic crust on the Galapagos Spreading Centre.

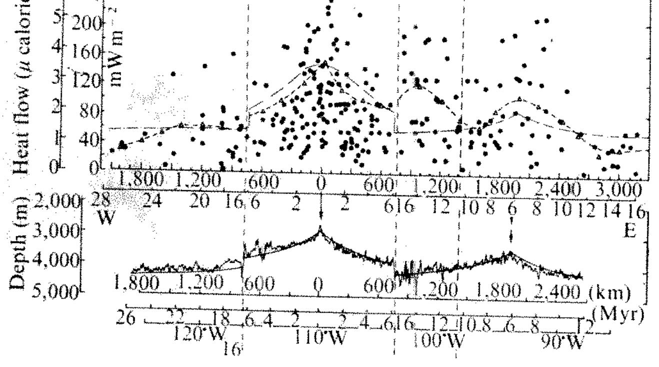

Fig. 2 Top, heat flow plotted against age for the south-eastern equatorial Pacific. Only those measurements shown in Fig. 1 are used for this compilation. Bottom, composite bathymetric profile (from Anderson and Sclater[18]) showing representative topographic features in the area. Solid circles, heat-flow values; open triangles, means for 400 km overlapping intervals; solid curves, empirical elevation against age (from ref. 25); — · —, empirical heat flow against age (from ref. 20); dashed line, averaged observed heat flow for the south-east Pacific.

In addition, thermal conductivity (K) measurements in the Bauer Deep made both on recovered cores[21] and *in situ*[22] produced some values 100% greater than those measured in 'typical' deep-ocean sediments. Values of 3.9 and 3.7 mcalorie cm^{-1} s^{-1} °C^{-1} (1.6 and 1.55 W mK^{-1})

were measured at 14°37.2′S, 104°33.2′W, and 14°53.3′S, 105°15.8′W (R. N. Anderson *et al.*, unpublished). The banding of layers of high conductivity was measured in cores from the Galapagos Rise (A. J. Halunen, jun., unpublished). Thus, the average heat flow in the Bauer depression (2.65 μcalorie cm^{-2} s^{-1} (~100 mW m^{-2}) for 33 measurements) may be biased low because most measurements have been determined by assuming conductivities from nearby locales rather than from measurement of sediments collected at the site. The existence of the newly discovered high conductivities in the metalliferous region implies to us that many assumed conductivity values may be as much as 25% too low.

Metallogenesis model

Spooner and Fyfe[24] have presented a model for subseafloor metamorphism which involves the circulation of seawater through oceanic crust at mid-ocean ridges, chemical exchange with basalt during hydration of the oceanic crust, and subsequent upwelling of hot, hydrothermal solution into the sediment column. They argue that inorganic precipitation from the hot brines can account for heavy metal enrichment found in ophiolitic cherts.

As already mentioned, Bauer Deep sediments have sulphur, uranium, oxygen, and strontium isotopic compositions and rare-earth element patterns consistent with formation from seawater[13-15], and lead isotopic compositions similar to those of mid-ocean ridge tholeiites[9]. The latter led Dasch *et al.*[15] to conclude that the iron-rich sediments from the Bauer Deep originate as precipitates from hydrothermal solutions injected into sea water. Bischoff and Sayles[25] point out, however, that the *p*H and major ion concentrations of the pore fluids from the core examined by Dasch *et al.*[15] do not differ significantly from the ion concentrations in the overlying bottom water. Sayles and Bischoff[7] therefore concluded that "at this point, it is not possible to evaluate the role of 'volcanic emanations' in supplying the major components of Bauer Deep sediments". We wish to add the previously unrecognised geophysical constraint of anomalously high and variable heat flow to the accumulating body of data, mostly geochemical, which will ultimately lead to the determination of the mode of origin of metalliferous sediments in the Bauer Deep.

A model can be suggested which can account for both the anomalous thermal structure and the metalliferous deposition in the Bauer Deep. The important distinction to be made is that hydrogenous precipitation of heavy metals cannot cause the anomalous heat-flow distribution in the Bauer Deep. Areas of high heat flow could be caused by hot hydrothermal fluids moving from the basaltic crust into the sedimentary column. The uniformly thin sediment cover in the basin means that such heat would be conducted to the surface in a relatively short time (<100,000 yr), (R. N. Anderson *et al.*, unpublished). Low heat flow would follow this initial period of high flux since significant heat would have been removed from the oceanic crust[12]. Therefore, hydrothermal circulation can account for the bimodality of observed measurements in the Bauer Deep.

The Bauer Deep is the only area of extensive metalliferous sediments so far discovered away from a mid-ocean ridge crest. It is also characterised by extremely rough topography associated with an age boundary or step marking a jump in spreading centres from the Galapagos Rise to the East Pacific Rise. The mechanics of this jump required the emplacement, 6 Myr ago of new, hot material from the ridge crest into crust at least 10 Myr old (ref. 18) at that time. The introduction of this new heat source into the area may have initiated hydrothermal circulation which had been dormant since the previous thermal event contiguous with the seafloor spreading process. Dehydration reactions driven by the reheating may have released H_2O for advection to the sediment interface and opened previously clogged cracks to allow further circulation[12]. Otherwise, the association between metalliferous sediments adjacent to a major ridge jump and the bimodal distribution of heat flow in the area must be related to different mechanisms and must be coincidental. The association of both on ridge crests seems, however, to argue against coincidence.

Additionally, JOIDES holes 320 and 321 show evidence for a cessation of hydrothermal precipitation approximately 10 Myr BP. Hart *et al.*[8] concluded that this may be related to the westward jumping of the ridge. They imply that precipitation may be generally related to proximity to the spreading process heat source.

Heat flow may prove to be an adequate exploration tool for the discovery of further metalliferous sediments on the sea floor. The process of ridge jumping is not unique to the Bauer Deep. That also occurred between 25°S and 35°S on the Nazca Plate, for example. This is perhaps an ideal place to prospect for heavy metals.

The IDOE Nazca Plate Project provided important geochemical information on composition and distribution of metalliferous sediments on the Nazca Plate. This work was funded by the National Science Foundation and the Office of Naval Research. J. Greenslate, J. Natland, R. Moberley and V. Vacquier reviewed the manuscript.

Manipulation of restriction targets in phage λ to form receptor chromosomes for DNA fragments

Noreen E. Murray & Kenneth Murray

MRC Molecular Genetics Unit and Deptartment of Molecular Biology, University of Edinburgh, King's Buildings, Mayfield Road, Edinburgh EH9 3JR, UK

*Fragments of DNA from derivatives of phage λ having either one or two targets for R.*Eco*RI have been joined in new combinations to give biologically active phage genomes. These include two classes of deletion mutants; in one, only the DNA between the targets is deleted, but in the second the deletions are more extensive. Other fragments of DNA have been inserted into these phage chromosomes.*

RECENT advances in the biochemistry of DNA offer means of creating combinations of genetic material that cannot be achieved by genetic recombination. Biologically active DNA molecules have been reconstituted from separated, sheared halves of bacteriophage λ DNA by the successive action of λ exonuclease and polynucleotide ligase[1] and a derivative of λ DNA has been fused to an animal virus genome[2]. The highly specific restriction endonucleases[3-5] have become powerful new tools for the fragmentation of DNA molecules and the study of the organisation of these fragments within viral genomes[6,7]. Of special interest in the present context are the enzymes that make breaks a few base pairs apart in opposite strands of duplex DNA to produce fragments with short, complementary, single-stranded projections or cohesive ends[8-11]. Such DNA fragments can be joined by annealing the cohesive ends and closing the single-strand breaks with polynucleotide ligase[12].

The first restriction enzyme of this type to be described was isolated from a strain of *Escherichia coli* carrying the RI drug-resistance factor[9]. Some small, circular DNA molecules have only one target[12,13] for the RI restriction endonuclease, R.*Eco*RI[14], making them suitable receptors for R.*Eco*RI fragments of DNA from other sources. Insertion of a fragment of DNA into the single R.*Eco*RI site of plasmid pSC101 destroyed neither the tetracycline-resistance phenotype nor the ability of the plasmid to replicate, so that the recombinant DNA molecules were able to transform *E. coli*[13]. This type of experiment has important potential for cloning, and hence studying, DNA from other sources. Bacteriophage λ, with its extensively studied genetics and biochemistry could be a particularly useful alternative vehicle for applications of this sort. The DNA of phage λ, however, has five targets for R.*Eco*RI[15], so our first problem was to construct derivatives of λ whose chromosomes have only one target for this enzyme. We have made a series of such phages and shown that their DNA can be broken with R.*Eco*RI to give fragments which we have joined in new combinations, thus introducing specific deletions. We have also shown that fragments of DNA produced by the action of R.*Eco*RI can be inserted between two fragments of λ DNA having respectively the right and left ends of the phage DNA. These recombinant DNA molecules were isolated as plaques following transfection of *E. coli*.

Construction of phage with single targets for R.*Eco*RI

Treatment of phage λ DNA with R.*Eco*RI gives six fragments of DNA separable by electrophoresis in polyacrylamide or agarose gels[15]. These fragments result from breakage of the DNA within the five restriction targets whose positions on the physical map of the λ chromosome have been deduced (Fig. 1)[15] (R. W. Davies, personal communication). We noted that two of these targets, designated *srl*1 and *srl*2 according to the con-

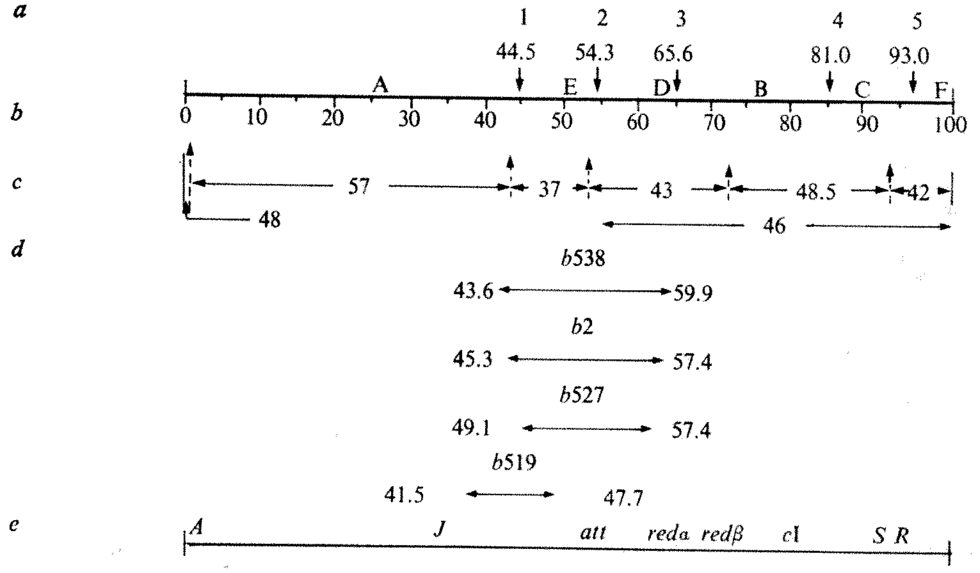

Fig. 1 Some characteristics of the λ chromosome. *a*, Positions of the targets, *srl*1–5, recognised by endonuclease R.*Eco*RI (R. W. Davies, personal communication) and location of the DNA fragments (A-F) (identified in Fig. 2) resulting from breakage of λ DNA by this enzyme. *b*, Unit length (%). *c*, The G+C content (%) of DNA fragments obtained by shearing[22]. The composition of DNA to the right of *srl*2 was calculated from that of the sheared fragments. *d*, Location of deletions[37]. *e*, Positions of some genetic markers on the physical map.[37] *A*, *J*, *red*α, *red*β, *c*I, *S* and *R* are genes; *att* is the attachment region within which recombination takes place to integrate λ into the *E. coli* chromosome.

Fig. 2 Electrophoretic separation of R.*Eco*RI fragments of DNA from λ^+ and various derivatives. The location on the chromosome of targets for the enzyme, of the DNA fragments, and of deletions is shown in Fig. 1. The faint band visible behind the largest fragment results from adhesion of fragments by means of the natural cohesive ends of λ DNA. Superscript *a* denotes phage with hybrid targets generated by recombination *in vitro*. Although the two fragments of DNA from phages VII, VIII, and XII were not readily resolved by gel electrophoresis under the conditions used here, they have been clearly separated by equilibrium centrifugation in Cs_2SO_4–$HgCl_2$ solutions. Phage were prepared from lysates (about 2l, titre usually 5.10^{10} p.f.u. ml^{-1}) made by infection of *E. coli* C600 in liquid culture. After two cycles of differential centrifugation (before and after treatment with RNase and DNase at 10 μg ml^{-1}) the phage were resuspended in phage buffer (KH_2PO_4, 0.3% w/v; Na_2HPO_4, 0.7% w/v; NaCl, 0.5% w/v; $MgSO_4$, 1 mM; $CaCl_2$, 0.1 mM; gelatin 0.001% w/v), CsCl was added to 41.5% w/w and the solutions centrifuged to equilibrium. The phage band was removed with a Pasteur pipette, diluted with more CsCl in phage buffer, again centrifuged to equilibrium, and the band of phage collected after puncturing the bottom of the tube. Phage were stored in CsCl solution and DNA prepared as required by extraction of a diluted, dialysed solution with freshly distilled phenol (three extractions) followed by extensive dialysis against 0.01 M Tris-HCl (*p*H 8.0) 1 mM EDTA. DNA (0.3 to 1.0 μg depending upon the number and size of fragments generated) was incubated with R.*Eco*RI, prepared essentially as described by Yoshimori[38], in 20 μl. 0.01 M Tris-HCl (*p*H 7.5) 0.01 M 2-mercaptoethanol, 0.01 M $MgCl_2$ at 37° C for 30 min and the reaction stopped by addition of excess EDTA. The necessary quantity of enzyme (about 0.1 μl) was determined by titration against varying quantities of DNA and analysis by gel electrophoresis. The digests were heated in sealed capillaries at 70° C for 10 min, cooled rapidly at 0° C, mixed with 0.1% bromophenol blue in 50% w/v glycerol (2 μl) and applied to wells in 1% w/v agarose gels[40] (approx. 40 cm × 20 cm × 0.3 cm) containing 0.4 μg ml^{-1} ethidium bromide [41] and after electrophoresis for about 16 h at a constant current of 40 mA the gels were photographed under ultraviolet light on Ilford FP4 film with a 4× red filter. For the *in vitro* recombination experiments, reaction mixtures of about 0.2 to 0.5 ml containing total DNA fragments, 10–30 μg ml^{-1}; Tris-HCl (*p*H 7.5) 66 mM; EDTA, 1 mM; $MgCl_2$, 10 mM; NaCl, 40–80 mM; dithiothreitol, 10 mM; ATP, 0.1 mM; bovine serum albumin, 0.1 mg ml^{-1}; T4 polynucleotide ligase (Miles Laboratories, Ltd), 0.5 u ml^{-1}; were incubated at 10° C for 45 min and then kept on ice for 2–10 d before sampling for transfectants.

vention of Arber and Linn[16], are within that part of the central, inessential region of the phage genome which is deleted in strain *b*538[17] (see Fig. 1). Should the magnitude of restriction *in vivo*, as defined by the restriction ratio (that is the titre of non-modified phage assayed on the propagating host, divided by the titre on the restricting host), decrease as the number of restriction targets decreases[18,19] then the deletion strain *b*538 should be restricted less efficiently than λ wild-type. Furthermore, phages with even fewer restriction targets should have a selective advantage on transfer from a non-modifying host to a restricting host.

Loss of the two restriction targets in the deletion strain, b538, is indeed accompanied by a fall in the restriction ratio from 5,000 to approximately 400, concomitant with which is the predicted change in the pattern of DNA fragments observed on restriction of the DNA *in vitro* (Fig. 2). Fragments A, E and D of the wild-type strain (phage I) were replaced by a single large fragment, while fragments B, C and F were retained in the *b*538 deletion strain (phage II). We attempted, therefore, to select for mutations resulting in the loss of the remaining restriction targets. Lysates of the deletion phage (phage II in Fig. 2) were made alternately on *E. coli* strain K and on a K strain harbouring the RI plasmid[20]. After seven such double cycles the restriction ratio had dropped from around 400 to 80 and after a total of eleven cycles the phage lysate comprised mainly restriction-resistant phages. Phages with restriction ratios of 80 (phage III) and 10 (phage IV) were isolated during the course of this enrichment and purified. Gel electrophoretic analyses of R.*Eco*RI digests of their DNAs (Fig. 2) showed that phage III differed from phage II in that fragments C and F had been replaced by a larger fragment (G): we conclude that this phage had lost the right-most restriction target (*srI*5). DNA from the phage with a restriction ratio of 10 (phage IV) gave two large fragments: since fragments G and B were replaced by fragment H (Fig. 2) this phage must have retained only *srI*3 rather than *srI*4. The DNA of the restriction-resistant phage (phage V) migrates as a single band in a position indistinguishable from that of whole λ DNA molecules. From a cross (Table 1, cross 1) of the restriction-resistant phage (phage V), to a suitably marked strain of phage λ having a full complement of restriction targets, phages having only the two left-most restriction targets were isolated. These phages have a low restriction ratio (~ 30), and the DNA fragments resulting from *in vitro* restriction (phage VI, Figs 2 and 3ii) included fragment E, as expected if phage VI had acquired *srI*1 and *srI*2. Attempts to isolate spontaneous mutants lacking either *srI*1 or *srI*2 were unsuccessful because the selection favours deletions that remove both restriction targets. Phages having only *srI*1 (phage VII) or only *srI*2 (phage VIII) were therefore isolated as recombinants from crosses of phage VI (see Table 1) to the appropriately marked deletion strains *b*527 and *b*519. The agarose gel does not readily separate the two large fragments expected when the DNA of either phage VII or phage VIII is restricted (Fig. 2) but these fragments were readily separated on caesium sulphate–mercuric chloride density gradients (data not shown). Phages having only *srI*4 (phage IX) or only *srI*5 (phage X) were isolated from a cross (Table 1, cross 4) by virtue of the close linkage of *srI*4 to *cI* and of *srI*5 to gene *S*. The restricted DNA from phage IX shows two fragments including that (G) expected as the sum of fragments F and C, while the restricted DNA from phage X again shows two fragments, the smaller of which is fragment F (Fig. 2).

Separation and joining of DNA fragments

Fragments of DNA can be separated by gel electrophoresis but this method is inadequate for the preparative resolution of the larger fragments (Fig. 2). Instead, we turned to equilibrium centrifugation in caesium sulphate solutions containing mercuric chloride[21] for this gave good separation of sheared fragments of λ DNA, enabling them to be placed in order on the λ chromosome[22]. These results (Fig. 1) show that the three fragments arising from breakage of phage VI DNA with R.*Eco*RI would have quite different densities, as would the corresponding two fragments of phage IV DNA. Fragments of DNA from these phages were separated as predicted (Fig. 3i and ii) and recovered quantitatively.

No. 1: *srI*1$^+$*srI*2$^+$ (that is *b*538$^+$) *c*Iam *P*$^+$ recombinants were selected as phages of normal buoyant density giving clear plaques at 32° C on a suppressor-free (*sup*°) host; those with R†~30 were shown to have only targets *srI*1 and *srI*2 (Phage VI, Fig. 2). No. 2: *b*527 *red*$^+$ cIam *R*$^+$ recombinants were selected on a *sup*° *polA* host[29] on a medium supplemented with sodium pyrophosphate (3 mM)[17]; most recombinants have R~10 and have only *srI*1 (Phage VII, Fig. 2). No. 3: *b*519 *red*$^+$ cIam *R*$^+$ recombinants were selected on a *sup*° *polA* host[29] on a medium supplemented with sodium pyrophosphate (3 mM)[17]; most recombinants have R~4, and have only *srI*2 (Phage VIII, Fig. 2). No. 4*a*; *h*λ *b*538 *c*1857 *S*$^+$ recombinants were selected as clear plaques at 39° C on a host resistant to phi80 and carrying *sup*II, which suppresses *c*Iam but not *S*am7[32]. A recombinant having R~10 was shown to have only *srI*4 (Phage IX, Fig. 2). No. 4*b*: *h*λ *b*538 *c*Iam phages were isolated as turbid plaques at 42° C (high temperature selects against phi80 host range) on a *sup*III host after enriching for those phages (*S*am7) unable to lyse a *sup*III° host. (The unlysed cells were concentrated and the phage released by chloroform.) An *S*am7 recombinant having R~10 has only *srI*5 (Phage X, Fig. 2).

*Abbreviations used: *c*Iam=*c*Iam509; *c*Its=*c*I857, *P*am=*P*am80; *R*am=*R*am5; *S*am=*S*am7; *red*=red3; 1$^+$=*srI*1; 2$^+$=*srI*1 etc. and 1°, 2° and so on refer to mutations conferring resistance to restriction.

†R=Restriction ratio=$\frac{\text{Titre on K strain}}{\text{Titre on K/RI strain}}$

The media, methods of making and assaying phage stocks and crosses were as described previously[19,31]. The standard *rec*$^+$ host for phage crosses was QR47[33].

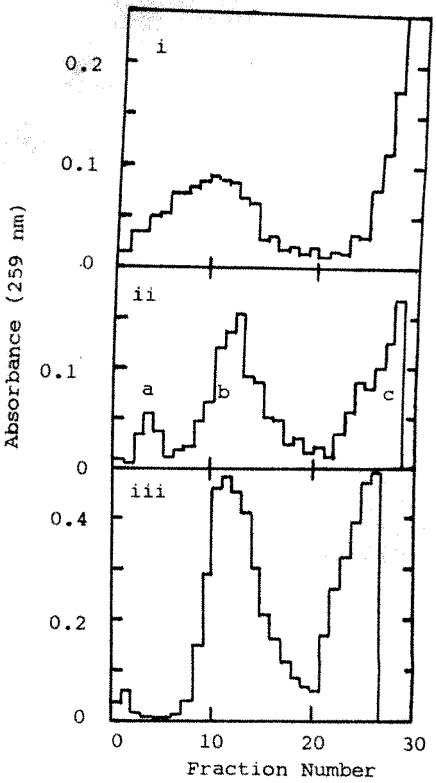

Fig. 3 Separation of DNA fragments in R.*Eco*RI digests by equilibrium centrifugation in Cs_2SO_4–$HgCl_2$ gradients. Density increases from right to left. (i) Phage IV, (ii) Phage VI, (iii) Phage XII. Solutions of DNA (100 μg in 1.0 ml 0.01 M Tris-HCl (*p*H 7.5) 0.01 M 2-mercaptoethanol, 0.01 M $MgCl_2$) were digested with R.*Eco*RI (10 μl concentrated DEAE-cellulose fraction; 37° C, 1 h), extracted with an equal volume of freshly distilled phenol and dialysed twice against 0.3 M Na_2SO_4 in 5 mM sodium borate (*p*H 9.0) and then twice against 5 mM borate (*p*H 9.0). The solutions were then heated at 65° C for 10 min, cooled in ice, weighed and their DNA concentration was determined spectrophotometrically. Mercuric chloride solution (1 mM) was then added to give an r_f of 0.22 (refs 21 and 22) and the solutions were diluted to 2.0 g with the borate buffer and Cs_2SO_4 added to 42.0% w/w. The solutions were transferred to 10 ml polypropylene centrifuge tubes, overlaid with liquid paraffin and centrifuged at 20° C at 30,000 r.p.m. for 60 h in an MSE SS65-II centrifuge, 8 × 40 Ti rotor with adaptors. Fractions of 4 drops were collected, diluted with 0.2 ml H_2O and analysed spectrophotometrically.

Our first experiments on the joining of R.*Eco*R*I* fragments of λ DNA involved the construction of phage chromosomes with specific deletions so that the phage head would be able to accommodate additional DNA. We therefore confined our attention to phages with the targets *srI*1, *srI*2 and *srI*3 because removal of the DNA between either *srI*1 and *srI*2 or between *srI*1 and *srI*3 would affect only the inessential region of the λ chromosome. Receptor chromosomes were constructed from (*a*) the left and right fragments of phage VI DNA, and (*b*) the left fragment of phage VI DNA and the right fragment of phage IV DNA. In (*a*) the mixture of fragments in an R.*Eco*RI digest of phage VI DNA was used but in (*b*) the isolated fragments of each DNA were used. The mixtures of fragments were stored in the cold for 2 d under conditions favouring the annealing of the cohesive ends of R.*Eco*RI breaks[12] and incubated with phage T$_4$ polynucleotide ligase[23]. After storage at 0° C for 2–10 d, samples were taken from the reaction mixtures for transfection of *E. coli* (ref. 24 and A. E. Jacob and S. J. Hobbs, personal cummunication) and the phages from the resulting plaques were isolated and investigated.

In a second series of experiments R.*Eco*RI fragments of DNA were inserted into the genomes of our receptor phages and into that of phage IV, which possesses only *srI3* and carries the *b*538 deletion. The central fragment of phage VI DNA, isolated from a caesium sulphate gradient (Fig. 3ii), and a DNA fragment carrying part of the *trp* operon of *E. coli*, isolated by agarose gel electrophoresis of an R *Eco*RI digest of DNA (with a ^{32}P marker) from a λ*trp* phage (λ*trp*13, which had incorporated the bacterial *trpD* and *E* genes without deleting *srI3*)[20], were used.

Annealing of DNA fragments with cohesive ends would be expected to yield a range of products, each convertible into single DNA molecules, linear or circular, by polynucleotide ligase. SV40 DNA, for example, contains one target for R *Eco*RI and gave monomeric and concatenated linear and circular molecules in these reations[12]. With λ DNA the situation is more complex because reactions will occur between the natural cohesive ends of the molecule[25] as well as the cohesive ends generated by R *Eco*RI. The length and composition of the natural cohesive ends[26] relative to those created by R *Eco*RI[9] is such that the former would cohere preferentially. The reaction products used for transfection will, therefore, comprise a complex population of DNA molecules, though many of these would not yield viable phage, either because they are too large to be packaged or because they lack essential parts of the λ genome[27]. In the experiments described here the yield of transfectants from the products of ligase reactions varied from 20 to 120 phage per μg DNA in the transfection mixture, compared with about 10^3 to 10^4 phage per μg from the corresponding DNA before restriction. (In subsequent experiments yields of transfectants from ligase reactions have been increased to about 5,000 per μg DNA and about 5 × 10^4 per μg from unrestricted DNA.) Omission of ligase reduced yields of transfectants from restricted DNA to about 1%, some of which appeared to result from joining of fragments *in vivo*.

Characteristics of the *in vitro* recombinants

(*a*) Receptor genomes. The three fragments from phage VI DNA could be joined to reconstitute parental phages or the two large fragments could be joined to give a phage lacking the DNA normally present between the two restriction targets (that is, ▽ *srI1-2*). Only one of twenty progeny made from the fragments of phage VI had the full complement of DNA, and could have resulted from the joining of all three fragments. The remaining 19 isolates showed an increased resistance to chelating agents[17], as expected for phages with deletions. Eighteen of these nineteen phages had a restriction ratio characteristic of phage with a single restriction target. The remaining phage was restriction-resistant and could have resulted from joining of fragments by means other than the short cohesive ends generated by R *Eco*RI. The deletion within this phage must extend through *srI1* and *srI2* and yet this and the other phages were able to integrate into the *E. coli* chromosome to give stable lysogens as shown by their ability to form stable, immune colonies[28]. (The alternative explanation that we have selected a deletion phage present in the original phage preparation seemed unlikely since the lysate had been purified by two cycles of equilibrium centrifugation in CsCl solution, furthermore most deletion mutants of phage λ are integration defective[17].) The conclusion that the essential features of the attachment region are right of *srI2*, is strengthened by the fact that the new deletion phages (▽ *srI1-2*) showed normal site-specific recombination in phage crosses (Table 2). Gel analyses of the restricted DNA of one of these ▽ *srI1-2* phages (phage XII) confirmed that fragment E was missing: the two large fragments present were separable in a caesium sulphate–mercuric chloride gradient (Fig. 3iii). The buoyant density of phage XII indicates a deletion equivalent to 9.7% of the λ chromosome.

Phage formed by joining the left-hand fragment of phage VI and the right-hand fragment of phage IV lack the DNA normally present between targets *srI1* and *srI3* (that is ▽ *srI1-3*). The five phages isolated from such an experiment all had a low restriction ratio (~ 7), showed an increased resistance to chelating agents, failed to integrate into the *E. coli* chromosome and failed to form plaques on a *polA* host. The latter property[29] is characteristic of all recombination-deficient (*red*$^-$) strains of phage λ and is consistent with the deletion of at least part of the *red* genes. Crosses of the new deletion phages to appropriately marked *red*$^-$ strains of phage λ (Table 3, line 4) confirm that ▽ *srI1-3* phages are defective in the *red*α gene but not in the *red*β gene (see Fig. 1). These data provide genetic evidence that *srI3* is either within the *red*α gene or between *red*α and *red*β. Gel electrophoreses of the restricted DNA of one of the ▽ *srI1-3* phages (phage XI) confirm the presence of the two predicted DNA fragments and the buoyant density of phage XI indicates a deletion of 20.7% of the λ chromosome.

(*b*) Phages made from three fragments. The purified fragment E from phage VI was annealed with the restricted DNA from phage IV, which has only target *srI3*, and the mixture treated with ligase. Since phage IV has the *b*538 deletion (see Fig. 1), it lacks the DNA of fragment E and, if *srI3* is within the *red*α gene, the insertion of DNA at this site will produce a *red*$^-$ phage. We isolated 78 transfectants from the reaction mixture and detected six defined as *red*$^-$ by their failure to form plaques on a *polA* host[29]. All six *red*$^-$ phages were characterised as

Table 2 Site specific recombination in phage crosses

Cross*					Frequency of site specific recombination (Twice the frequency of turbid (c^+) J^+R^+ recombinants)
*J*am6	*att*$^+$	*red*3	c^+	+	1.33%
+	*att*$^+$	*red*3	*c*I857	*R*am5	
*J*am6	*att*$^+$	*red*3	c^+	+	0.024%
+	*b*538 (*att*▽)	*red*3	*c*I857	*R*am5	
*J*am6	*att*$^+$	*red*3	c^+	+	1.46%, 1.37%, 1.44%**
+	*srI1–2*	*red*3	*c*I857	*R*am5	

* These crosses of *red*$^-$ phages were made in a *recA* host (QR48)[33].

** Three different ▽ *srI1–2* recombinants were used, one of which was restriction resistant and another was a recombinant made from purified fragments.

Table 3 The *red* functions of *in vitro* recombinants

Test phage	Recombination frequency (%) between immunity and gene R expressed as twice the frequency of $i^{4*}R^{+}$ recombinants	
	(*a*) Cross to *red*α i^{4}*R*am5	(*b*) Cross to *red*β i^{4}*R*am5

* The abbreviation i^{4} is used for the immunity of phage 434
† 2 different *srI*1–3 deletion phages
‡ The six *red* phages resulting from insertion of DNA at *srI*3
The Red phenotypes of the phages were deduced from the frequencies of $i^{4}R^{+}$ recombinants generated in crosses to a *red*α phage (λ *bio*69 i^{4}*R*am5) and to a *red*β phage (λ *red*β113 i^{4}*R*am5)[39] All crosses were made in the *recA* host, QR48[33], and the recombinants selected on a sup^{0} (λ i^{λ}*R*am5) strain of *E coli*

*red*α⁻*red*β⁺ (Table 3, line 5) Five of these six resembled the original phage IV in having a restriction ratio of around 10, as expected for a phage with only *one* restriction target the remaining *red*⁻ phage (Phage XIII) had a restriction ratio of 80, suggesting two restriction targets This phage meets the predictions for a recombinant in which the whole of fragment E had been inserted at *srI*3 Gel electrophoresis of the restriction products of the DNA from phage XIII (Fig 4) shows two large DNA fragments like those of phage IV and a third fragment of the same size as fragment E

One of the other five phages was investigated further This phage (Phage XIV) had a buoyant density less than that of the receptor phage (Phage IV) and analysis by gel electrophoresis of the restricted DNA from this phage showed one fragment moving in the same position as the smaller fragment of the receptor DNA and a slower fragment moving slightly faster than the larger fragment of the receptor genome The formation of this and the other *red*⁻ phages with only one restriction target can be explained if fragment E joined to one end of the receptor chromosome via its cohesive end and then at the other end via an illegitimate recombination event[30] In the case of phage XIV the illegitimate recombination event was associated with the deletion of more than 10% of the phage DNA This explanation for the origin of those *red*⁻ phages having a single restriction target is supported by a control experiment in which fragment E was not added to the receptor DNA and here the ten *red*⁻ phages isolated were all restriction resistant

A fragment of DNA containing the *trpD* and *E* genes of the *trp* operon of *E coli* together with their operator and promoter was isolated and purified from an $h^{80}i^{\lambda}$*cI trp*-transducing phage (λ*trpI*3)[20] This fragment was fused to the restriction products of the receptor phage ▽ *srI*1-2 (Phage XII) and among 120 transfectants we detected[31] one $h^{\lambda}i^{\lambda}$ *clam* phage having the *trpD* and *E* genes This λ*trp* phage expresses the *trp* genes from the *trp* promoter and from a λ promoter (N E M and W J Brammar, unpublished observation) Like four of the five recombinant *red*⁻ phages described above, this phage has a low restriction ratio ($R \sim 10$) and has not incorporated the whole of the DNA fragment In fact, the phage has become integration defective consistent with loss of DNA to the right of *srI*2 The buoyant density of the new λ*trp* phage indicated that it has about 3% more DNA than λ wild type Had the whole fragment been incorporated into the receptor genome then a phage with at least 10% more DNA than λ wild type would be expected At least two other phages had acquired extra DNA but did not contain the *trp* genes

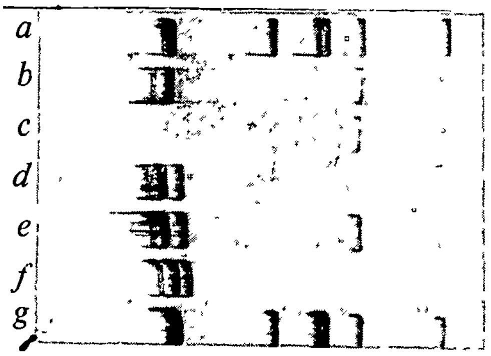

Fig 4 Agarose gel electrophoresis of R *Eco*RI digests of DNA used in and obtained from recombination experiments *in vitro* Experimental details were the same as described in the legend to Fig 2 (*a*) Phage I, (*b*) Phage VI, (*c*) Fragment E purified from phage VI (peak a from Fig 3*b*), (*d*) Phage IV, (*e*) Phage XIII, (*f*) Phage XIV (Phages XIII and XIV are the recombinant phages), (*g*) Phage I The faint, slowest-moving band visible in (*b*), (*d*), (*e*) and (*f*) results from adhesion of the large fragments of DNA via their normal cohesive ends

Practical implications

Our results show that the phage λ genome can be used as a receptor for genetic material that cannot be incorporated by conventional genetic techniques The biochemical approach used provides a convenient means of cloning DNA, but more importantly it lends the extensive genetic and biochemical experience acquired with phage λ[34] to the study of the additional genetic material This DNA can be inserted into the phage chromosome so that its expression is controlled autonomously, or by the phage regulatory systems[12], when advantage can be taken of the efficient λ promoter, P_L, and *N*-gene protein which allows RNA polymerase to read through transcriptional stops[43] By appropriate choice of the phage genotype the yields of gene products can be greatly enhanced[35], experiments with λ*trp* phages, for example, have shown that the five enzymes of the *trp* operon can be boosted to comprise as much as 50% of the soluble protein of the host cell (A Moir and W J Brammar, personal communication) The insertion of appropriate DNA fragments into marked receptor phages offers new approaches for extending the biochemical genetics of eukaryotic systems We have shown that eukaryotic DNA can be inserted into the λ receptor phages (unpublished results) It has been established that eukaryotic DNA can be transcribed within the *E coli* cell[36], but it is not known whether a eukaryotic messenger RNA is translated

We expected that transfectant phages would result from covalently linked fragments of DNA as either linear or circular chromosomes[24] because a linear molecule could circularise by joining of free cohesive ends after its entry into the bacterial cell Our results suggest that the bacterial cell may provide an alternative way of joining two non-homologous regions of DNA and in so doing generate deletions Further experiments have proved that deletion phages are indeed created rather than merely selected (N E M and K M , unpublished observations) and they confirm the use of this method for the production of localised deletions Illegitimate recombination events were first suspected because restriction targets were lost, those deletions generated in the region of *srI*2 have been characterised further as integration proficient, integration defective, or integration and recombination defective (K Borck and N E M , unpublished observation) Lai and Nathans[41] have detected an analogous class of deletion mutants following the *in vivo* association of restriction fragments of SV40 DNA and have made elegant use of these deletions to further the genetic analysis of the SV40 virus

Insertion of DNA fragments into a receptor chromosome *via* illegitimate recombination destroys the RI restriction target, and can therefore be a disadvantage if one is concerned with the recovery of a cloned DNA fragment It does provide, however, a means of incorporating part of the DNA from a fragment that is too large to be accommodated within the phage genome Removal of the DNA between *srI*1 and *srI*3 in the presence of a deletion between genes *P* and *Q* (*nin*R5)[45] eliminates 27% of the λ DNA Since phage λ can accommodate about 10% more than its normal complement of DNA these deletions permit the insertion of DNA equivalent to about 15 genes Although we have not used them in these experiments, powerful methods are available for selecting only those phages that have gained DNA

We thank Sandra Fleming and Janet Brown for assistance and Dr W J Brammar for his constructive interest The work was supported in part by the Science Research Council

Glutamine synthetase and ammonium regulation of nitrogenase synthesis in *Klebsiella*

Roy S. Tubb

ARC Unit of Nitrogen Fixation, University of Sussex, Brighton BN1 9QJ, Sussex, UK

Glutamine synthetase seems to act as a positive control element for nitrogenase synthesis in a way similar to that already proposed for histidase synthesis in Klebsiella *Studies along lines opened up by these findings may provide answers to many of the problems in establishing nitrogen fixation in non-leguminous plants*

IN both fungi and bacteria, synthesis of enzymes involved in the utilisation of nitrogen sources such as amino acids, purines, nitrate and nitrite, is normally repressed when sufficient ammonium nitrogen for growth is provided in the culture medium Arst and Cove suggested that ammonium repression of all such enzymes in *Aspergillus nidulans* was effected by a single mechanism the *areA* gene product, as yet unidentified biochemically, seems to be essential for enzyme synthesis but is absent, or cannot function, in the presence of NH_4^+ Prival, Brenchley and Magasanik[2,3] have studied utilisation of histidine and regulation of histidase and other enzymes of the *hut* operons in *Klebsiella aerogenes* Histidine can serve as nitrogen source or carbon source, histidase is subject to both ammonium repression and glucose (carbon–catabolite) repression and the relief of either derepresses histidase synthesis (see ref 2) Derepression of histidase synthesis under limiting nitrogen is independent of cyclic AMP but requires high levels of glutamine synthetase, mutants lacking glutamine synthetase fail to derepress synthesis of histidase under these conditions[3] Moreover, in mutants which are constitutive for glutamine synthetase, histidase and proline oxidase (the first enzyme of proline catabolism) escape from ammonium repression[3] Purified unadenylylated glutamine synthetase, but not the fully adenylylated enzyme, activates correct transcription of *hut* DNA *in vitro*, glutamine synthetase is as effective in this respect as cyclic AMP plus catabolite activating protein (CAP) and has been proposed therefore as a positive control

Table 1 Growth of *K pneumoniae* M5a1 and mutant RT4 on various compounds as sole N source

	Nitrogen-source	M5a1	RT4

	Adenine	++++	−
	Hypoxanthine	+++	−
	Xanthine	++	−
b	N_2	+++	−
c	Casein hydrolysate	+++	+++

Nutrient broth cultures of M5a1 and RT4 were centrifuged, washed, resuspended in saline-phosphate and plated out on minimal medium containing, g l^{-1}, 20 glucose, 3 40 KH_2PO_4, 12 06 K_2HPO_4, 0 025 $Na_2MoO_4\,2H_2O$, 0 025 $FeSO_4$, 0 1 $MgSO_4$, supplemented where indicated with 1 g of nitrogen source *a*, Growth was estimated visually after 48 h at 30° C in air on a scale ranging from − (no growth) to +++++ (very good growth) *b*, Growth was estimated similarly after 5 d incubation at 30° C in an anaerobic bag[12] with a throughput of N_2/CO_2 (99 1) No nitrogen source was included in the medium *c*, Growth estimated from overnight liquid cultures grown under argon

element for transcription of *hut* DNA[4]

Nitrogenase synthesis in *Klebsiella pneumoniae* is repressed by NH_4^+ (ref 5), there is no evidence for glucose repression and this is reasonable since N_2, unlike histidine, can serve only as a nitrogen source Here I report (i) the characterisation of a mutant of *K pneumoniae* which was altered in its regulation of glutamine synthetase, had lost the ability to grow on a large number of compounds as sole nitrogen source and failed to synthesise both nitrogenase components, (ii) the transfer of nitrogen fixation (*nif*) genes to glutamine synthetase-constitutive mutants of *K aerogenes* resulting in constitutive expression of *nif* These results strongly implicate glutamine synthetase as being involved in ammonium regulation of nitrogenase synthesis

Pleiotropic mutation which blocks nitrogenase synthesis

Mutant strain RT4 was obtained by mutagenesis of *K pneumoniae* M5a1 with IPMS (isopropylmethane sulphonate)[6] followed by selection with ampicillin and D-cycloserine for glutamine auxotrophs RT4 grew well on glutamine-supplemented minimal medium, grew well, but with a longer lag, on unsupplemented minimal medium (with $(NH_4)_2SO_4$ as sole nitrogen source) and failed to grow on NH_4^+-free medium (NFM) with histidine, nitrate or N_2 as sole nitrogen source The mutation was, in fact, extremely pleiotropic resulting in loss of the ability to utilise many nitrogen sources (Table 1) and was superficially very similar to the *asm*⁻ mutation described by Nagatani, Shimizu and Valentine[7], such *asm*⁻ mutants produce low levels of glutamate synthase[7 10] (glutamine-amide-2-oxoglutarate amino transferase) This enzyme is responsible for the second step in the glutamine synthetase–glutamate synthase pathway, the primary route of NH_4^+-assimilation in *Klebsiella* grown with low NH_4^+ or poor nitrogen sources[7–10] Although *asm*⁻ mutants fail to grow on N_2 as sole nitrogen source, Streicher *et al*[11] mentioned that nitrogenase, as determined by the acetylene reduction test, is induced, nitrogenase levels are comparable to the wild-type level in aspartate-supplemented medium RT4, however, showed no acetylene reduction in Pankhurst tube tests[13,14] on NFM with either vitamin-free casein hydrolysate (160 μg ml^{-1}) or L-glutamine (100 μg ml^{-1}) as nitrogen source It was possible that NH_4^+ produced from these nitrogen sources was not readily assimilated and therefore accumulated to repress nitrogenase synthesis In neither case, however, was NH_4^+ detectable in the culture supernatant at the end of the test

Comparison of nitrogenase, glutamine synthetase, glutamate synthase and glutamate dehydrogenase activities in RT4 and M5a1 confirmed that RT4 was not *asm*⁻ (Table 2) Cultures were grown in conditions which allowed derepression of nitrogenase synthesis yet in which growth was independent of nitrogen fixation and in which Nif⁺ revertants of Nif⁻ RT4 had no selective advantage Glutamate synthase activity in RT4 was very similar to that in M5a1 But, glutamine synthetase activity ($-Mg^{2+}$) was 40% lower and below the 0 7 units of activity required for the escape of histidase synthesis from ammonium repression[3] Glutamate dehydrogenase was 50% higher Nitrogenase activity was again absent from whole organisms of RT4 When ATP + dithionite-dependent nitrogenase activities were assayed in anaerobically prepared cell-free extracts of RT4, both component activities were absent (Table 3) Brenchley, Prival and Magasanik[10] showed that levels of glutamine synthetase and glutamate dehydrogenase varied inversely in *Klebsiella aerogenes* During growth on low NH_4^+, glutamine synthetase level is high, glutamate dehydrogenase low, ammonium assimilation through glutamine synthetase and glutamate synthase is favoured When NH_4^+ is in excess, glutamine synthetase is low, glutamate dehydrogenase high ammonium assimilation can proceed through glutamate dehydrogenase Brenchley *et al*[10] suggested that glutamine

Table 2 Nitrogenase, glutamine synthetase (GS), glutamate synthase (GOGAT) and glutamate dehydrogenase (GDH) activities of M5a1, mutant RT4 and revertants of RT4

Strain	Relevant phenotype	Nitrogenase*	GS†			GOGAT‡	GDH‡
			$-Mg^{2+}$	$+Mg^{2+}$	$\%+Mg^{2+}/-Mg^{2+}$		
M5a1	Hut⁺ Nif⁺	38	0 99	1 34	135	92	79
RT4	Hut⁻ Nif⁻	0	0 60	1 02	170	97	125
RT48	Hut⁺ Nif⁺	24	0 73	1 13	155	—	—
RT49	Hut⁺ Nif⁻	0	0 64	1 06	166	—	—

Cultures were grown at 28° C on NFM supplemented with 1 2 mg casein hydrolysate ml^{-1} and sparged with argon When a culture reached approximately 0 25 mg bacterial protein ml^{-1} (40 EEL Spectra units at 540 nm) a sample was removed and assayed for whole-cell acetylene reduction[5] Cell-free extract was prepared from the rest of the culture as described by Prival *et al*[3] except sonication was with a Dawe Soniprobe for 4 × 15 s at 2 5 A with 1 min cooling intervals Glutamine synthetase activities were measured by 'transferase' assays[15] with and without 60 mM $MgCl_2$ (ref 3) Assaying in the absence of Mg^{2+} gives a measurement of total glutamine synthetase (both adenylylated and unadenylylated subunits are active) whereas assaying in the presence of Mg^{2+} gives a measurement of unadenylylated enzyme which is believed to be the biosynthetically active form *in vivo* $MgCl_2$, although it inhibits adenylylated subunits, appears to stimulate activity of unadenylylated glutamine synthetase in crude extracts (see ref 3) Activities measured with Mg^{2+} therefore overestimate *in vivo* glutamine synthetase activity '$\%+Mg^{2+}/-Mg^{2+}$' overestimates % unadenylylated enzyme Glutamate synthase and glutamate dehydrogenase activities were measured at 20° C by following NADPH oxidation at 340 nm (ref 9) with a Unicam SP1800 spectrophotometer Glutamate synthase activities here have been corrected by subtracting 10% of the measured glutamate dehydrogenase activity[10]

*nmol C_2H_2 reduced per min per mg bacterial protein

†μmol γ glutamylhydroxamate formed per min per mg protein

‡nmol NADPH oxidised per min per mg protein

— = not determined

synthetase repressed synthesis of glutamate dehydrogenase, thus the higher level of glutamate dehydrogenase in RT4 (Table 2) may be a consequence of an inability to derepress full synthesis of glutamine synthetase

Glutamine synthetase levels in RT4 and M5a1 were compared in extracts from cultures grown under both depressive conditions (glutamine as sole nitrogen source) and repressive conditions (glutamine and NH_4^+ as nitrogen sources) RT4 constitutively synthesised glutamine synthetase as a level intermediate between repressed and derepressed M5a1 (Table 4) It follows that the mutation in RT4 must directly affect regulation of glutamine synthetase synthesis, a mutation causing increased intracellular NH_4^+ production by some other pathway would explain a low level of glutamine synthetase when derepressed, but not the high level when repressed Glutamine synthetase activities in M5a1 were comparable to those reported by Prival *et al*[3] in *K aerogenes* MK-53 In agreement with these authors, the adenylylation of glutamine synthetase was increased to compensate for overproduction (see RT4 grown with NH_4^+ and L-glutamine, Table 4) Moreover, glutamine synthetase was more unadenylylated in RT4 grown on L-glutamine where overall levels of enzyme were lower than in M5a1

Table 3 Nitrogenase activities of M5a1 and RT4

Strain	Whole cell	Extract	I*	II†
M5a1	31	28	37	30
RT4	0 0	0 0‡	0 0	0 0

Activities are expressed as nmol C_2H_2 reduced per min per mg protein Cultures were grown and whole-cell activities measured as described under Table 2 Cell-free extracts were prepared anaerobically from spheroplasts by combined osmotic shock and Triton-X-100 lysis (Christina Kennedy, personal communication) ATP+dithionite-dependent nitrogenase activity was assayed in extracts as described by Eady *et al*[16] 0 5–1 0 mg of protein was used per assay

*Component I (Fe-Mo protein) activity 50 μg purified component II added to assay

†Component II (Fe protein) activity 50 μg purified component I added to assay

‡When RT4 extract was assayed in the presence of both components I and II, no inhibition of the activity of the added purified nitrogenase components was observed lack of nitrogenase activity in RT4 was not a consequence of enzyme inhibition

Spontaneous 'revertants' of RT4 were obtained at a frequency of about 1 in 10^8 organisms by plating on NFM or NFM supplemented with 1 mg L-histidine or KNO_3 per ml Clones obtained on NFM-histidine were either prototrophic or revertants which grew on histidine as sole nitrogen source but not on nitrate or N_2 Similarly, clones obtained on NFM-nitrate were either prototrophic or revertants which grew on nitrate but not on histidine or N_2 But, all of 62 clones obtained on N_2 were prototrophic, repeated attempts failed to produce a Nif^+ revertant which did not grow on histidine or nitrate Glutamine synthetase activities of typical RT4 derivatives are shown in Tables 2 and 4, RT48 was a typical prototrophic Hut^+ revertant with wild-type glutamine synthetase activities and regulation, RT49 had regained only the ability to grow on histidine as sole nitrogen source and showed glutamine synthetase activities like RT4 Apparently derepression of *hut* enzymes had become independent of high levels of glutamine synthetase in this strain

Glutamine auxotrophs of *K aerogenes* have lesions which map at two separate loci, *glnA* and *glnB* (ref 3) Most revertants of a *glnB* strain produce glutamine synthetase constitutively, these revertants ($GlnC^-$ strains) have a second mutation at a site cotransducible with *glnA* (ref 3) An F′ *nif-his* plasmid (FN68) which also confers carbenicillin-resistance[17] was transferred to RT4 from *Escherichia coli* JC5466 (provided by Dr R A Dixon) Nitrogenase activity was not restored to RT4 by this means so, unlike most *nif* mutations[11] the mutation in RT4 did not appear to be linked to *his*. The map position of the RT4 mutation is currently being sought, this work will be reported in a subsequent communication

Table 4 Regulation of glutamine synthetase in M5a1, RT4 and derivatives

$(NH_4)_2SO_4$ and L-glutamine were used at 1 g^{-1}, glucose at 5 g^{-1} Overnight cultures, grown up under air on an orbital shaker, were suitably diluted into fresh medium, grown for 2–3 doublings and harvested from log phase Extracts were prepared and glutamine synthetase assayed as described under Table 2

Constitutive synthesis of nitrogenase

Prival *et al*[3] showed that $GlnC^-$ strains which are fully constitutive for glutamine synthetase produce depressed levels of histidase and proline oxidase in the presence of NH_4^+, similar strains derived from nitrogen-fixing *K pneumoniae* M5a1 might be constitutive for nitrogenase synthesis If the RT4 mutation was in the *glnB* site, $GlnC^-$ strains might be found among revertants of RT4 Over 80 prototrophic clones obtained by reverting RT4 to a Hut^+ or Nif^+ phenotype were checked for the production of a yellow-brown pigment when grown on tryptophan plus NH_4^+ as nitrogen sources Pigment production under these conditions is characteristic of $GlnC^-$ *K aerogenes*[3] No $GlnC^-$ revertant of RT4 was identified by this means either the test was not applicable to *K pneumoniae* M5a1 or mutation to $GlnC^-$ does not repair RT4 Additionally, 25 out of 25 Nif^+ revertants of RT4 tested failed to reduce acetylene when anaerobically grown in the presence of 1 mg $(NH_4)_2SO_4$ per ml

K aerogenes strain MK-53 and its $GlnC^-$ derivatives MK-94 and MK-142 (see ref 3) do not naturally fix nitrogen The F′ *nif-his* factor (FN68) which carries the *nif* genes of *K pneumoniae* M5a1 (ref 17) was therefore introduced into these strains to determine the effect of constitutive synthesis of glutamine synthetase on expression of *nif* Significantly, Nif^+ His^+ exconjugants obtained by introducing the F′ *nif* into his^- derivatives of the GlnC *K aerogenes* strains MK-94 and MK-142 retained 10–20% of their derepressed level of nitrogenase activity (Table 5) when grown on NH_4^+ This partially constitutive synthesis of nitrogenase was specifically associated with the $GlnC^-$ character since it was not shown by *K aerogenes* MK-53 (FN68) or *K pneuomoniae* M5a1 Mutants of *Azotobacter vinelandii* which show 25% of their derepressed level of nitrogenase in the presence of ammonium have been described[18] but have not been characterised with respect to glutamine synthetase

Glutamine synthetase and nitrogen fixation

The possibility that synthesis of both nitrogenase and glutamine synthesis is positively regulated by an unidentified factor which is defective in RT4 and unaffected by NH_4^+ in $GlnC^-$ strains cannot be ruled out completely But it is difficult to see how a common defective regulator in RT4 could produce both low constitutive synthesis of glutamine synthetase and no synthesis of nitrogenase It seems most likely, therefore, that glutamine synthetase itself is required as a positive control element for nitrogenase synthesis in the same way as has been proposed for histidase synthesis in *Klebsiella*[3,4], a direct demonstration of activation of transcription of *nif* by glutamine synthetase *in vitro* is still required That nitrogenase synthesis only partially

Table 5 Expression of *nif* in GlnC$^-$ (glutamine synthetase-constitutive) hosts

Organism	Strain	Derivation Mating performed	 Character selected	Relevant phenotype	Nitrogenase activity (nmol C_2H_2 reduced min^{-1} mg^{-1}) Grown on NH_4^+	 Aspartate
K pneumoniae	M5a1	—	—	GlnC$^+$	<0 01	39-55*
K aerogenes	MK-53 (FN68)	MK-53 × JC5466 (FN68)	Carbenicillin resistance	GlnC$^+$	<0 01	
K aerogenes	MK-94 *his* (FN68)	MK-94 *his* × JC5466 (FN68)	His$^+$	GlnC$^-$	6 0	
K aerogenes	MK-142 *his* (FN68)	MK-142 *his* × JC5466 (FN68)	His$^+$	GlnC$^-$	7 5	

K aerogenes MK-53, MK-94 and MK-142 (≡MK-140) are published strains[3] MK-94 *his* and MK-142 *his* were derived by IPMS mutagenesis and subsequent antibiotic selection for histidine auxotrophs For matings using *E coli* JC5466 (FN68) as donor, 0 1 ml of overnight broth cultures of both donor and recipient were spread together on nutrient agar After 6–7 h organisms were scraped off, resuspended in saline-phosphate buffer at 10^8–10^9 organisms ml^{-1} and 0 1 ml plated out on selective medium The Nif$^+$ *K aerogenes* hybrids and *K pneumoniae* M5a1 were grown under a stationary argon gas phase on NFM supplemented with 1mg $(NH_4)_2SO_4$ or aspartate ml^{-1} When a culture reached 0 15–0 20 mg bacterial protein ml^{-1} a sample was removed and assayed for nitrogenase activity (see legend to Table 2)
*Dependent on age of culture

escapes ammonium repression in GlnC$^-$ strains may reflect a specific requirement for highly deadenylylated glutamine synthetase GlnC$^-$ strains contain derepressed levels of glutamine synthetase in the presence of excess NH_4^+ but the enzyme is more adenlylyated than under nitrogen limiting conditions (see ref 2) If the adenylylating 'cascade' system for glutamine synthetase[19,20] can be blocked by mutation, such a mutation in a GlnC$^-$ strain may produce fully constitutive nitrogenase synthesis

If glutamine synthetase does exert a direct effect on *nif* expression, proposed transgenosis[21] of repressible *nif* genes from *Klebsiella* to plants would require homologous glutamine synthetase structural and regulatory genes to be transferred along with *nif* This problem could be avoided if *nif*-constitutive strains in which nitrogenase synthesis was independent of activation by glutamine synthetase could be obtained If *nif* genes are in a single operon, one might have expected to obtain this class of mutants among Nif$^+$ revertants of RT4 That such attempts failed may mean that *nif* genes in *Klebsiella* are located in more than one operon

Dunican and Tierney[22] have recently succeeded in picking up *nif* genes from *Rhizobium trifolii* thereby adding conviction to the widespread, but unsubstantiated, belief that genetic material from rhizobia codes for nitrogenase proteins in the nitrogen-fixing legume symbiosis No *Rhizobium* has been shown to fix nitrogen in the free-living state Dunican and Tierney[22], however, obtained expression of presumptive *Rhizobium nif* genes by R-factor-mediated conjugation into *K aerogenes* strain 418, naturally a non-fixer In addition, expression of *Rhizobium nif* in *K aerogenes* was repressed by NH_4^+ It is tempting to speculate that free-living rhizobia do not synthesise nitrogenase because *Rhizobium* glutamine synthetase is unable to activate transcription of *nif* DNA by *Rhizobium* RNA polymerase *R japonicum* glutamine synthetase is known to be immunologically distinct from the glutamine synthetases of the coliform bacteria, *E coli, K pneumoniae* and *Salmonella typhimurium*[23] Nitrogenase is synthesised, however, within the root nodules of leguminous plants, either the plant provides suitable 'machinery' for transcription of *nif* or changes occur in *Rhizobium* RNA polymerase during establishment of effective symbiosis, such that *nif* genes can be transcribed in the absence of activation by glutamine synthetase Possible answers to questions raised by studies on symbiotic nitrogen fixation therefore can be suggested from basic knowledge of regulation of synthesis of nitrogenase in *K pneumoniae,* such information must also greatly increase the chances of success in any attempt in the future to establish nitrogen fixation in non-leguminous crop plants

I am grateful to Drs Christina Kennedy, F C Cannon and R A Dixon for useful discussions, to Drs R R Eady and B E Smith for purified nitrogenase components and to Dr S L Streicher of Massachusetts Institute of Technology, for the necessary strains of *K aerogenes* I acknowledge advance information from Dr S L Streicher and his colleagues that they have performed complementary experiments to those reported here and have reached similar conclusions

Possible antineutrino pulse of extraterrestrial origin

We report an unusual event observed during our search for electron antineutrino $\bar{\nu}_e$ bursts of extraterrestrial origin[1] Our experiment uses a deep underground $\bar{\nu}_e$ burst-detector station, adjacent to the Brookhaven Solar Neutrino Observatory[2] at a depth of 4,400 metres water equivalent (m w e) in the Homestake Gold Mine in Lead, South Dakota At this station we have placed a number of large water Cerenkov counters (Fig 1) designed to detect $\bar{\nu}_e$ interactions by the Cerenkov radiation from positrons resulting from $\bar{\nu}_e + p \rightarrow n + e^+$ (ref 3)

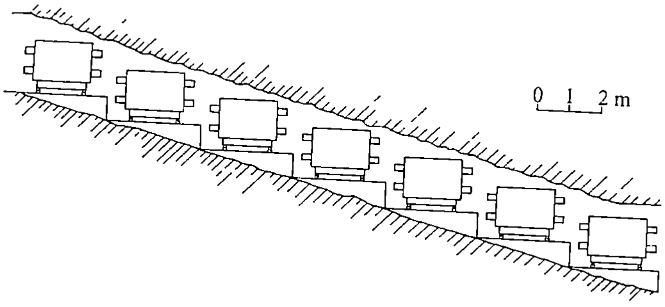

Fig 1 Arrangement of water Cerenkov counters in a tunnel 1,480 m below surface in the Homestake Mine in Lead, South Dakota The lowest right hand counter is No 1 and the highest left hand one is No 7

Each Cerenkov counter is a 2 m^3 cylinder, 1 78 m long by 1 22 m filled with deionised water containing Amino-G wave length shifter and viewed by eight photomultipliers 12 5 cm in diameter The majority logic coincidence circuit associated with each counter gives an output pulse whenever five or more of the eight photomultipliers viewing that counter give coincident signals The occurrence of either a single large amplitude pulse from any one counter or of two or more counter pulses within 0 1 s initiates a magnetic tape recording of the time distribution of the pulses in each counter, the summed photomultiplier pulse amplitude associated with each pulse and the photomultiplier pattern of each counter involved in the coincidence The time difference between pulses within an event is measured with a 20 MHz oscillator providing 50 ns time resolution for these differences

On January 4, 1974, at 17 h 16 min 48 s GMT we observed an event involving a total 24 pulses within 3 ms in six of our detectors These pulses occurred in four groups, each ~ 1 μs wide The first and second groups were separated by 640 μs, the second and third by 968 μs and the third and fourth by 928 μs The first group consisted of nine pulses distributed over the six counters, the second group involved six pulses and the third group eight pulses These three groups used up 23 of the 24 available readout channels leaving only one readout channel available for the last pulse From our detector thresholds and pulse height data, we estimate the energy of the particles involved in these pulses to be 20 MeV $\leqslant E \leqslant$ 100 MeV These pulse heights indicate that the charged particles responsible for these pulses had ranges considerably less than half of the diameter of our counters and so are unlikely to have traversed our counters

Since our readout channels were completely filled by the four recorded bursts we do not know if there were any subsequent pulses We only know that 0 8 s after the first pulse, when our transfer to tape was completed, there were no more counts, so that the pulse duration period was less than this time

Figure 2 shows the time distribution of the observed bursts and Fig 3 gives the pulse distribution within each burst Details of the burst data are given in Table 1

We have considered and eliminated the possibility that this event is due to an electronic instrumentation effect, a random accidental correlation, or a rare version of one of the well known 'local' physical phenomena The evidence we used to rule out the first possibility lies both within the event itself and in the other tape records acquired in the hours preceding and following this event A normal record containing one pulse occurred 30 s before the event and another one 9 s after the event

We observe about 300 twofold coincidences per day and about four threefolds per day within our 0 1 s time resolution These rates are in good agreement with an accidental prediction based on our 'singles' rates From these rates we would expect

Table 1 Details of the burst data

Burst	Counter 1	2	3	4	5	7
1	0 10 μs 0 60 μs	0 15 μs	0 05 μs	0 05 μs 0 45 μs 1 00 μs	0 15 μs	0 00 μs

4					*2535 7* μs All readout scalers filled	

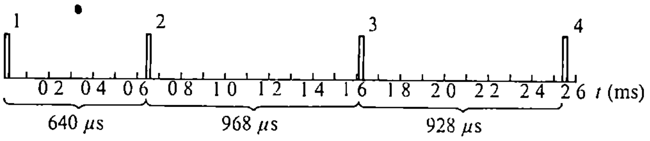

Fig. 2 Time distribution of narrow bursts of observed pulses

a 24-fold accidental correlation within 0 1 s $\approx 10^{-40}$ times per second A 3-ms correlation requirement would reduce this rate considerably

A higher rate can be obtained by considering the probability of three large angle muons traversing the apparatus within 3 ms We observe about 7 5 vertical muons per day traversing each detector and see a large angle muon going through two detectors about once in two days From these numbers we predict about one muon traversing all our detectors once a year or three muons within 3 ms $\approx 10^{-30}$ times per second Of course, this mechanism would not account for the multi-pulse structure of the bursts, nor for the small pulse heights associated with our pulses

Extensive cosmic-ray showers can have a spread in time of arrival spread of ~ 150 ns (ref 4) This spread is consistent with the time distribution of pulses within one of our bursts We observe about one cosmic ray shower per week at our apparatus but very few of them are spatially spread over more than one detector In 3 months of observation we have seen only one shower involving three detectors and none that spans more than three detectors Clearly the frequency of showers that span all our detectors $\leqslant 10^{-7}$ s^{-1} and so the probability of having three such showers within 3 ms $\leqslant 10^{-26}$ s^{-1} This process is also in disagreement with the small observed pulse heights

We have considered several other correlation chains including those involving local radioactivity, and have found similar low occurrence probabilities We are thus led to consider the 24 counts as correlated and probably due to ν_e interactions Using 24 counts in 12 m^3 of H_2O we obtain a lower limit ν_e to the $\bar{\nu}_e$ flux of 1 5 × 10^{11} (50 MeV/E_ν)$^2\bar{\nu}_e$/cm^2, or 1 2 × 10^7 erg cm^{-2} for 50 MeV anti neutrinos

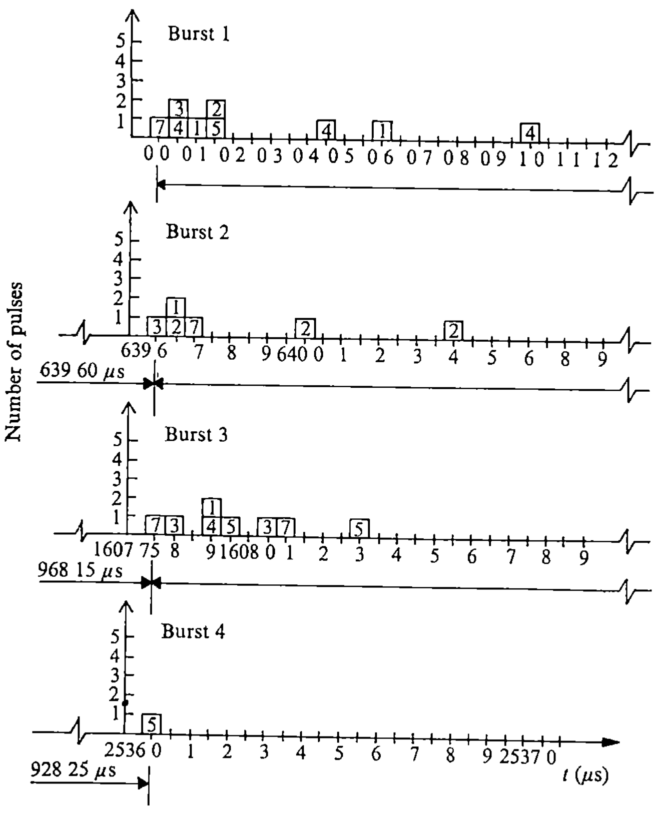

Fig 3 Time distribution of counter pulses within each burst The number within each box indicates the number of the counter giving rise to that pulse

No additional direct experimental information is available We can, however, speculate on possible sources such as the gravitational collapse of stars For such a source near the galactic centre ($d \approx 3 \times 10^{22}$ cm) we find a source flux of 1 4 × 10^{53} erg (for $E\bar{\nu}_e$ = 50 MeV) which is consistent with the prediction of Zel'dovich and Guseinov[5] for the emission of neutrino energy by a collapsing star Various people[6-10] have pointed out that a collapsed star is likely to 'bounce' a number of times and that the bouncing periodicity is ≈ 1 ms The narrowness of the pulses of emitted radiation may be a consequence of the fact that the collapsed star emits antineutrinos mainly during the period its density is maximum, at the minimum of its bounce

If we assume that the energy distribution of the $\bar{\nu}_e$ has a width comparable to $E\bar{\nu}_e$ then from the observed narrow pulse width we can place an upper limit on the mass of $\bar{\nu}_e$ of 10^{-2} eV/c^2

We thank Dr Raymond Davis, jun and his group and the Homestake Mining Company for use of their facility Ms Lila Shapiro provided programming assistance and Mr Lauren Taylor and Mr James Cook designed our electronics This work was partly supported by the United States Atomic Energy Commission

Brookhaven solar neutrino detector and collapsing stars

THE Brookhaven solar neutrino detector has been in continuous operation in its present form since 1970 The basis of the detection method is the inverse beta decay reaction on ^{37}Cl to produce ^{37}Ar ($t_{1/2}$ = 35 1 d) which can be detected at a sensitivity level of 10 to 20 atoms The detector, consisting of 380,000 l of C_2Cl_4, is described in detail elsewhere (refs 1-3 and references therein) Measurements with this detection system establish[1-3] an upper limit for solar neutrinos of 1 SNU (1 SNU = 10^{-36} captures/^{37}Cl atom-s) This limit is in substantial disagreement

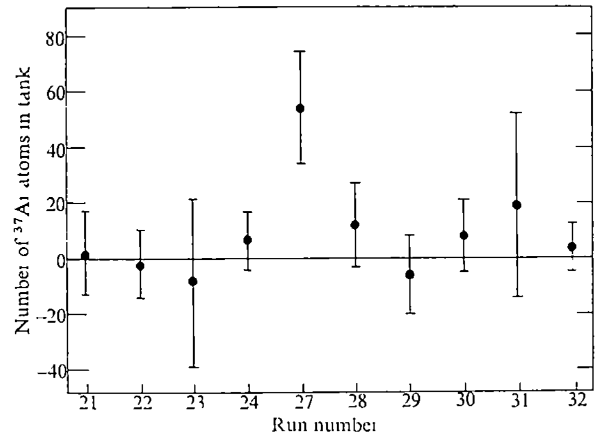

Fig 1 The number of ^{37}Ar atoms found in the C_2Cl_4 tank at the end of each helium sweep is plotted for each run A cosmic-ray background correction has been subtracted The error bars shown are purely illustrative and are based on the square roots of the small counted numbers

with accepted solar model calculations[4] which predict a result of 5 6 SNU (ref 5) The significance of this discrepancy has been recently analysed in detail[6], this number also represents a base line for comparison with other possible sources of high energy neutrinos[3,7], in particular those produced by collapsing stars

On January 4, 1974 a possible collapsing star event was observed by the University of Pennsylvania water Cerenkov antineutrino detector located next to the Brookhaven detector in the Homestake Gold Mine[8] The C_2Cl_4 tank was swept as soon as possible after this event in an attempt to detect an associated neutrino pulse The result of this search was negative and can be used to set a limit on the ratio of antineutrinos to neutrinos escaping from a collapsing star—if that is indeed the source of the event

Figure 1 shows the experimental results for ten runs with the Brookhaven neutrino detector in its present form The cosmic ray correction[9] amounts to a subtraction of about 3 to 4 atoms per run Of the ten measurements to date, only one, run 27 (July 7 to November 5, 1972) seems to contain any measurable ^{37}Ar, in contradiction with the other runs A simple statistical test, Chauvenet's criteria, suggests that the point is abnormal and for that reason it is not included in the solar neutrino calculation A more sophisticated statistical analysis of the data[10] also suggests that the measurement is anomalous The number of ^{37}Ar atoms in the tank at the time of purging run 27 (November 5, 1972) was 58 ± 20, compared to an average of 8 ± 7 ^{37}Ar atoms for all other runs The number of ^{37}Ar atoms in the tank produced by cosmic rays is estimated[9] to be 4 ± 2 Apart from statistical considerations, the data for run 27 show a rather convincing signature for ^{37}Ar Auger electron decays, agreeing well in energy, pulse rise time and half life The possibility that this ^{37}Ar was introduced by some type of contamination was carefully considered and found to be extremely unlikely The various contaminations considered were (1) the activity of ^{37}Ar in atmospheric argon from underground nuclear bomb testing and the amount of air argon introduced in the sample, (2) ^{37}Ar in the argon added directly to the counter filling, and (3) ^{37}Ar remaining in the counter and the filling line from previous measurements The amount of ^{37}Ar found was about 10 to 20 times the normal cosmic ray rate Pallister and Wolfendale[10] examined the possibility that this amount was simply due to a large fluctuation in the cosmic-ray interaction rate and concluded this was also extremely improbable A solar flare occurred on August 4, 1972 which was the largest ever observed But this is an unlikely source of neutrinos The experimental facility is sufficiently deep underground to be totally unaffected by the relatively low energy charged particle flux On September 2-11, 1972 a large radio outburst was recorded from Cygnus X-3, but again this is generally believed to be an unlikely source of neutrinos A γ-ray pulse of unusually sharp rise time was observed by the Vela satellites on November 1, 1972 (ref 11) The energy flux in this pulse was very small and it is difficult to say whether or not this event is related to the excess in run 27 The University of Pennsylvania detector was not yet operational at the time and so it is not possible to say whether or not the excess was related to a collapsing star

Run 32 was collected on January 25, 1974 about three weeks after the event detected by the University of Pennsylvania water Cerenkov detector The result, with cosmic-ray background subtracted, is 4 5 ± 9 ^{37}Ar atoms in the tank at the time of the sweep This is in good agreement with eight other runs which give an average of 4 ± 7 ^{37}Ar atoms (Fig 1) If a decay correction is included, a 1σ limit of $\leqslant$21 atoms of ^{37}Ar produced on January 4, 1974 is obtained To compare this number with the University of Pennsylvania result, a knowledge of the relative sensitivity of the two detectors is required The cross sections for the two reactions were calculated[12] using the best available values for the matrix elements and Fermi function A calculation of the ratio of the neutrino reaction (σ_{37}) to antineutrino reaction (σ_1) at various particle energies shows that the ratio is about 1 1 at 20 MeV (σ_{37} = 3 1 × 10^{-41} cm^2), the threshold for the Cerenkov detector, and approaches an asymptotic value of 1 6 at high energy At very high energies, the ratio would presumably start to drop again due to nucleon recoil effects, but that is outside of the energy range of interest for collapsing stars Since the chlorine detector contains about 2 6 times as many usable target atoms as the Cerenkov detector, the efficiency of the chlorine detector is 2 9 to 4 2 times that of the Cerenkov detector for equal particle fluxes and energies in the energy range of interest Combining this result with the 24 counts seen in the Cerenkov detector, a minimum of 70 atoms ^{37}Ar should have been produced in the chlorine detector for equal particle fluxes and energies The antineutrino to neutrino flux ratio is $\geqslant$4 1 assuming a typical particle energy of 50 MeV (σ_{37} = 2 9 × 10^{-40} cm^2) The pulse recording system used in the water Cerenkov system was only capable of recording a maximum of 24 pulses during the time period of interest There is therefore a large uncertainty in the true size of the event The corresponding flux ratio may in fact be significantly larger since the chlorine detector integrates the entire event

There are several restrictive conditions that must be satisfied if the January 4 event is to be interpreted as a collapsing star First, the expected time duration for a pulse of neutrinos to diffuse out of the central regions of a star is $\sim(R/c)$ (R/λ), where R is the characteristic size of the collapsing star ($\sim 10^{6\ 5}$ cm) and λ is the average mean free path of the antineutrinos In order for there to be significantly more antineutrinos than neutrinos leaking out, (R/λ) must be large The characteristic time for changes in the physical conditions is of the order of the dynamical time and is also long, ~ 1 ms So the main pulse width should be $>10^2$ μs instead of the observed width ~ 1 μs The main pulse should have (see equation (14) of ref 14) $\gtrsim(R/3)$ times (approximately 100 times) as many neutrinos and antineutrinos as in the prompt burst This increases the total estimate of energy in neutrinos and antineutrinos for the model of ref 12 to ~0 3 to $1M_\odot c^2$ × (distance/10 kpc)^2 if a fairly flat spectrum of energies is assumed

The failure to observe neutrinos associated with the event of January 4 is also a serious constraint on possible interpretations in terms of collapsing stars Under most astrophysical circumstances one would expect approximately equal numbers of neutrinos and antineutrinos whereas the combined observations imply an antineutrino flux more than four times the upper limit on the neutrino flux The University of Pennsylvania water Cerenkov detector is not sensitive to neutrinos below ~20 MeV whereas the Brookhaven ^{37}Cl detector has considerable sensitivity in this region[12] If one interprets the event of January 4 as being produced by antineutrinos then one must say the flux was primarily antineutrinos more energetic than

20 MeV But one numerical calculation of neutrino transport in a collapsing star yields[14] spectra with a peak at about 10 MeV

Also the initial stages of the collapse of a white dwarf to form a neutron star would produce predominently neutrinos[14] through electron capture, transforming protons into neutrons, and would yield very few antineutrinos (provided the star is made out of matter, not antimatter)

The likely production processes at higher temperatures and densities yield equal numbers of neutrinos and antineutrinos, this is true for all processes based on the interaction $e^+ + e^- \rightarrow \nu_e + \bar{\nu}_e$ and for two nucleon collisions ($n + n \rightarrow p + n + e^- + \bar{\nu}_e$, $p + n + e^- \rightarrow n + n + \nu_e$) In nondegenerate, high temperature regimes ($T^3_{20\mathrm{MeV}}\rho^{-1}{}_{\mathrm{nuclear}} \gtrsim 10^3$) such as might occur in shock waves formed by supernovae[15], the principal opacity would be due to lepton–lepton scattering[16] ($\nu_e + e^- \rightarrow \nu'_e + e^{-\prime}$, $\bar{\nu}_e + e^- \rightarrow \bar{\nu}'_e + e^{-\prime}$ and so on) which leads to equal opacities for neutrinos and antineutrinos if, as is true under such conditions, the number of electron–positron pairs in equilibrium with the radiation field is large compared to the number of atomic electrons (The maximum difference between ν–e and $\bar{\nu}$–e cross sections for any intermediate vector boson theory with μ–e symmetry is a factor of three[18] and for the Weinberg–Salam model with $\sin^2\theta_w = 0\,3$ to 0 4 is a factor of two) (compare ref 19)

Most astrophysical events are expected to give rise to at least as many neutrinos as antineutrinos Moreover, accompanying the prompt antineutrinos to which the University of Pennsylvania detector is sensitive one would expect a much larger number (on a longer time scale) of lower energy neutrinos (and antineutrinos) to which the Brookhaven detector is sensitive The absence of detectable neutrinos is puzzling if the event of January 4 was caused by antineutrinos from a collapsing star

We thank the Homestake Mining Company for assistance and Professor Kenneth Lande and his group and Professor Arnold Wolfendale and his associates for collaboration This research is supported in part by the United States Atomic Energy Commission

Possible explanations of the 'high' number of counts in the solar neutrino experiment

EVANS *et al*[1] (see also refs 2, 3) have presented data on the rate of production of ^{37}Ar with the Brookhaven Solar Neutrino Detector, two facts stand out the overall mean rate is low compared with expectation[4], and one run, No 27, may be significantly higher than the remainder The present note is primarily concerned with the statistical significance and explanation of this high rate The calculation of the rates and uncertainties is not a simple procedure and it is important to have an independent determination, with the cooperation of the authors, we have made our own analysis using their basic data (β-ray counter measurements of the β-activity of the abstracted ^{37}Ar over successive periods of ~30 d), for the important run 27

Several methods have been adopted to determine the rate R I, the maximum likelihood method, II, a similar method used in the Case-Wits-Irvine Experiment by Meyer[5], and III, a graphical method in which isoprobability contours of the observed configuration of counts are calculated, and cuts through them taken and the resulting, normalised differential probability curves integrated to determine the probability that the true number of atoms at the end of exposure was less than some particular value N_o

$$P(<N_0) = \int_0^{N_0}\int_0^{\infty} P(N_0,b)\mathrm{d}P\mathrm{d}b$$

where b is the small but finite counter background The values of N_0 at which $P(<N_0)$ are 16% and 84% correspond to the 'error' in the mean rate All the calculations gave R_{27} as 1 18 ^{37}Ar per day (some of the residual difference with the Davis estimate of 1 24±0 43 ^{37}Ar per day arises from small differences in input data) Methods I and II gave the standard deviation of the rate (σ=0 43), but because of the skew nature of the probability distribution this bears no simple relationship to the probability that the mean rate is within the above bounds Method III gave errors of −0 31 and +0 41 ^{37}Ar

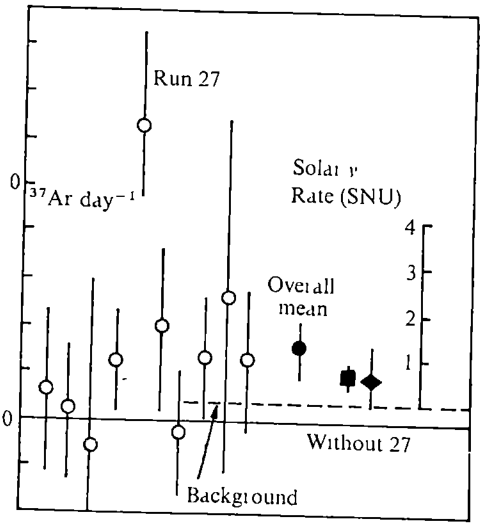

Fig 1 Results of the solar ν experiment, after Evans *et al*[1] The errors on individual run rates (open circles) quoted for Run 27 come from the present work, the rest from ref 1 The mean values are those derived by us

Table 1 χ^2 and probabilities for various situations

Adopted 'true' value	Data Examined	χ^2	$p(\chi^2)$
Overall	All data	11 7 (14 0, 21 8)	16% (8%, 0 5%)
mean	R_{27} excluded	2 9 (4 0, 11 0)	90% (78%, 14%)
Mean ex-	All data	13 2 (15 0, 22 2)	10% (6%, 0 5%)
cluding R_{27}	R_{27} excluded	1 8 (3 6, 10 7)	97% (82%, 15%)
Expected	All data	16 3 (18 8, 30 1)	4% (1 5%, 0 02%)
background	R_{27} excluded	2 6 (5 1, 16 3)	92% (66%, 2 3%)

The figures in parenthesis refer to the situation where the errors for runs other than No 27 are multiplied by factors of 0 7 and 0 4 respectively It is likely that the true situation gives χ^2 probabilities intermediate between the values in parenthesis

per day, an increase of 0 12 on the lower limit estimated by Davis, lending further support to the suggestion of the anomalous character of run 27

To establish the significance of the high value of R_{27}, various χ^2 tests have been performed using the data shown in Fig 2, including and excluding run 27, and using several reasonable estimates of the true mean rate The results shown in the table indicate that there is some evidence of an excess in R_{27} But as was pointed out by Evans *et al*[1], there is a suggestion that the quoted errors (other than R_{27}) are too large, this is borne out by the high probability (90%) for the appropriate conditions

An alternative approach is to examine the errors and the dispersion of the mean rates about their mean Excluding run 27, the dispersion error α, is 0 05 which is much smaller than the value expected ($\simeq\langle\sigma\rangle/\sqrt{n}\simeq0$ 12, where $\langle\sigma\rangle$ is the median of the individual errors), on the basis of the errors of the individual rates This confirms that the quoted errors are probably overestimates In view of the uncertainty of the individual errors, the χ^2 probabilities have also been calculated with the errors on runs other than 27 reduced by factors of 0 7 (the ratio of 'our' error on R_{27} and the quoted error) and 0 4 (the ratio of the dispersion and 'expected' errors) respectively The results (see the Table 1) show that the significance of the excess is considerably enhanced In particular, if the smallest errors are adopted then Run 27 is almost certainly anomalously high More data over the next year or so will surely enable a more definite conclusion to be arrived at

It is interesting that if the dispersion errors are correct, then, neglecting R_{27}, the upper limit on the residual solar neutrino rate is only 0 9 solar neutrino units (SNU), and the solar model calculations are in disarray[4] Inclusion of run 27 raises the upper limit to ~1 9 SNU and the discrepancies are not quite as severe

Assuming R_{27} is anomalously high, various possibilities arise

(i) The presence of an unusual, non-Poissonian, increase in background

(ii) The effect of a large solar flare (August 4, 1972)

(iii) The arrival of neutrinos from a cosmic source

The background is composed of two parts

(a) Cosmic ray neutrinos produced in the atmosphere contribute ~30% to the background and are extremely unlikely to have large fluctuations over the integrated time scale of the detector

(b) The contribution from protons, 'knocked on' by fast cosmic ray muons to the reaction ^{37}Cl (p,n)^{37}Ar Knowledge of the muon spectrum, nuclear cross section, and yield of ^{37}Ar atoms per interaction ($\propto$ (Energy transfer)$^{0\ 7}$, following Wolfendale *et al*[6]) enables the contribution to the background from rare events producing many ^{37}Ar atoms (when large fluctuations may occur) to be determined This contribution is very small which implies that the background fluctuation should be strictly Poissonian with a total mean value of 0 09±0 04 ^{37}Ar atoms per day

Solar flare. Evans *et al* have rightly implied that the muons formed from protons in the solar flare have insufficient energy to penetrate to tank depth More important is the increase in the neutrino flux from the low energy muons decaying high in the armosphere but their contribution ismuch too small to provide the excess in R_{27} (We thank C J Hatton for comments on this point)

Cosmic source. Evans *et al* have sought an explanation of the neutrino excess in terms of cosmic sources (the γ-ray pulse event of November 1, 1972)[7] The unusually short pulse width (~0 1s) is of the same order as the expected collapse time of a star to the neutron stage when a large neutrino burst is expected[8] The probability of the solar neutrino detector recording a signal of more than 50 counts per run from collapsing stars has been considered by us[9] and shown to lie in the range 10^{-1}–10^{-2} if all stars of mass >1 5 $M_\odot$ collapse Such a probability does not disagree with run 27 corresponding to a collapsing star (one ν-burst in 10 runs), and assuming R_{27} is anomalously high, we would regard this explanation as perhaps the most probable

Finally, regarding the exciting result reported by Lande[10] we point out that events of this type, if genuine, are detectable by extensive air shower arrays, when the positrons released in the detector simulate a shower of completely flat lateral distribution Comparing the threshold sensitivity of the two major arrays, 60 MeV m^{-3} μs^{-1} water at Haverah Park and 80 MeV m^{-3} μs^{-1}at Sydney, with the energy deposition observed by Lande (15–75 MeV m^{-3} μs^{-1}) both figures are seen to be in the region of observed energy deposition Neither array observed a coincidence with the 'Penn' event but this is understandable if the energy deposition was near 15 MeV m^{-3} μs^{-1}

We thank the Science Research Council for support, Drs Davis and Evans for discussions and for suggesting the publication of this note, and Mrs D M Greig and Professor A M Aurela for help with the statistical analysis Dr A A Watson and Professor C B A McCusker provided the extensive air shower information

Anomalous mercury in near-bottom water of a Mid-Atlantic Rift valley

MERCURY analysis[1] of over 1,000 water samples from GEOSECS stations in the western Atlantic indicated extremely low mercury concentrations (2–40 ng l^{-1}) in much of the ocean between 15°N and 35°S, and identified a large core of water of relatively high concentration (80–400 ng l^{-1}) between 25°N and 50°N These increased concentrations may result[1] from the entrainment of Hg which diffuses from the active spreading centre of the Mid-Atlantic Ridge, by Mediterranean water which flows over

Table 1 Mercury in samples of seawater from the FAMOUS area

Sample number	Hg (ng l^{-1})	NaCl (‰)	F Cl (× 10^5)	O_2 (ml l^{-1})
2	1,380±90	35 024	6 66	—
10	1,190±90	35 020	6 64	6 11

68	1,130±90	35 012	6 76	6 03
69	880±90	35 012	6 74	5 99
Mean	1,090	35 012	6 69	6 01
s d of mean	±193	±0 017	±0 04	±0 07

the ridge into the western basin of the Atlantic Ocean Mercury concentrations are as high as 1,370 ng l^{-1} at a depth of 2,435 m at GEOSECS station 27 (42°00′N, 41°59′W), (ref 1)

Bostrom and Peterson[2] have described sediments enriched in Fe, Mn, B, As, Cd, V and Cr in areas of high heat flow on the East Pacific Rise They suggested that these sediments have incorporated precipitates of the volcanic emanations from active ridge crests White[3] examined the composition of hot spring waters and suggested that trace elements such as Ba, W, Zn, Hg and Cu could also be enriched in the products of outgassing Mercury in Japanese hot spring waters has been reported[5] to range from 100–30,000 ng l^{-1}

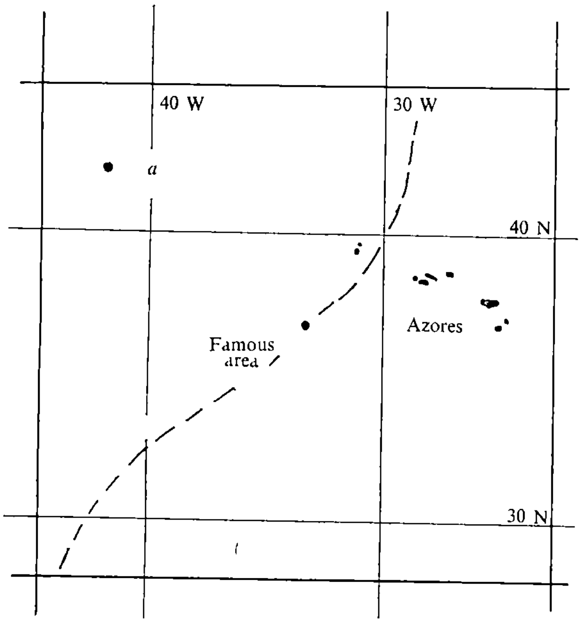

Fig 1 Location of the FAMOUS Area Dashed line, Mid-Atlantic Ridge, *a*, GEOSECS Station 27

During one phase of Operation FAMOUS (French–American Mid-Ocean Undersea Study), we took water samples from near the bottom of a rift valley at 36°49′N, 33°16′W (Fig 1), at a depth of 3,200 m The iron manganese ratio of the samples averaged 9 2, close to the average value of 10 observed for ocean water (unpublished data from this laboratory) The 15 samples were analysed for mercury using the method of Carr *et al* [5], with a best estimate of error ± 90 ng l^{-1} The analysis showed a mean value of 1,090 ng l^{-1}, with a standard deviation of the mean of 193 ng l^{-1} (Table 1) The difference between samples is significant All the samples seem to have come from the same water parcel, as is indicated by the uniformity of values for salinity, dissolved oxygen (Table 1), and by the temperature 3 97 ± 0 03° C The F Cl ratio was that of normal sea water These data support the hypothesis that mercury is introduced into the sea water column at active spreading centres

We wish to thank H Fleming, and the scientific complement and the officers and crew of the USNS Mizar for the opportunity to obtain water samples

Three dimensional image reconstruction on an extended field—a fast, stable algorithm

WE describe an improved alogrithm (EFIRT) for solving iteratively the linear equations relating a three-dimensional density to a given set of its projections, when the unknown density is expressed as samples on a grid The need to solve such equations arises in electron microscopy, medical radiography, radio and X-ray astronomy and other fields The projection equations comprise a very large, sparse and often underdetermined set If the number of unknowns is not too large, the equations may be solved by a least squares procedure, using filtering to combat the ill-conditioning[1] The number of unknowns is often too great for such a procedure to be computationally feasible and iterative techniques[2,3] must be used Alternatively the Fourier transform provides a stable and computationally efficient means of solution[1] Sometimes use of the Fourier transform is not convenient, for example, if point rather than plane projections are given or if the projection data are weighted by a non-uniform but linear response of the measuring device Such problems are much more readily expressed in terms of projection equations and the development of stable methods for their solution is therefore important

If the observations contain noise the set of projection equations will in general be inconsistent This is aggravated by the approximations involved in representing the continuous density in the object by a discrete set of samples Existing iterative methods of solution are unstable in these circumstances, though the SIRT algorithm has proved much better than the ART algorithm[3,4] The Extended Field Iterative Reconstruction Technique (EFIRT) presented here attempts to overcome this instability by performing the reconstruction on an extended field which is larger than the object Unlike any iterative technique so far described, this allows errors and inconsistencies to propagate outside the object domain in the reconstruction The extended field effectively provides a 'rubbish bin' for a large proportion of the noise, so that it does not spoil the region of interest The rationale for this approach comes from a Fourier analysis of the problem

We take the simple case of data collected by tilts about a single axis, so that reconstruction reduces to solving for a two-dimensional section from a set of line projections We denote the unknown sampled density values in the object by

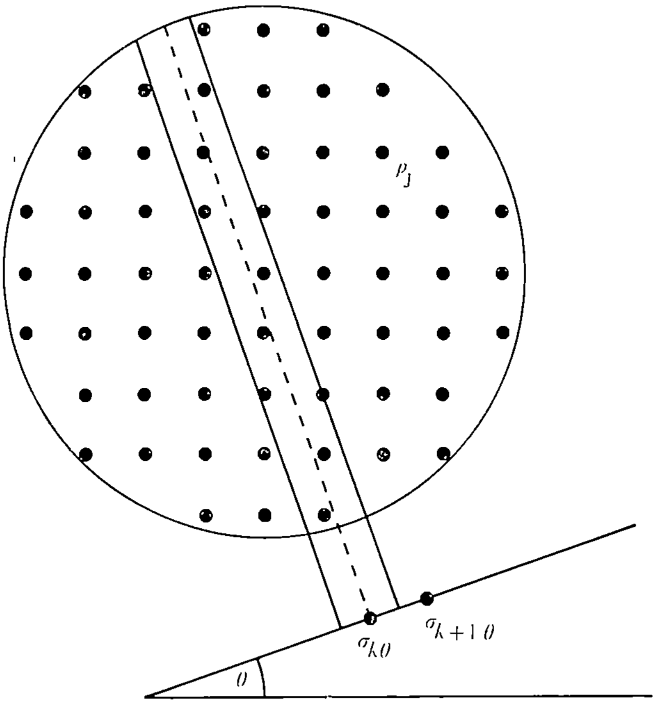

Fig 1 Densities ρ_j of the object are reconstructed from projection data $\sigma_{k\theta}$ The diagram shows the k^{th} ray for the projection at angle θ, which is used in calculating the ray sum $R_{k\theta}^{(q)}$ of the current approximation $\rho_j^{(q)}$ The number of sample points ρ_j included in the ray is $N_{k\theta}$ and the length of the ray within the circular object domain is $L_{k\theta}$ The width of the ray is equal to the spacing of the sampling lattice for the ρ_j

ρ_j and the total set of sampled projected densities by σ_i (Fig 1) The two sets of quantities are related by the projection equation

$$\sigma_i = \Sigma_j p_{ij}\, \rho_j$$

If a simple ray sum approximation is made, the elements p_{ij} of the projection matrix are 0 or 1 If some form of interpolation is used to express the density between sampled values ρ_j, the p_{ij} are fractions between 0 and 1 We assume the former simple approximation here

Initially all the density values $\rho_j^{(0)}$ are set equal to the mean density level in the object, which can be estimated from the projections We then generate successive approximations $\rho_j^{(q)}$ to the density using the formula[3]

$$\rho_j^{(q+1)} = \rho_j^{(q)} + (\sigma_{k\theta}/L_{k\theta} - R_{k\theta}^{(q)}/N_{k\theta}) \qquad (1)$$

Here $\sigma_{k\theta}$ represents the observed projected density at point k in the projection at angle θ, $R_{k\theta}^{(q)}$ represents the ray sum of the current approximation $\rho_j^{(q)}$ for the kth ray in the projection at angle θ, and $L_{k\theta}$, $N_{k\theta}$ are respectively the length of the ray lying in the object and the number of sample points ρ_j within it For a given j in equation (1), only one point k is included for each θ (Fig 1) It is used for all points in the first projection, then the second and so on until all projections have been used, completing one cycle of iteration Further cycles of iteration can then be made The use of equation (1) makes each ray sum $R_{k\theta}^{(q+1)}$ for the approximation $\rho_j^{(q+1)}$ equal to the observed projected density for the particular projection θ most recently used

The overall size of the object can be estimated from the given projections and we assume that it is contained within a circle of radius a If it is clear from the projections that the object is not isometric, some other choice of domain can be made The essential point of EFIRT is that we apply equation (1) not only to points within the object domain of radius a but to all points within a circle of radius b, say, where $b > a$ We thus have an annular region outside the object in which errors can propagate Initially the density $\rho_j^{(0)}$ is set to the mean density within the estimated object domain and to zero in the annular region In the iteration, those projected density values, $\sigma_{k\theta}$, which correspond to rays passing only through the annular region and not through the object, are taken to be zero

The density in the annular region arises from noise, inconsistencies and possibly 'fringe effects' due to the limited resolution obtainable from the finite set of projections and it need not therefore be positive Indeed, in general it will be equally positive and negative So the algorithm (1) must not be constrained to give positive density in the annular region, though the constraint can be applied within the object itself Clearly multiplicative algorithms, which correct each ray sum by multiplicative rather than additive scaling, are not applicable

With noisy data the use of this extended field leads to a great improvement in both the stability of the iteration and the quality of the resulting reconstruction From numerical experiments with a known test object and its projections, it is possible to tell how close the reconstruction is to the true object density after each iteration We express the root mean square difference in density between the reconstruction and the object as a fraction, δ, of the standard deviation of the density within the object Thus normalised, δ is a measure of how much closer to the object is the reconstruction, than would be a uniform distribution equal in value to the mean of the density in the object

The test object (Fig 2) consists of a set of uniform discs[3], whose projections are easy to compute analytically We have taken 25 equally spaced projections $(0 < \theta < \pi)$ The true projections are made noisy by adding at each point a pseudo-random number uniformly distributed in the interval $(-0\,1\bar{\sigma},\ 0\,1\sigma)$, where $\bar{\sigma}$ is the mean projected density In a second example each projected density is multiplied by a pseudo-random number from a Gaussian distribution with mean 1 0 and standard deviation 0 1 The course of the iteration is plotted in Fig 3 for the two examples We have held constant the radius a of the object at 12 sample steps and increased the radius b of the total field giving an increasing annular region for error propagation Shannon sampling corresponding to the Fourier cutoff $R_{max} = (25)/(\pi 2a)$ appropriate to 25 views[1] would give about 8 samples in the radius of the object, so the

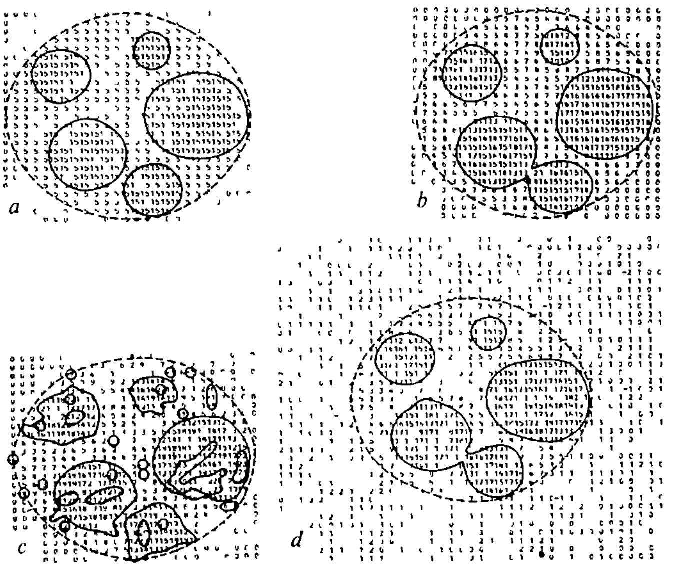

Fig 2 a, Model structure, consisting of a set of circular discs of uniform density, used for testing the algorithm The printout is compressed by 20% in the vertical direction giving a distorted appearance The reconstructions were made from 25 equally spaced projections to which 10% uniform noise has been added b, Reconstruction by R-weighted back-projection c, Reconstruction after 1 cycle of iteration with a non-extended field (b/a = 12/12) d, Reconstruction after 1 cycle of iteration with EFIRT (b/a = 24/12) Only part of the extended field is shown

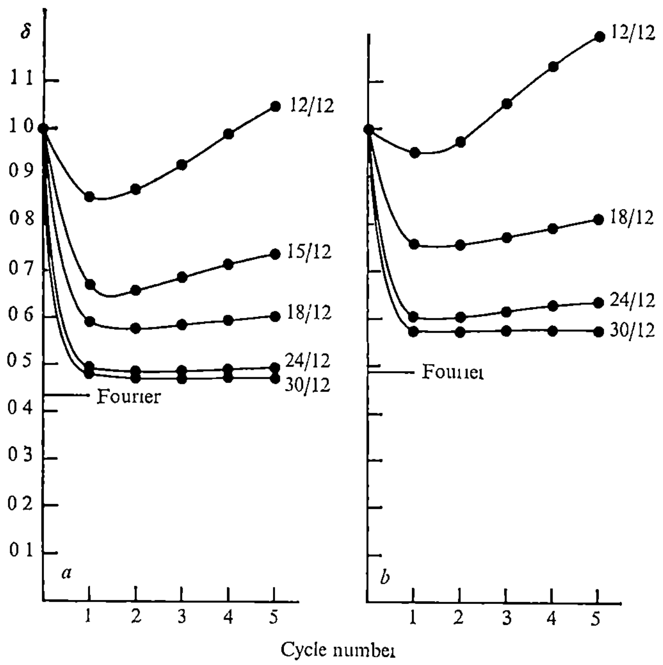

Fig. 3 The discrepancy δ (see text) plotted against the number of cycles of iteration of EFIRT, for the reconstruction of the object shown in Fig 2*a* from 25 projections containing noise The values of δ are computed using only those densities within the circle of radius *a* Each curve is for a different size of extended field as indicated by the value of *b*/*a* appended Also shown is the value of δ for a reconstruction made by a Fourier method, as described in the text In *a*, 10% uniform noise was added to the projections In *b*, 10% Gaussian multiplicative noise was included

sampling chosen is fairly generous Increasing the frequency of sampling to 18 in the radius produced only a slight improvement Presumably this is because the total number of grid points in the object domain is already about equal to the number of recoverable parameters set by the number of views[5]

When $b/a = 12/12$ and there is no annular region (so that we are essentially using the ART algorithm[2]), the value of δ falls slightly at the first iteration but thereafter increases rapidly giving rise to a reconstruction which bears little resemblance to the original The effect is of an increasing 'peppering' of the reconstruction (Fig 2*c*) But as the value of *b* is increased, the value of δ after the first cycle falls dramatically (Fig 3) Even a small extension of the field produces a significant effect Figure 2*d* shows the improved reconstruction obtained after one cycle when $b/a = 24/12$, again for the case of additive noise There is now density in the annular region outside the object Furthermore after the steep fall at the first cycle of iteration, δ tends to become more and more constant in successive cycles as *b* is increased (Fig 3) But increasing *b* beyond a certain size produces little extra improvement A similar behaviour was observed with other test objects although the effects were less marked when fewer views were used The extended field algorithm is so rapidly convergent that only one complete cycle of iteration is required, compared with about 15 cycles when using SIRT (ref 3) In spite of extra computation required when working with an extended field, the method is at least as fast as any other stable iterative method

Also indicated in Fig 3 are the values of δ obtained when the reconstruction is done by a Fourier transform method, in this case *R*-weighted back-projection[6,7] We perform one-dimensional transforms on the projections and weight[5,7] the frequency components by transform radius R out to a radius R_{max} and then by $(2R_{max}-R)$ out to a radius $2R_{max}$, where R_{max} is set by the number of views and the noise level We then inversely transform to produce a set of modified *R*-weighted projections The reconstruction is then made by back-projecting these modified projections The reconstruction from the data containing additive noise is shown in Fig 2*b* Although the values of δ obtained by this Fourier method are lower than the best δ achieved by EFIRT for both types of noise, the differences are probably not significant since the projection equations used in EFIRT were of the simplest type, without interpolation

Fourier analysis shows that besides the recoverable components giving density inside the object, there are a further set of recoverable components which build density outside the object[1,8] In the Fourier method[1], these external components are not explicitly calculated, but are implicit and serve to carry a certain part of the noise With perfect data from a spatially limited object, the external components will be zero and the set of projections can be completely interpreted, to a resolution set by the number of projections, in terms of the density within the object Once there is noise in the projections, the external components will be non-zero and the projections will no longer be completely interpretable in terms of density within the object In these circumstances, the projection equations set up for the object domain only, become inconsistent But by taking an extended field, which admits the possibility of building density outside the object, the equations become consistent and the convergence of the iterative procedure is stable and rapid Similar rapid and stable convergence was observed[2] when the ART algorithm was applied to pseudo projection data (when the ray sums $R_{k\theta}$ of the object are used in place of the true projected densities $\sigma_{k\theta}$), in which case the projection equations are again perfectly consistent, but this situation does not correspond to actual reconstruction from true projections

It is clear from Fig 3, that in these examples at least, most of the improvement to be gained by extending the field has already been obtained when the diameter of the total field is twice that of the object Further increases in the size of the field make only small changes to δ If all the external components were of equal weight, the annulus between *a* and 2*a* can be calculated from Fourier theory to contain about 75% of the external squared density It seems that in the examples considered here an even larger proportion of the total external density is contained in the annulus between *a* and 2*a* The optimal size of the extended field will almost certainly depend on the type of object being reconstructed and on the nature and amount of noise in the projections It is clear, however, that the extension of the field has a profound effect on the behaviour of the iterative procedure, and, contrary to what might have been expected, the prescription of the boundary of the object, far from being a useful constraint in solving the equations, is actually harmful

Effects of sulphur content on superconductivity and intercalation in transition metal disulphides

THE nearly two-dimensional character of the group IVB and VB transition metal dichalcogenides intercalated with organic molecules[1] makes the superconducting metals logical choices for the study of superconductivity in two dimensions Many anisotropic semiconductors could be used as electronic devices But scientific investigation has been restricted partly by the quality of available crystals A number of complexes are metastable at room temperature, and others deintercalate below 150° C Many intercalation compounds become greatly exfoliated so that measurements of single crystals become quite difficult Other crystals exhibit little or no registry between adjacent layers In one case—TaS_2 (pyridine)$_{1/2}$—two phases of intercalated material have been detected We have found that the addition of sulphur to the intercalate both orders and thermally stabilises the resulting complex The removal of sulphur by the intercalate increases disorder and thermal instability

A layered, transition metal dichalcogenide can be intercalated with an organic molecule (typically a Lewis base) if the dichalcogenide and organic material are brought together at a sufficiently high temperature In the intercalation complex the organic molecule resides between layers of the dichalcogenide In each case where intercalation occurs the supernatant organic liquid changes colour In the case of ammonia intercalations in disulphides the colours range from dark blue to yellow and red For other intercalations in disulphides, such as pyridine and aniline, the colour is dark brown to black These colours have been found to be a result of sulphur in the supernatant Sulphur forms coloured solutions with ammonia[2] and reacts to form long chain polysulphides with amines[3] We have found that sulphur, dissolved in the various intercalates and heated to the intercalation temperature, forms a colour which is characteristic of intercalation at that temperature Comparison of the ultraviolet with the visible spectra has verified the presence of sulphur in the supernatant

Two experiments have been undertaken to determine the importance of the effect of sulphur on the intercalation product First, some crystals of TaS_2 were repeatedly intercalated with ammonia until the supernatant remained clear These crystals were then intercalated with pyridine Second, a number of crystals were intercalated from pyridine saturated with dissolved (molten) sulphur The results measured by the thermogravimetric analysis of deintercalation, are shown in Fig 1 From these data it is apparent that the TaS_2 (pyridine)$_{1/2}$ intercalated once from pure pyridine is a two-phase material, that preintercalation with ammonia produces the low temperature phase, and that intercalation with excess sulphur produces the high temperature phase

X-ray powder diffraction has shown that two layer spacings are associated with the two-phase material, 12 01 Å and 11 85 Å The phase that deintercalates at 100° C is a single-phase with $c=2\times 11\ 85$ Å and that which deintercalates at 300° C is single-phase with $c=2\times 12\ 01$ Å There is a qualitative difference between the diffractograms the 12 01 Å phase has very sharp lines characteristic of a highly ordered crystal, whereas the 11 85 Å phase has broad, rather diffuse lines, giving evidence of considerable disorder Thus, intercalation of pyridine from a saturated solution with sulphur produces a material with greater thermal stability, a larger c axis, less disorder, and little or no exfoliation

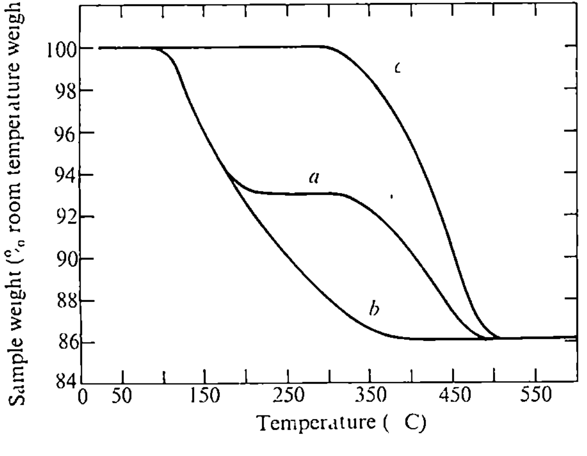

Fig. 1 Thermogravimetric analysis during deintercalation for three types of TaS_2 (pyridine)$_{1/2}$ *a*, intercalated from neat pyridine, *b*, preintercalated with ammonia—deintercalation is complete at 100° C, *c*, intercalated from a mixture of sulphur and pyridine—deintercalation occurs at 300° C

The addition or removal of sulphur also influences the electronic and magnetic properties of intercalation complexes Fragile, exfoliated crystals of TaS_2 (pyridine)$_{1/2}$ which are preintercalated with ammonia exhibit unusual anisotropies in the electrical properties at low temperatures[4] These same crystals have a superconducting transition temperature that is higher than that of crystals intercalated with excess sulphur We believe[5] that the rise in T_c in intercalated TaS_2 is related to the suppression of the low temperature crystal distortion and to non-stoichiometry on the metal rich side

Results which are essentially identical to these have been obtained from TaS_2 and TiS_2 intercalated with aniline Previously, only one phase had been observed in TaS_2 (aniline)$_{3/4}$ with a c axis parameter of 18 15 Å Intercalation from a sulphur-rich aniline solution produced an increase in c to 18 32 Å, with a corresponding increase in deintercalation temperature from 75° C to 150° C The increase of 0 17 Å in the c axis dimension is very similar to the value of 0 16 Å obtained with pyridine The sulphur-rich TaS_2 (aniline)$_{3/4}$ material also proved to be less exfoliated

Intercalation normally proceeds more slowly in the presence of excess sulphur, but in the case of TaS_2 (pyridine)$_{1/2}$ the intercalation time is doubled by the addition of sulphur The intercalation temperature seems to be correlated with the temperature at which sulphur reacts with the intercalate, thus, pyridine and sulphur do not react noticeably at room temperature, but form a dark brown-black, viscous liquid at 200° C This reaction has been attributed to the formation of polysulphide chains on the pyridine[3] A number of other intercalates have been tested (butylamine, N,N-dimethylaniline, and thiobenzamide) with similar results For example, butylamine intercalates in TaS_2 at room temperature and there it forms a black viscous liquid with excess sulphur

Only small amounts of sulphur are removed from the crystal during intercalation In several ammonia intercalations the amount was too small to weigh accurately and was certainly less than 1% of the total weight of the sample Sample intercalated in the presence of excess sulphur exhibit essentially the same increase in weight as materials intercalated with pure intercalate Thus, any mechanism involving the transport of one sulphur atom per intercalated molecule must be rejected

Hsu *et al*[6] have found that 4-vinyl pyridine can be intercalated in TaS_2, and that the thermal stability of the final product depends on the conditions of preparation They showed that the product obtained from preintercalation with aniline is less stable than the material prepared at 140° C from 4-vinyl pyridine and *p*-methoxyphenol (a polymerisation inhibitor) They claim that the increase in stability results from the *in situ* polymerisation of the 4-vinyl pyridine We find it more probable that they have produced two phases of the TaS_2 (4-vinyl pyridine)$_{1/4}$ complex, analogous to those reported here The addition of sulphur has the same effect on monomeric intercalations as does polymerisation they both increase the thermal stability

I thank F R Gamble and M D Dines for discussion, and R Pisharody for taking some of the optical spectra

Thin films from liquid crystals

THE properties of thin film drawn from liquids into air have been determined in many investigations[1–3], because the films form suitable systems for testing the theory of colloidal stability[4,5] Recent results have provided an improved understanding of the state of the aqueous layer of the film[6,7]

Films from liquids containing surfactants display stratification in the last stages of thinning[8], and the presence of a liquid crystal enhances foam stability[9] These facts have illustrated the structural connections between a thin film and the repeated lamellar unit in a liquid crystal[10] The lamellar liquid crystal itself has been used repeatedly as a model for the bimolecular layer of biological membranes The results[11] on the specific influence of the distance between layers in a lamellar liquid crystal on the diffusion coefficient of sodium and chloride ions, have further increased the interest in the structural relationship between lamellar liquid crystals and thin films with a bimolecular structure

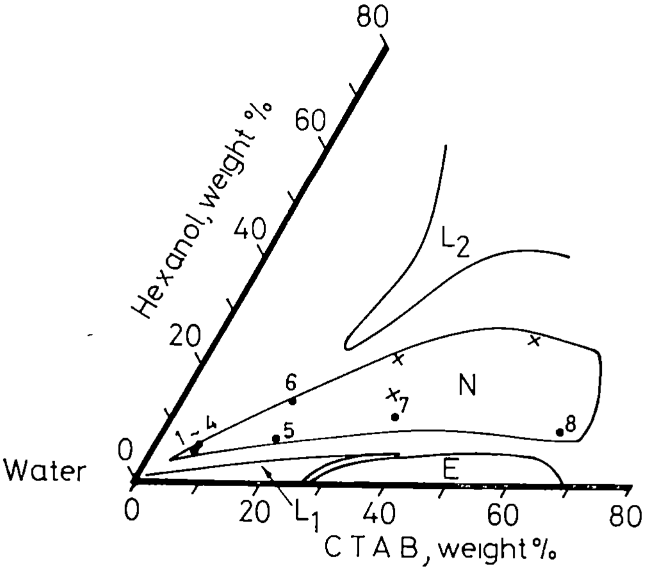

Fig 1 The composition of the liquid crystal samples (1–8) from which a thin film was drawn Crosses, compositions which did not give stable films, L_1, L_2, regions for isotropic liquid solutions, N, region of a 'neat phase' liquid crystal, E, region of 'middle phase' liquid crystal[12]

Previous investigations of these phenomena have, however, been concerned with comparisons between structure in thin films from liquids, and the dimensions in lamellar liquid crystals[10] We here report the first experiment in which a thin film has been drawn directly from a lamellar liquid crystal

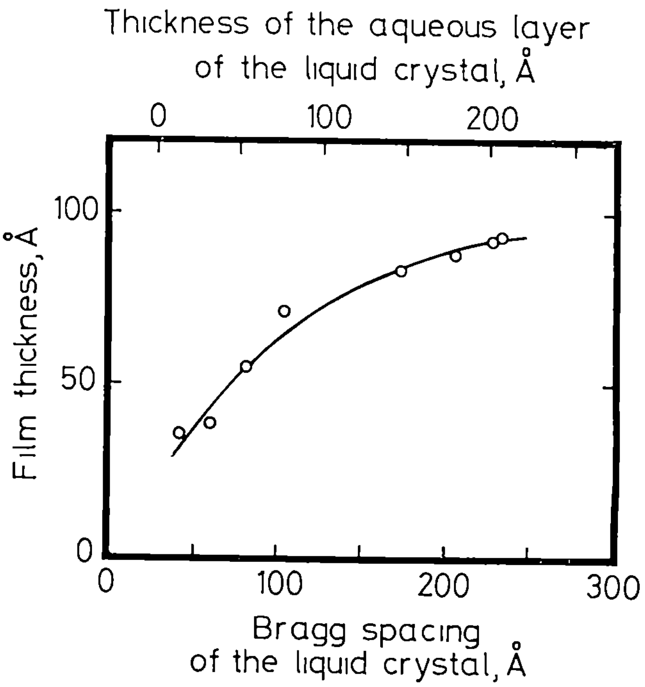

Fig 2 Thickness of the thin film against the dimension of the lamellar unit of the liquid crystal from which the film was drawn

A glass frame was used and the film was drawn slowly from the neat phase with known spacings[12] in the system water, cetyl trimethylammonium bromide (CTAB) and hexanol (Fig 1) The thickness of the film did not decrease gradually like a film from a liquid, but reached the black film state discontinuously from large thicknesses Consequently, in the calculation of thickness the Rayleigh equation had to be applied directly after determination of the intensity of the laser beam The results will be less accurate than those obtained using a combination of the intensity from the silvery and the black film The com-

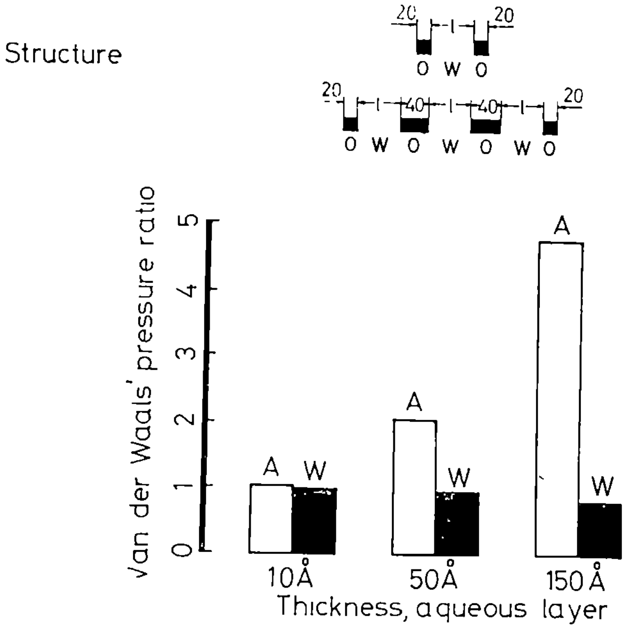

Fig 3 The ratio between structures I and II of the Van der Waals pressure over the central aqueous layer W (upper part of the figure), water layers, the thickness of which was varied according to the lower part of the diagram White columns denoted by A imply infinite layers of air outside the outer oil layers, black columns represent corresponding water layers

parison of the value from the two methods for a thin film from a solution gave, however, a difference of less than 3% The thickness was corrected according to Frankel and Mysels[13]

The results show that the film was thinner than the corresponding distance in the liquid crystal This difference became more marked as the thickness of the lamellar unit increased (Fig 2) One reason for this behaviour was found in the change in Van der Waals pressure when the adjacent layers in the liquid crystal were replaced by air to give the thin film The pressure over the central aqueous layer was calculated using the Lifshitz approach[14] with the extensions and approximations of Parsegian[15] Increase of the Van der Waals pressure over the central layer occurred when three bilayers were reduced to one, pressure increased rapidly with the thickness of the layer (Fig 3) The pressure change when the number of layers was increased from three to higher numbers was negligible

A thin film in water gives a slight decrease of the Van der Waals pressures in the last stages of thinning (Fig 3) and the liquid crystal in the water did not thin

Our results show that the liquid crystal may well serve as a good model for a thin film surrounded by water, in air the usefulness seems to be limited to films which have a central aqueous layer less than 50 Å thick The use of a lamellar liquid crystal as a model to clarify the structure of biological membranes thus seems justified

Excess ^{26}Mg in the Allende Meteorite

VARIATIONS in the isotopic abundance of magnesium (78 6% ^{24}Mg, 10 1% ^{25}Mg, 11 3% ^{26}Mg) have been sought[1,2] in meteorites because of the possible addition of radiogenic ^{26}Mg by the decay of ^{26}Al This short-lived nuclide (half-life 7 4×10^5 yr) is formed by proton bombardment of light elements[3] and is of particular interest in theories of nucleosynthesis and heat generation during the early history of the Solar System Analysed material must have a high Al/Mg ratio to avoid the dilution of any radiogenic ^{26}Mg by common Mg Consequently, previous workers have chosen mainly feldspars from basaltic achondrites and metamorphosed chondrites The apparent absence of excess ^{26}Mg in such meteorites is, however, not surprising, because the condensation of chondritic material from the solar nebula now seems[4] to predate its later metamorphism by some 80 Myr, and the magmatic activity that produced the basaltic achondrites is younger still Thus, the feldspars that formed as a result of these processes would incorporate aluminium that was separated from a nucleo-synthetic event by at least 80 Myr and because of its short halflife insufficient ^{26}Al would remain to generate a detectable ^{26}Mg anomaly

A new possibility for the generation of magnesium isotope anomalies has arisen from the discovery by Clayton *et al*[5] of excess ^{16}O in the Allende Meteorite, and from

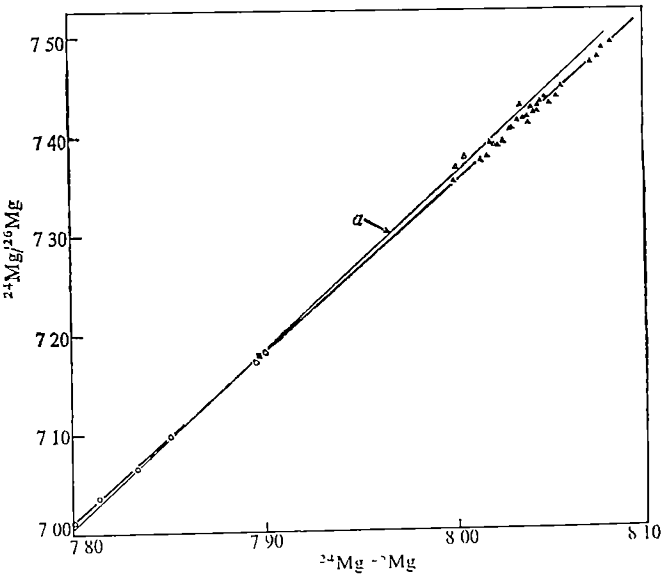

Fig. 1 ^{24}Mg/^{26}Mg against ^{24}Mg/^{25}Mg as measured by silica-gel[2] (open triangle) and triple-filament[7] (open circle) runs for the same terrestrial pyroxene, the runs were chosen to show extreme isotopic fractionation *a*, One stage Rayleigh fractionation, solid square, absolute value The mass spectrometer was a single focusing, 23 cm, 60° sector machine designed for high ion transmission[10], with magnetic field switching, Faraday cup collection and a calibrated digital readout for the electrometer Peaks other than ^{23}Na and ^{27}Al were never observed in scans of up to 10 mass units above and below ^{24}Mg, so that spectral interference from hydrocarbons and doubly charged ions can be discounted Data were collected when the ^{24}Mg beam current was within the range 5×10^{-12} and 5×10^{-11} A Each point in both Figs 1 and 2 comprises the mean of a set of fifteen ^{24}Mg/^{26}Mg ratios and the combined mean of one preceding and one following set of fifteen ^{24}Mg/^{25}Mg ratios The data are dispersed because of isotopic fractionation produced by diffusion and evaporation during the ionisation processes in the mass spectrometer Only silica-gel runs were made with the meteoritic samples, as this mode of ionisation is far more sensitive Sample sizes were of the order 1×10^{-6} g Mg, and laboratory contamination was approximately 7×10^{-9} g, mainly from the silica gel, which caused a maximum correction of 0 03% to two runs on chondrule 1 Magnesium was separated from the samples by standard silicate dissolution procedures followed by cation exchange in HCl

their prediction of possible excess ^{24}Mg derived from stellar nucleosynthesis

The Ca–Al-rich chondrules in the Allende Meteorite are the oldest objects known[4] They are comparable chemically to the initial condensates from the solar nebula[6], and their age, chemistry (high Al/Mg ratios) and unmetamorphosed character make them promising candidates in the search for radiogenic ^{26}Mg

Variations in the isotopic composition of magnesium may result from mass-dependent fractionation in physical and chemical processes, and from nuclear effects Mass-dependent fractionation is unknown in nature, but it occurs in the mass spectrometer used for isotopic ratio measurement That, and the variation with time during mass analysis, make the determination of absolute isotopic ratios exceedingly difficult The changes in the various magnesium isotopic ratios observed during measurement are, however, correlated with each other, because of the essential mass-dependence of the isotopic fractionation process Measured isotopic ratios from runs on a terrestrial pyroxene illustrate the effect (Fig 1) All points fit the same line even though two different methods of ionisation were used, and 'absolute' magnesium isotopic ratios[7] also fit It is curious that the slope of the line, 1 695±0 013 (σ), from the pooled data of all runs including those on meteorite samples, is less than the calculated slope for the single stage Rayleigh distillation (1 79 for Mg) that is usually fitted by the isotopes of other elements That can be attributed, however, to the operation of a multistage fractionation process A sample with an excess of one or more magnesium isotopes because of a nuclear effect would also define a line of the same gradient, but it would be displaced from the terrestrial line Thus, a nuclear isotopic anomaly can be detected despite the effects of variable isotopic fractionation during mass analysis Furthermore, a numerical correction for fractionation can be made by adopting an arbitrary standard value for one of the magnesium isotopic ratios, for instance, ^{24}Mg/^{25}Mg, and calculating the so-called 'normalised' value for ^{24}Mg/^{26}Mg by translation along the fractionation line In the case of magnesium it is essential to use the empirical slope, 1 695

We have analysed a melilite-bearing chondrule[8] (1) comprising large melilite crystals in a matrix of very finely crystalline grossularite, an aggregate[8] (2) containing spinel and enstatite, and an aggregate[8] (3) containing spinel and diopside It was not possible to remove all of the adhering matrix from the last sample, and the analysed material includes some foreign magnesium

Minerals were identified using X-ray powder diffraction Interpretation of the photographs was, however, difficult and unrecognised phases are doubtless present Chemical analyses by electron microprobe are given in Table 1

Table 1 Chemical composition of Allende inclusions

* Electron microprobe analysis of a fused 2 mg sample

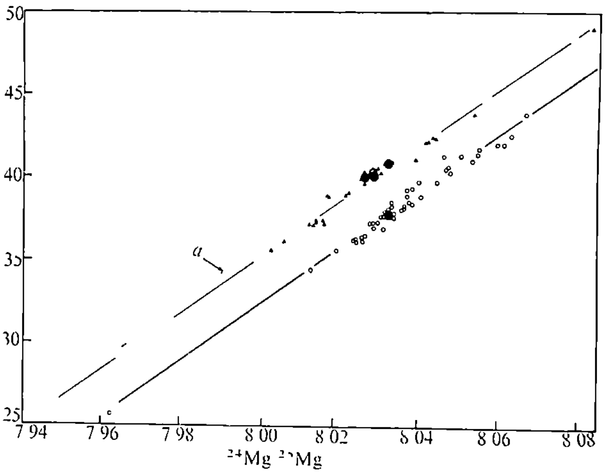

Fig 2 ^{24}Mg/^{26}Mg against ^{24}Mg/^{25}Mg for the four runs (Table 2) of the anomalous chondrule 1 (open circles) compared with the three runs on Px 5415 (open triangles) *a*, One stage fractionation, solid circles, average for 'unfractionated' runs The points for chondrule 1 define a separate fractionation line lower than the pyroxene line in ^{24}Mg/^{26}Mg but with the same mean ^{24}Mg/^{25}Mg All other data in Table 2 fit the pyroxene line

All but one of the analysed samples has a terrestrial isotopic composition The anomaly in chondrule 1 (Table 1) can be displayed on a plot of measured isotopic ratios (Fig 2) which compares data for the chondrule with those from a terrestrial sample The data for the chondrule fit a fractionation line that has a slope identical to the terrestrial line (respectively, 1 70±0 04 and 1 68±0 02) but is displaced from it towards lower ^{24}Mg/^{26}Mg Thus we have detected a nuclear effect in the magnesium isotopic composition of chondrule 1

Five out of fifteen runs showed no variable isotopic fractionation They are termed 'unfractionated' in Fig 2 although they are clearly biased with respect to the Catanzaro[7] 'absolute' values For these runs, as well as for the means of the fractionated runs, the ratios ^{24}Mg/^{25}Mg are all nearly the same This fact strongly implies that the principal component of the nuclear effect in Fig 2 is undoubtedly an excess of ^{26}Mg The entire effect may result from the addition of a pure ^{26}Mg component to common magnesium Our data do not, however, exclude the possibility that very small amounts of ^{25}Mg and/or ^{24}Mg may be present in the added ^{26}Mg-rich component as well The ^{24}Mg/^{25}Mg ratio of this hypothetical magnesium could be greater or less than in terrestrial magnesium

Because any difference between the ^{24}Mg/^{25}Mg ratios of chondrule 1 and common magnesium is so small, the results can be described by normalising values of the ^{24}Mg/^{26}Mg ratio to a fixed ^{24}Mg/^{25}Mg value For that we have chosen our mean measured ^{24}Mg/^{25}Mg (8 03) rather than the 'absolute' value thus minimising the shifts which result from normalisation and also any error resulting from uncertainty in the slope of the fractionation line (Table 2) The terrestrial isotopic composition was determined in two pyroxenes, six runs giving a mean ^{24}Mg/^{26}Mg ratio of 7 404±1 The most precise of the runs seems to be an outlier (Px 5414 R2) but there are no grounds for its rejection Measurements on the total Allende Meteorite fall into the range of the terrestrial population (mean 7 406±1) as does that for aggregate 2 (7 406±2) The mean ratio for aggregate 3 (7 402±1) is slightly lower than the terrestrial value and may be anomalous, although it is matched by the outlying terrestrial measurement Two separate dissolutions of chondrule 1 were both analysed twice and the results agreed excellently The mean value of (7 374±1) is quite distinct from the terrestrial range, indicating a 0 41% anomaly

There are very obvious needs to find anomalous magnesium in other Allende inclusions, to find the particular mineral phase(s) which bears the anomaly, and to relate the magnesium anomaly to the excess ^{16}O found by Clayton *et al* [5] Nevertheless, some conclusions can still be drawn First, because of the constant ^{24}Mg/^{25}Mg ratio, it is likely that the magnesium anomaly of chondrule 1 results entirely from excess ^{26}Mg, and this in turn implies strongly an origin by the radioactive decay of ^{26}Al formed during intense proton irradiation in the early stages of the Solar System As the ^{26}Al must have been made within the Solar System because of its short halflife, then it is likely that the excess ^{16}O in the Allende Meteorite and also other short-lived nuclides such as ^{129}I (ref 9) were formed within the Solar System, rather than outside it[5] Second, the absence of a comparable magnesium anomaly in the other two chondrules can be attributed easily to their law Al/Mg ratio (Table 1) This strengthens the idea that the anomaly results entirely from radiogenic ^{26}Mg On the basis of a 0 4% excess of ^{26}Mg for chondrule 1, excesses may be expected of 0 08% and 0 05% for aggregates 2 and 3, respectively, from their Al/Mg ratio, of which the 0 8% excess may just be detectable (compared with 0 035% for the coefficient of variation of the six pyroxene runs) If the failure to detect an anomaly in aggregate 2 is not because of insufficient data, two other possibilities may be suggested the introduction of common magnesium after the assembly of the Allende Meteorite (alkalis have been added to many such chondrules, particularly to aggregates, after more than 10^9 yr[4]), or the condensation of much of of the material of inclusion 2 at a later time than that of chondrule 1 Finally, we note the value $3\ 8 \times 10^{-5}$ that may be calculated for the ^{26}Al, ratio in condrule 1 at its time of chemical isolation That may be related to the radioactive heating of planetesimals[2] and provided that accretion occurred immediately after the formation of ^{26}Al, it is more than sufficient to account for the heating to metamorphic temperatures of chondritic planetesimals

Magnetic telechemistry is elegant but nature is complex

VOGT and Johnson[1] have suggested that the bulk chemistry of *in situ* abyssal basalts may be diagnosed using sealevel magnetic anomalies Their suggestion is based on two sets of assumptions and observations

First, they assume that the concept of mantle 'plumes'[2,3] is a valid way of explaining the existence of selected oceanic island platforms and other positive elements on the sea floor, and that 'plumes' are associated with increased magnetic anomally amplitudes

The second assumption is that the observed increases of magnetic anomalies which are associated with the Galapagos positive element, or 'plume', result from a relative increase in Fe and Ti concentrations The assumption is based on a comparison between published chemical data and anomaly amplitudes for the Juan de Fuca and Gorda ridges

In contrast to Vogt and Johnson's assertion, however, oceanic platforms (the most idealised surface expression of 'mantle plumes'), or 'hot spots'[1,5], do not generally have magnetic anomalies of significantly higher amplitude A characteristic of most island platforms is the general loss of the high amplitude linear magnetic anomalies which are normally caused by dyke injection during seafloor spreading[6,7] This is probably because the extrusive igneous activity increases relative to intrusive activity during the formation of the island platform, the process also involves hydro-explosions[8] as the platform becomes shallower than 500 m (ref 9) A probable concurrent loss of a regular stress field also occurs, because of the mass of the platform on the seafloor[10] Vogt and Johnson recognise that problem they comment that magnetic anomalies above the Cocos Ridge and Carnegie Ridge, associated with the Galapagos 'Plume' are low amplitude So they invoke the local existence of non-magnetic layers of tephra, and layers with opposing (cancelling?) polarities Similarly, Campsie *et al* [3] have suggested that these ridges may be chemically composite partly 'plume' and partly normal oceanic ridge materials These special arguments detract

[illegible] SCIENCE COLLEGE

severely from Vogt and Johnson's idea Their high anomaly–mantle plume association is based on high and low magnetic anomalies observed over the Juan de Fuca and Gorda ridges, respectively, which they claim are 'plume' and 'non-plume' material, respectively An equally feasible explanation is that the standard deviation of the width of the zones of active dyke injection[6 7 11] is narrower for the Juan de Fuca Ridge than it is for the Gorda Ridge

Although there is a direct relationship between the FeO content (%) of dredged samples and the amplitudes of the magnetic anomalies for the Juan de Fuca Ridges (ref 1 Fig 2), there is no increase in the amplitudes of the anomalies over the Iceland 'plume' despite the high Fe and Ti content in the dredged rocks The absence of expected correlation is attributed to an 'anomalous' situation "increasing ash content and lava fracturing at low hydrostatic pressures" This does not, however, prevent Vogt and Johnson from using chemical data from the Rekjanes Ridge[12] in order to extend their idea to a possible inference of several different elemental concentrations

Although Vogt and Johnson clearly state their assumptions, much evidence exists to show that a constant Fe/Ti ratio could not be maintained reasonably during an unequal increase in the total concentrations of FeO and TiO_2 in basalt Variation of the intensity of magnetisation, *J*, within the $FeO–Fe_2O_3–TiO_2$ system[13], shows that factors such as oxygen fugacity, degree of quenching, and oxyexsolution, are much more important controls of *J* than simple FeO and TiO_2 concentrations[14 15], unless order of magnitude differences are involved Of major importance is the fact that the Curie point decreases to below room temperature with increasing TiO_2 content and decreasing oxidation state of Fe, thus rendering as minimal the prospects of high remanent *J* in such rocks Magnetic stability (which depends primarily on magnetic grain size[14,16]) is also important if it is absent, then no reversed polarity would persist and the essential polarity variation required for the production of high amplitude anomalies would not occur Unless of single domain size, Fe is quite unstable, and so an increase of Fe alone would not necessarily contribute to an increase in anomaly amplitude For Johnson and Vogt's proposal to be correct, it would (as they state) be necessary for 'plumes' to generate greater amounts of titanomagnetite, with relatively unvarying Fe/Ti ratios, and grain sizes But these parameters are to a large extent a function of the cooling rates of the igneous bodies involved, so it seems very unlikely that they would remain constant between those bodies which constitute abyssal crust and oceanic platforms, which have inherently different modes of emplacement Different modes of igneous emplacement alone can vary drastically the amplitude of magnetic anomalies[10], and as primary chemical properties do not depend on the mode of emplacement, there is no reason whatsoever to believe that they are the controlling factors in the character of all magnetic anomalies

Despite the elegance of Vogt and Johnson's idea, I suggest that insufficient rigour had been applied to the concept of magnetic telechemistry

DRS VOGT AND JOHNSON REPLY We re-emphasise that we never attributed all of, or even most of, the amplitude variations of oceanic magnetic anomalies to the chemistry of basalt We simply proposed that chemistry does play a role in certain areas and should not in any case be ignored as a possible factor Even if the hypothesis explains only three areas of high amplitude anomalies[1] this amounts to about 8×10^5 km^2 of oceanic crust, certainly more than a very restricted marine geological circumstance

At the outset Watkins wrongly asserts that 'magnetic telechemistry' is based on the acceptance of 'mantle plumes' But the connection between high magnetic anomalies and high Fe–Ti concentration never depends on whether the geochemical anomaly is the result of differentiation in the uppermost mantle[2] or on whether there are two distinctive 'primary' (Fe–Ti rich) and 'depleted' magmas in the mantle[3] The hypothesis does not depend on the fixed position of the hot spots with respect to the Earth's spin, nor on whether there is deep rising convective motion below the hot spots[4] But areas of high magnetic anomaly are found in association with some hot spots, and so the two phenomena are apparently related

Hot spots can be 'Icelandic' (close to spreading axes) or 'Hawaiian'[5], only Icelandic hot spots can have a 'telechemical' signature The topographically positive element of Icelandic hot spots really consists of at least two parts First, there is an aseismic ridge or platform, or volcano chain, distinctly, and relatively sharply, elevated above the surrounding oceanic crust Examples are the Cocos, Carnegie, and Iceland–Faeroe ridges and the seamount chains extending north-westwards from the Juan de Fuca Ridge These ridges represent, in the stationary hot spot hypothesis, trajectories of plates over the deeper mantle Such ridges are constructed at least in part by 'Hawaiian' igneous activity extrusive and intrusive activity away from the spreading axis If some sort of spreading is involved in their creation, it is of a more complicated variety Surely this is so on Iceland These ridges usually involve an oceanic crust thicker than normal Perhaps as a result of these differences, many aseismic ridges have confused magnetic signatures of relatively lower magnetic amplitude There are obviously factors other than basalt composition involved, and there was never any reason to expect that an unqualified telechemical hypothesis could explain the magnetic signatures of the Cocos, Carnegie, Iceland–Faeroe, and similar ridges or platforms These aseismic ridges are simply another and more complicated form of oceanic crust, but are distinct as far as magnetic anomalies are concerned

The second part of the topographic anomaly is a broad, smooth, regional elevation in the spreading axis and older isochrons It is here that we observe, at least in some cases, regions of unusually high magnetic anomalies of seafloor spreading origin Parts of these regional bulges are also characterised by relatively smooth basement and reduced seismicity, but whereas the aseismic ridge *sensu strictu* is sharply demarcated, this broader bulge is not In the Iceland area the

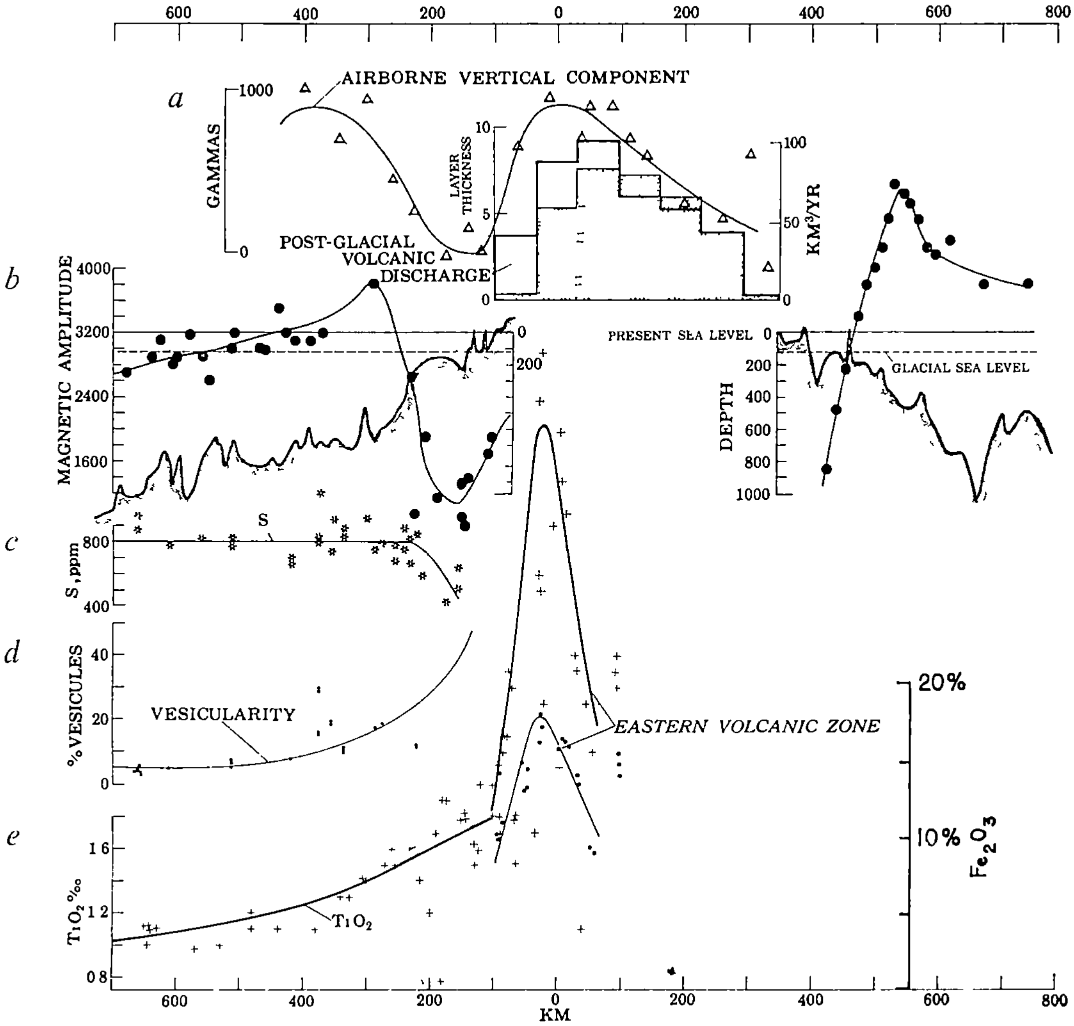

Fig 1 Chemical and physical parameters plotted against distance from the centre of the Iceland plume along the axis of spreading North-east to the right *a* Triangles, maximum vertical component[10] magnetic anomaly relief (axial high to negative west of it along Reykjanes Ridge), heavy line histogram, postglacial volcanic discharge (km^3 yr^{-1}), (ref 8) *b*, Axial magnetic high of the western negative (from the shipborne profiles[11,15], *c*, sulphur content[6], *d*, vesicularity[6], *e* Fe_2O_3 (filled circles), and TiO_2 (crosses) along the Reykjanes Ridge[3] and eastern neovolcanic zone of Iceland[8] Bathymetric profile along the axis was constructed from United States Naval Oceanographic Office charts Note the approximate correspondence in peaks of TiO_2, Fe_2O_3, discharge, and the maximum vertical component of the magnetic anomaly Where these quantities peak may mark the plume centre There is a sharp drop of anomaly amplitude as the spreading axis rises to within less than about 400 m of sea level This may reflect increasing oxidation states of titanomagnetites as volatiles are lost at low pressures[16], as evidenced by the high vesicularity[7] and low sulphur[7] in the same region Between 300 and 700 km south-west and 550 to 750 north-east the systematic variation in the anomalies is primarily the result of varying source depth

regional bulge extends southward through the Reykjanes Ridge to the Gibbs Fracture Zone, some 2,000 km from the centre of Iceland, it seems to extend a similar distance northwards The Greenland–Iceland–Faeroe Ridge, although concentric with the broader bulge, is an order of magnitude narrower Similarly, the Cocos and Carnegie ridges are only 50–100 km wide whereas the topographic bulge of the Galapagos Ridge, centred north of the Galapagos Islands, extends 500–600 km westwards, and eastwards and is up to 500 km wide at the longitude of the islands The Juan de Fuca Ridge is 500 km long, much more extensive than the width of seamount chain(s) terminating near its axis

The Iceland area (Fig 1) is, Watkins claims, another 'exception' to our hypothesis In fact, the Mid-Oceanic Ridge rises above sea level there, and there was no *a priori* reason to expect magnetic anomalies not to be affected It has been known for a long time that the magnetisation of subaerial and suboceanic basalts is quite different, even if initial magma compositions were identical Beginning at depths of 500 m or so, and increasing at shallower depths, vesicularity and explosiveness of the lavas increase as they erupt under lower confining pressures The greater fracturing and ash content would decrease the bulk magnetisation of the oceanic crust[1], degassing at vesicularities above 15% (~500 m depths) results in reduced sulphur concentrations[6] High *J* values of oceanic pillow basalt are possible because rapid quenching allows the retention of volatiles and the maintenance of titanomagnetites in low oxidation states[7] As the Reykjanes Ridge shoals toward sea level, volatiles are lost (Fig 1) and there is every reason to expect magnetic amplitudes to decrease The observed dramatic decrease in amplitude of the axial anomaly as the spreading axis shoals toward Iceland (Fig 1) means, if our telechemistry argument[1] is valid[4], that the degassing effect overpowers the opposing effect expected from the increasing[3,8] Fe and Ti content Fluctuations in Pleistocene sea level would have smeared out the decline in magnetic amplitudes beyond that expected from sampling only post-glacial basalts Glacial erosion could also have removed some of the magnetised layer

Unfortunately, the Ti and Fe concentrations decrease linearly south-westwards, away from Iceland so steeply that there is only a small section of the Reykjanes Ridge deeper than the degassing depth (as defined by reduced S concentrations) but still anomalously high in Ti and Fe In that small section Ti and Fe are only slightly above the normal levels occurring further south on the Reykjanes Ridge, and any increase in anomaly amplitude in that small section may be within the noise level The observed increase of amplitude as Iceland is approached from either side seems to be accounted for largely by the changing source depth We are investigating this

As degassing should not, in general, affect concentrations of rare earths, trace and minor elements such as Fe and Ti, and as the Reykjanes Ridge is the only geochemically anomalous region for which detailed data exist, we adduced the Reykjanes chemical data[3] in support of our hypothesis, in spite of the absence of high magnetic amplitudes This absence does not demand a new *ad hoc* hypothesis on our part nor is it an additional latitude as construed by Watkins[9] In fact, low pressure degassing is a second kind of 'magnetic telechemistry', which reduces J and therefore magnetic amplitudes It is uncommon because the mid-oceanic spreading axis rarely approaches within 500 m of sea level.

Watkins implies that the differences on magnetic amplitude observed in the Galapagos, Juan de Fuca and Pacific-Antarctic areas[1] are perhaps explained more plausibly by differences in thickness of the magnetised layer, mode of emplacement, oxygen fugacity, degree of quenching, and oxyexsolution The thickness of the magnetised layer is not measured readily as its meaning in terms of seismically determined crustal structure is still somewhat obscure[11] In any case, there is no evidence that the crust in the anomalous areas discussed is thicker than elsewhere We are talking about regional bulges of oceanic crust produced by simple spreading, not about aseismic ridges with thickened crusts If a thicker layer provides the explanation, deep tow magnetic/seismic profiling would reveal the same apparent magnetisation of minor basement features in both areas But profiles collected in the Galapagos area show that the high-amplitude region has more intensely magnetised basement irregularities[11], and Fe/Ti basalt also has higher J values in the few dredge samples available[11] Basement depth is generally continuous across the regional boundary, and both kinds of lavas are exposed to the same physical environment when they erupt There seems no reason to postulate that the other factors cited by Watkins are necessarily important variables but it is also hard to show that they are not The advantage our telechemical argument has is that chemical differences have been reported from all hot spots so far studied

Differences in the mode of emplacement cannot be discounted entirely, especially in the case of the Juan de Fuca Gorda ridges with their different morphologies and different levels of seismicity[12] If the zone of active igneous activity is broader, anomaly amplitudes fall, and the resolution of short-period reversal events deteriorates[13,14] It is doubtful, however, whether this mechanism could explain the uniform amplitude difference between the Jaun de Fuca and Gorda ridges In the Galapagos area, no such deterioration is evident and the width of the 'variable dyke zone' hypothesis seems quite unlikely

So until a more plausible hypothesis is advanced, we stick with magnetic telechemistry This does not mean that the two regions (of high and average amplitude respectively) are likely to differ only in their bulk chemistry Nor does it mean that magnetic amplitudes are necessarily a linear function of Ti and/or Fe For example, if the rate of increase of magnetisation decreases with increasing iron content, then relatively uniform, high amplitude provinces, within which there is substantial geochemical variation, would result Should the analysis of rock samples demand such a complex relationship between chemistry and magnetic anomalies—possibly involving additional 'hidden' variables—it would in no way demolish our hypothesis

The reaction of monkeys to 'fearsome' pictures

THE phenomena a man or animal most needs to know and understand must often be potentially dangerous or discomforting We report here evidence that monkeys, given the opportunity to look at a picture which excites both interest and fear, choose first to look at it and only later, once their interest has abated, to avoid it

We have measured the preference for a visual stimulus by allowing the monkeys to choose between looking at the test stimulus and a blank white screen of the same subjective brightness In earlier experiments[1,2] we found that the response to an informative but affectively neutral stimulus, for example a repetitive loop of cartoon film, was typically an initial strong positive preference which declined within a few hundred seconds to relative indifference By contrast, the response to an uninformative but unpleasant stimulus, such as a plain field of red light, was a strong and stable aversion When a stimulus was both informative and unpleasant, for example a black and white film loop projected through a red filter, the monkeys' 'interest' overrode—so long as it lasted—their 'unpleasure' The purpose of the present study was to find out what would happen with stimuli which now were deliberately chosen to be both informative and 'scaring'

A television screen was used for displaying the stimuli, which were recorded on video-tape loops so that each action sequence was repeated approximately every 10 s We made up 15 potentially fear-evoking stimuli, selected partly on the basis of our own hunches and partly on the basis of Hebb's suggestion[3] that 'anomalous' objects give rise to fear in primates The stimuli included a toy snake, burning paper, a lavatory brush, a mop-head wearing a human mask and

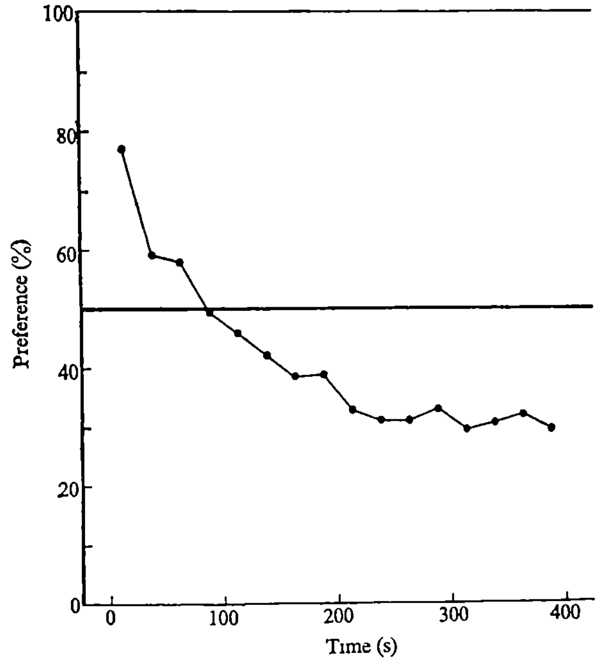

Fig 1 Preference for 'fearsome' pictures (preference measured as the ratio of the total time spent with the test stimulus to the total time spent with either the test stimulus or the blank white screen)

other objects similarly bizarre Each object was given some kind of life-like motion

The method for measuring the monkeys' preferences has been described in detail in earlier papers[1,2] The monkey sat in a small dark chamber with a television screen (37 cm × 30 cm) at one end, taking up most of the wall On the screen could be displayed either the test stimulus or a blank white field of the same subjective brightness The monkey controlled the presentation of the two alternative stimuli by pressing a button successive presses on the button produced the two stimuli in strict alternation, the stimulus staying on as long as the monkey held the button down The test was terminated after 400 s exposure (at which point two peanuts were delivered) The monkeys worked eagerly and generally completed the test in under 500 s, alternating rapidly between the two stimuli (on average about 30 alternations per 100 s of exposure)

The subjects were five young male rhesus monkeys (*Macaca mulatta*) All had taken part in previous experiments on preference, in the course of which they had completed several hundred tests and had become thoroughly familiar with the apparatus and with the fact that strange stimuli were likely to be presented to them They had, however, never before been deliberately exposed to fear-evoking stimuli

The monkeys were tested with two new stimuli each day over a period of three weeks It was immediately apparent from the results that it was not so easy to scare the monkeys as we had imagined In fact in many of the tests there was no sign that the monkeys were anything other than interested in the stimuli Since our aim was specifically to study the interaction of interest and fear, we needed to select for analysis only those tests in which we could be reasonably sure that the monkeys were indeed afraid Independent indices of distress (cries, urination and so on) showed that the stimuli which the monkeys found most upsetting were, as might be expected, those to which they showed the greatest overall aversion We decided therefore to treat any test in which the monkey's preference was predominantly negative as a case of the monkey being scared, and accordingly we defined a stimulus as being 'fearsome' to a particular individual if he chose to look at it for less than 200 s of the 400 s test By this criterion, 13 of the 15 stimuli turned out to be fearsome to one or more of the monkeys, while the five individual monkeys were scared of eight, seven, seven, three and three of the stimuli, respectively

Figure 1 shows the typical pattern of preference for 'fearsome' stimuli, as defined above, in each successive 25 s of the test To obtain this graph we took for each monkey, the mean of his preference for those stimuli which were fearsome to him and then the mean of these means for the five animals The point to notice is the time course The characteristic pattern was for aversion to appear only after a short-lived positive preference This pattern was fully borne out by the data from the individual tests of the 28 tests in which the stimulus proved fearsome, the preference, taken over each successive 50 s, was positive for the first 50 s in 24 instances and negative for the last 200 s in every instance

The pattern of preference was very similar, at least in quality, to that obtained with the red film loops in the earlier study[2] We showed previously that the response to 'red films' could be accurately accounted for by a mathematical model which treats 'interest' and 'pleasure/unpleasure' as two separate factors which interact to determine behavioural preference, subject to a combinatorial rule which gives precedence to 'interest' Our results suggested that the response to fearsome pictures might likewise be dually determined, and the intriguing possibility arose that we might be able to 'synthesise' the curve of Fig 1 by using suitably chosen 'compound' stimuli in which we could separately identify components of interest and unpleasure

To this end we undertook a second experiment in which we presented the monkeys with non-fearsome television pictures to which an unpleasant auditory stimulus ('white noise') was added The non-fearsome pictures consisted of 10 s video loops of relatively bland material, chosen to be roughly comparable in information content to the fearsome

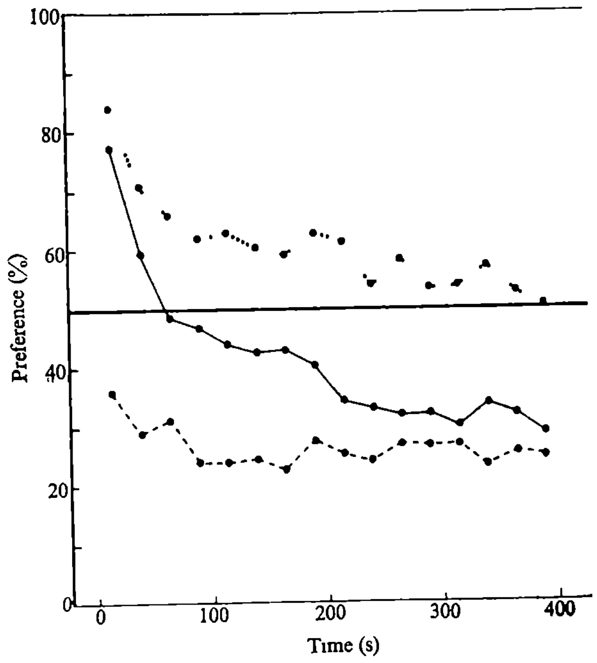

Fig 2 Preference for, ● ···· ●, 'picture only' (a choice between a non-fearsome, silent, video loop and the blank white screen), ● ---- ●, for 'noise only' (a choice between the blank white screen plus white noise and the blank white screen without the noise), ●——●, for 'picture+noise' (a choice between a non-fearsome video loop plus white noise and the blank white screen without the noise) Monkeys were given 10 tests in each category, taken in rotation Graphs show the means of the mean preferences of the five animals

pictures The white noise was set at an intensity level of 68 db (16 db above the background level of the testing chamber) which preliminary observations indicated would create an appropriate degree of unpleasure

The monkeys were given three categories of tests 'picture only', 'noise only' and 'picture plus noise' As Fig 2 shows, the response to the pictures only was an initial strong positive preference which declined towards indifference, that to the noise only was a steady aversion (increasing slightly over the first 100 s of the test), that to the pictures plus noise was an initial positive preference which then turned into a marked aversion In line with the predictions of the mathematical model, the response to pictures plus noise could be almost perfectly fitted by a theoretical curve computed from the separate responses to pictures only and noise only[1]

Comparison of Figs 1 and 2 illustrates the close correspondence between the response to the fearsome pictures and that to the non-fearsome pictures plus noise It seems fair to say that the 'fearsomeness' of the fearsome pictures had on average the same effect as 68 db of white noise But we believe there are grounds here for a stronger assertion, namely that at a causal level fearsomeness influences behavioural preference in the same way as noisiness (or redness) through the evocation of a common factor of 'unpleasure', a factor which is strictly subservient to 'interest'

In functional terms the lesson of these results seems clear the benefits that come from increased understanding outweigh the immediate rewards of a comfortable life

Behavioural thermoregulation in a wolf spider

LABORATORY studies have shown that wolf spiders (Lycosidae) may prefer temperatures above the ambient air temperature of their normal environment[1,2] They are commonly active on clear days in winter and may repeatedly move in and out of the sun In addition, they carry their egg sacs on their spinnerettes and apparently incubate them in the sun[3,4] While the observations suggest that these spiders may exhibit behavioural thermoregulation, it has not been demonstrated

During a study into the ecological energetics of the large, burrow-inhabiting wolf spider *Geolycosa godeffroyi* (L Koch 1865) in the Australian Capital Territory[5], continuous temperature records were obtained of both the egg sac temperature and the temperature of the cephalothorax of the spiders

Egg sac temperature was measured by implanting a temperature transmitter into the egg sac after the removal of about 70% of the eggs The egg sac was returned to the female in the field and the transmissions monitored during the daylight hours The resulting magnetic tapes were transcribed at intervals and records obtained from six individuals The temperature of the spiders was recorded in the field by implanting a fine thermocouple junction into the cephalothorax and recording the temperature with an electric thermometer with an external reference junction at 0° C The fine thermocouple lead (2 3 mg cm^{-1}) allowed the spider free movement within the burrow and through its normal activity range The ambient air temperature was recorded from the dry bulb of an aspirated hygrometer placed 1 cm above the ground surface Temperatures were recorded for 24 h periods from spiders weighing 0 1–1 5 g from February to November 1972

Figure 1 shows two representative records of the cocoon temperature in summer Figure 1*b* is the record for an intermittently overcast day showing that the egg sac could achieve a considerable temperature excess[6] In Fig 1*a* the spider provided its own control At A the spider was placed with its 'bugged' cocoon next to its burrow which was partly occluded by debris The spider began to clear the debris from the burrow but at B dropped the egg sac in full sunlight outside the burrow and continued with its work The sun was masked by cloud at C and when the spider had cleared the burrow it recovered the egg sac (D) and entered the burrow Between D and E the sky cleared and the spider began to sun the egg sac at E The burrow was lightly shaded by trees after 1500h but was bathed in full sunlight at 1800h, just before sunset The spider maintained a fairly constant egg sac temperature in full sunlight (1200h to 1500h) but the temperature excess potentially reached was considerably greater (A to E in Fig 1*a*) than that maintained by the behaviour of the spider

Figure 2 shows three representative records of the cephalothorax temperature of the spiders at different times of the year Figure 2*b* represents part of the record obtained on a subfemale on March 13, 1972 At 0600h the spider was still benefiting from the thermal lag in the soil temperature profile and by remaining at the bottom of the burrow maintained its temperature 8° C above the ambient air temperature As the ambient temperature rose in the morning the spider came to the top of the burrow and maintained a temperature close to the ambient temperature until the sun struck the burrow entrance at about 1000h The body temperature rose rapidly to about 40° C when

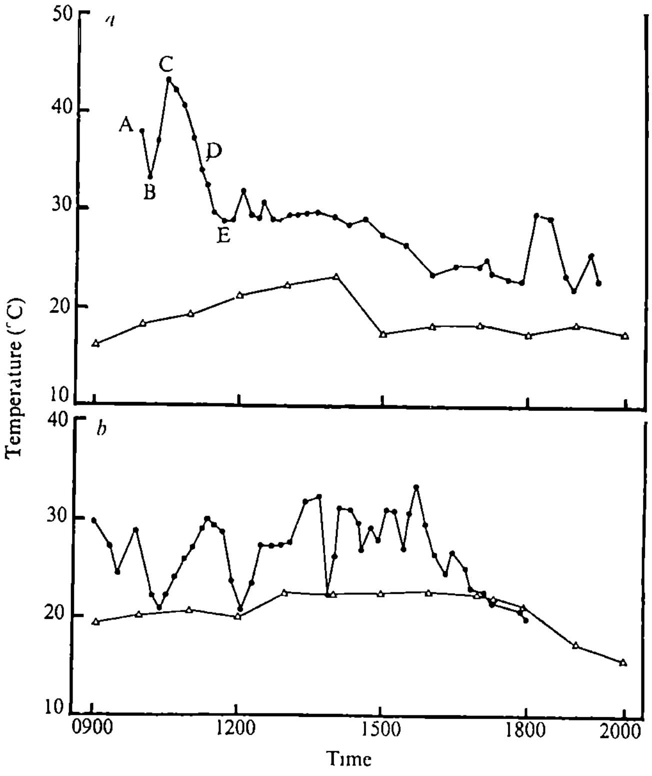

Fig 1 Egg sac temperatures of *G godeffroyi* obtained from implanted temperature transmitters (●) and ambient air temperatures (△) The letters A–E are explained in the text

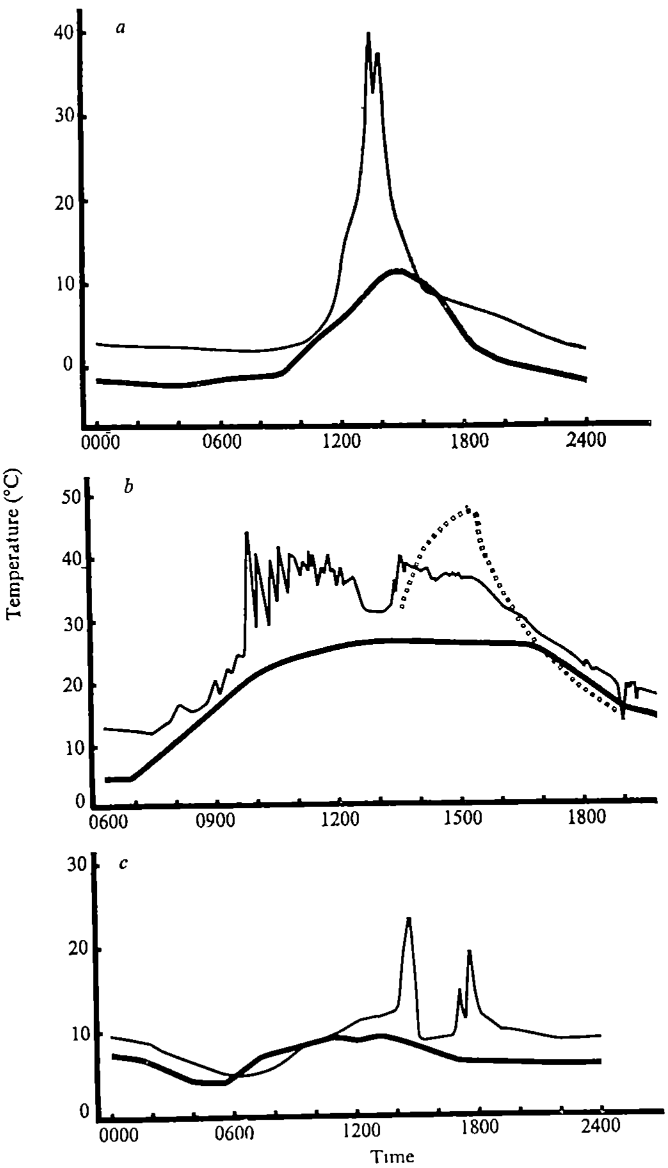

Fig 2 Cephalothorax temperatures of *G godeffroyi* obtained from implanted thermocouples (———) compared with ambient air temperatures (▬▬▬) and dead spider temperatures (☐) The records were obtained in, *a*, midwinter (June 25, 1972), *b*, early autumn (March 13, 1972) and, *c*, late winter (September 13, 1972)

the spider retreated into the shade of the burrow This pocess continued until about 1200h when the sun was partially obscured by cloud until 1330h The ambient temperature dropped after 1600h and the spider retired down the burrow, save for some minor excursions up the burrow at about 1900h, and again maintained its temperature above the ambient air temperature At 1400h a freshly killed spider of similar size was placed on the grass next to the burrow and its temperature monitored The temperature excess obtained by the dead spider greatly exceeded that of the live spider and shows the controlling effect of the spider's movement within the burrow on the body temperature and showing, at night, the moderating influence of the burrow The finer control over the body temperature in the afternoon was characteristic and may result from the spider adopting thigmothermic as well as heliothermic regulation This is supported by the more gradual drop in temperature in the afternoon after the ground had been thoroughly heated compared with the rapid temperature changes in the morning and in winter (Fig 2*a* and 2*c*) whenever the sun was obscured

Figure 2*a* represents the temperature of a spider on a clear winter's day While the ambient air temperature reached 11° C, the spider's temperature rose rapidly to 39 7° C when the sun was on the burrow, resulting in a temperature differential of 30° C at 1345h At night the spider's temperature fell to only 1 8° C in spite of the ambient temperature falling to −2 3° C Figure 2*c* is the record from a spider on a generally overcast day in early spring and shows the immediate use the spider made of radiant energy when the sun struck the burrow at 1300h and 1800h

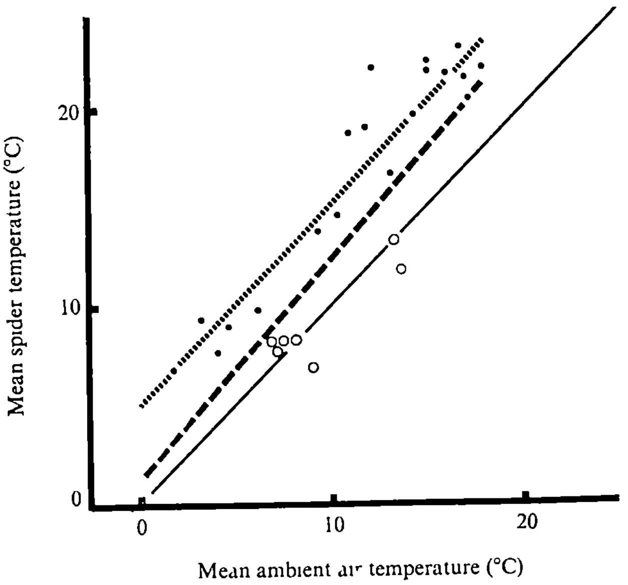

Fig. 3 The relationship between the mean daily cephalothorax temperature and the mean daily air temperature for each of 26 individual *G godeffroyi* recorded throughout 1972 The null line (———) assumes that the ambient and spider temperatures are equal The records are divided into those obtained on clear days (●) and overcast days (○) and the regressions shown for all days (– – – –) and clear days (- - - - -)

In Fig 3 the mean daily spider and ambient temperatures are plotted for the 26 d of recording throughout 1972 The slope of regression through the data for the clear days only is not different from a slope of 1 0 (t_{19}=0 845, 0 5>P>0 4) On clear days throughout the year the spiders maintained their body temperature an average of 4 6° C above the ambient air temperature by basking in the sun during the day and retreating down their burrows at night

The similarity between the thermoregulation in *G godeffroyi* and that found in some lizards[6–8] is striking, the main difference lying in the finesse of the control in the plateau temperature While the lizards exhibited fine control at the upper temperature, that of the spiders was erratic, probably due to their low thermal capacity

I thank Dr R E Barwick for building the temperature transmitters

Functional reinnervation in kitten visual cortex

MOST cells in the adult cat visual cortex, and even in the very young kitten can be activated by visual stimuli presented to either eye[1-3] The retention and refinement of these normal binocular connections depends critically on simultaneous correlated visual experience through both eyes early in life If a kitten is deprived of vision in one eye during a 'sensitive period', which stretches from about 3 weeks to 3 months, the normal pattern of functional connections is grossly disrupted, the deprived eye loses its influence and most cells can only be driven by stimuli through the experienced eye[4] Blakemore and Van Sluyters[5] have recently shown that this situation can be partly or totally reversed by covering the previously experienced eye and opening the deprived eye, and allowing that eye a substantial period of visual experience Thus one set of afferent terminals, robbed of almost all influence in the visual cortex, can re-establish working connections We have now analysed the form and rate of this functional reinnervation

In six kittens the lids of the right eye were sutured together at or before the time of natural eye opening (normally 6–10 d) Reverse suturing was performed at the age of 5 weeks the lids of the right eye were opened and those of the left eye sutured shut All precautions were taken to ensure that the animals never received simultaneous binocular vision As a control, one kitten was monocularly deprived in the right eye for 5 weeks, and recordings taken immediately

Animals were prepared for electrophysiology under barbiturate (Brietal) or steroid (Althesin) anaesthesia They were then paralysed with Flaxedil and artificially respirated with 75–80% nitrous oxide[6] The corneas were covered with contact lenses and 3 mm artificial pupils, and refractive errors corrected with supplementary lenses Single units in the visual cortex were isolated with tungsten-in-glass microelectrodes[7], and their action potentials were conventionally amplified and displayed

All penetrations were later shown histologically to be largely or wholly within area 17 The electrode was driven down the medial bank of the postlateral gyrus, obliquely crossing a large region of cortex The first cells encountered in each penetration had receptive fields within 5° of the area centralis and all receptive fields were within 15°

We studied the responses of neurones to flashing and moving patterns back projected on to a tangent screen 57 cm from the cat's eyes Receptive fields were classified into one of five groups orientation selective[1] (simple, complex or hypercomplex), pure direction selective, orientational bias, nonoriented or visually unresponsive[5] Units with the brisk response, fibre waveform and clear concentric receptive field organisation of afferent fibres from the lateral geniculate nucleus were excluded from the analysis For all cells that were excited by visual stimuli we assessed the relative responsiveness through the two eyes and classified them using Hubel and Wiesel's seven-point scale of ocular dominance[1] Cells in groups 1 and 7 are solely monocularly driven, group 1 by the eye contralateral to the recording site, group 7 by the ipsilateral eye Group 4 cells are equally influenced by the two eyes Groups 3 and 5 are slightly more strongly driven by the contralateral and ipsilateral eyes respectively, groups 2 and 6 are strongly dominated by the contralateral and ipsilateral eyes respectively All recordings were made from the right hemisphere, contralateral to the initially experienced left eye

The ocular dominance histograms in Fig 1*a* show the results for 27 cells from the control animal, monocularly deprived in the ipsilateral eye until recording at 5 weeks of age, and for 189 cells from six kittens reverse sutured at 5 weeks and allowed various periods of time in which to use the previously deprived ipsilateral eye As expected, the first histogram shows that 5 weeks of monocular deprivation silenced virtually all connections from the deprived ipsilateral eye almost all cells are in group 1 But 3 d after reverse suturing many neurones could be driven by the initially deprived eye After only 1 week the process was about half complete, and within 3 weeks there was almost no influence from the previously dominant eye These data are presented graphically in Fig 1*b* where the proportion of cells dominated by the initially deprived eye is plotted against the number of days after reverse suturing

We observed striking changes in the functional architecture of the cortex during reversal of monocular deprivation Cells were clustered into distinct regions dominated by one eye or the other—the 'ocular dominance columns' of Hubel and Wiesel[8] We judged the dimensions of these columns by the distances between obvious switches in ocular dominance during each long penetration The relative size of the columns seemed to change from animal to animal in an ordered manner In kittens where the two eyes commanded roughly equal numbers of cortical cells, the columns for the two eyes were of about the same size, in the more extreme cases the regions devoted to the eye that, overall, dominated fewer cells were smaller and sparser

Thus, after reverse suturing, areas dominated by the initially deprived eye appear, then expand and ultimately occupy the whole cortex Such an orderly anatomical progression suggests that this physiological recapture may represent actual growth and reorganisation of afferent

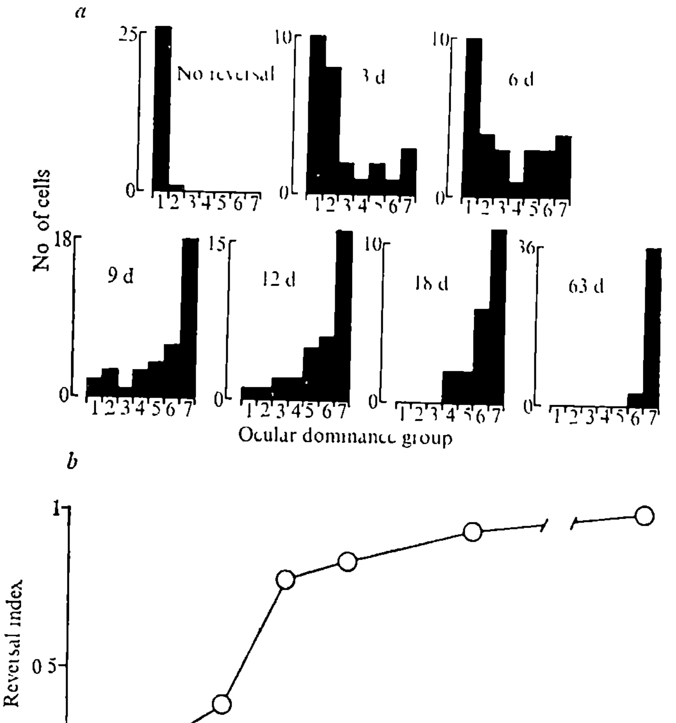

Fig 1 *a*, The ocular dominance histograms of 216 visually responsive cells from the series of seven kittens recorded at varying times after reversal of lid suture The ocular dominance classification is described in the text *b*, The process of reversal is shown graphically, plotting reversal index against days after reverse suturing The reversal index is calculated by dividing the number of cells dominated by the previously deprived eye (groups 5, 6 and 7) by the total number of cells terminals, not merely the strengthening of existing but silent synapses. If so, it implies that the mammalian central nervous system, at least early in life, has some powers of rapid regeneration.

Intercellular gap junctions in pigment epithelium cells during retinal specification in *Xenopus laevis*

DURING embryonic development the cells of the retina acquire positional information which predisposes the future optic axons to connect with specific loci in the optic tectum. In *Xenopus* embryos the eye becomes irreversibly polarised along the naso-temporal and dorso-ventral axes by stage 32[1], after which it is insensitive to any specifying influence previously exercised by the tissues surrounding the eye[2].

In a recent electron microscope study[3] of the developing *Xenopus* retina we described the fine structure of the developing retina between stages 26 and 36. We noted then, the presence of intercellular gap junctions which occurred throughout the retina up to stage 30/31. Beyond stage 32 these junctions could only be found at the periphery of the retina where stem cells contribute new cells to the growing retina[4]. Hence the disappearance of these gap junctions from the central portion of the developing retina appears to be correlated with the time of retinal specification.

We have recently re-examined our data on the developing *Xenopus* eye and noted a significant feature which we failed to report in our original paper. Namely, that cells of the embryonic pigment epithelium, as well as cells of the neural retina, establish gap junctions with one another throughout the eye prior to stage 30/31. We also observed gap junctions between retina and pigment epithelium (Fig. 1). After stage 32 these gap junctions disappear from the centre of the eye but persist for some time in the periphery.

Many results support the view that the flow of molecules through cell junctions may be important in the control of cellular growth and differentiation[5]. In our previous paper we suggested that the disappearance of gap junctions from the central part of the eye and the time of retinal determination might be causally related. Our present observations on the distribution of gap junctions between developing retina and pigment epithelium prior to stage 32 suggests that not only the retina, but also the pigment epithelium, may be subject to the specifying influence of the surround through intercellular channels. This is particularly interesting in view of recent indications that pigment epithelium cells from the centre of the eye of an adult newt may pass on positional information to a new regenerating retina[6].

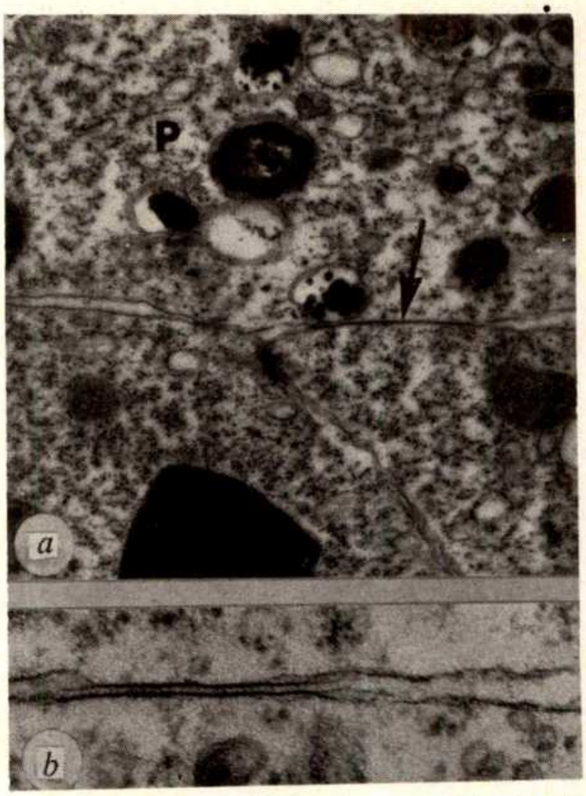

Fig. 1 *a*, The arrow indicates an intercellular junction between a germinal pigment epithelial cell (P) and a retinal cell at stage 26. (×24,000); *b*, A similar junction at higher power illustrating the characteristic narrow gap of 3–9 nm. (×94,000).

Specificity of regenerating optic fibres for left and right optic tecta in goldfish

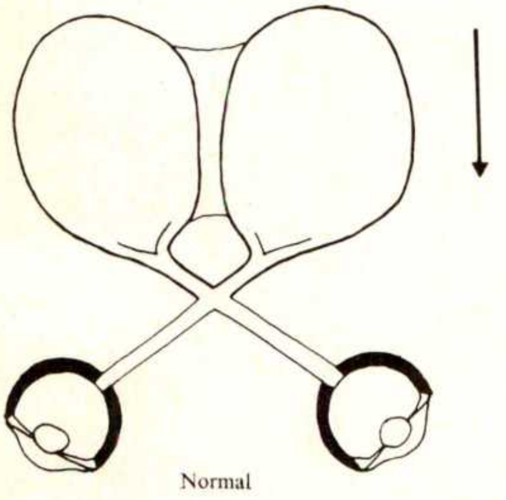
RECENT studies[1] on the regeneration and development of the visual nervous system of inframammalian vertebrates have concentrated on the topographic patterning of retinotectal connections, neglecting the problem of what specifies the pathways of large tracts. Embryologically the eye is an outgrowth from the ipsilateral side of the brain, but during development the optic nerve fibres cross the midline and terminate on the opposite side where they "mirror" the topographical disposition of their retinal ganglion cells. Sperry[2,3] proposed that the precise patterning of such neuronal circuits resulted from specific affinities between individual nerve fibres and their target loci within the brain, but recent evidence[4] suggests that what is important is the preservation of the overall pattern of fibre connections, rather than the position occupied by individual terminals[5].

Investigation of the pattern of recovery following reinnervation of muscles in fish[6,7] suggests that competitive interaction between different nerve fibres may in some species lead to the selection of correct connections. We now report some preliminary results where both optic nerves in goldfish were directed into the same tectum to test for competitive interaction for occupancy of the same tectal site.

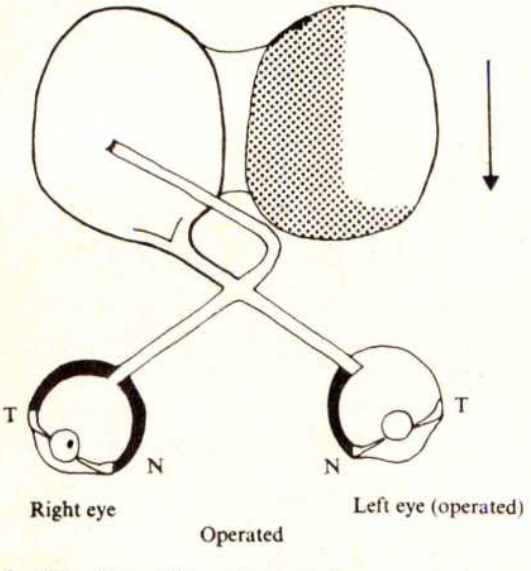
Goldfish were anaesthetised in a 0.4% solution of MS222 (Sandoz), and mounted in a holder which allowed the gills to be continuously perfused with water, or with a solution of MS222, as required. Two operations (Fig. 1) were then performed on the fish. The tectum of the anaesthetised fish was exposed by opening a cranial bone flap which was replaced after surgery. A small tungsten wire hook was then inserted under the left optic tract, optic fibres stripped away from the left tectum, and the length of nerve brought right over to lie across the right optic tectum. A medial strip from the left tectum was excised by aspiration along its whole length to prevent the nerve from growing back to the original tectum and the bone flap replaced. A second operation was then performed to remove the temporal hemiretina from the fish's left eye (other experiments where a hemiretina was removed from each eye will be reported later). In each case an incision was made to remove the hemiretina by cutting along the vertical meridian at the back of the eye. Bleeding was reduced by a noose of silk thread slipped around the optic nerve. After the operation the fish were returned to individual home tanks where they were kept for a year before recording. The length of the postoperative period was to allow any possible neuronal respecification[8] to occur before investigation.

For electrophysiological recording anaesthetised fish were mounted in their holder, and the tectum exposed. One eye was centred on a projection perimeter (the other eye was always covered with a plasticine occluder) and the visuotectal representation for that eye on the right tectum mapped with a Woods-metal microelectrode[9]. The same procedure was then repeated for the other eye.

In 21 of the 24 fish which survived the recovery period, the nerve from the right eye failed to form connections with the ipsilateral tectum and showed a marked tendency to curve back to try and reach the remaining fragment of lateral tectum on the contralateral (and correct) side. Unfortunately the left tectal fragment was often placed too far laterally to enable us to record from it effectively. In three fish, where the operation was successful, one was a control, where in addition to uncrossing the chiasma we removed the nasal hemiretina from the left eye and the temporal hermiretina from the right eye. In this control fish, the representation of the hemiretinas from the right and left eyes, were each confined to their 'correct' half of the right tectum. The other two fish gave results that were similar to one another. Figure 2 shows the tectum of one of them, where we succeeded in getting the optic nerve from the right eye (or at least part of it) to deploy itself in the ipsilateral optic tectum. There was also some suggestion that optic fibres from the right temporal hemiretina had crossed back to the correct (left) tectum via the tecto-mesencephalic commissure. Indeed, a band of what appeared to be newly myelinated fibres was clearly visible at the caudal end of this commissure (Fig. 2). Furthermore, on the right optic tectum, we found no evidence, electrophysiologically, of any representation of the temporal retina from the right eye (Fig. 3). Two zones innervated exclusively by one eye or the other are separated by a zone in which the two projections overlap. The area of overlap seemed to vary in different fish, and it is possible that during the early stages of recovery the two projections may have overlapped completely and only later become segregated from one another.



Normal



Operated

Fig. 1 Operations. The optic nerve from the right eye was uncrossed surgically and diverted to the right tectum, and the temporal half of the retina from the left eye was removed. Shaded region shows area of tectum removed.

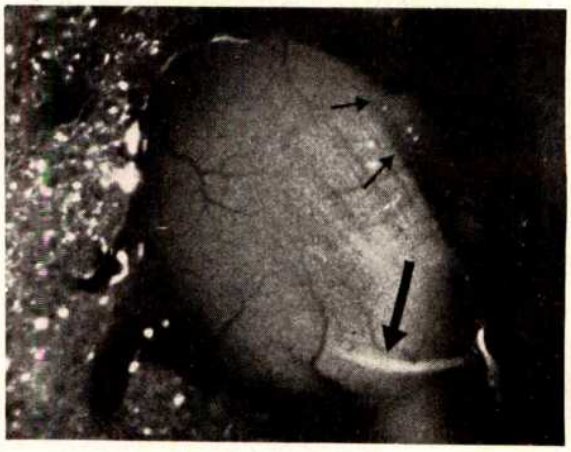


Fig. 2 Large arrow: insertion of the uncrossed optic nerve from the right eye into the ipsilateral optic tectum. A band of newly myelinated fibres can just be seen in the caudal region of the tecto-mesencephalic commissure (small arrows).

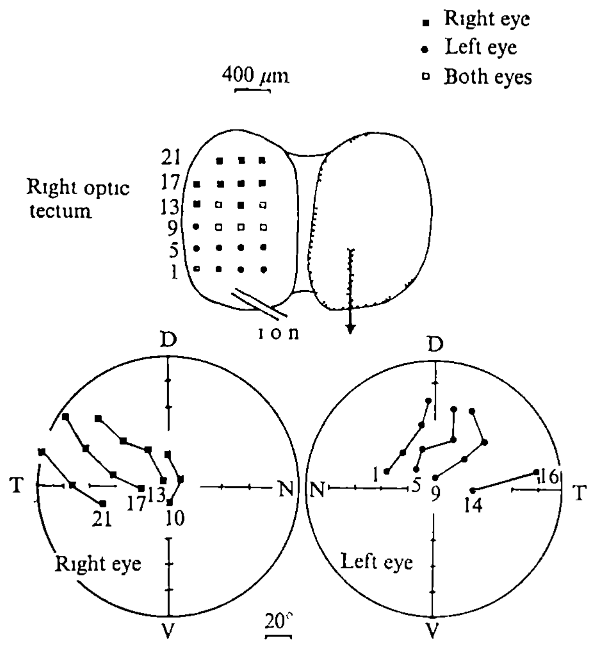

Fig 3 Visual field projections from the right and left eyes onto the right optic tectum Shaded region shows area of tectum removed i o n , optic tract from ipsilateral eye

Previous studies[10] have shown that if a sufficient period is allowed for recovery, the fibres from a nasal hemiretina can spread and occupy a whole normal tectum By contrast, in Fig 3 the projection from the left nasal hemiretina only extends over approximately half the dorsal surface of the tectum Moreover, in this instance the nerve from the contralateral eye occupied the wrong half of the tectum (in the normal contralateral projection[11] optic fibres from the nasal hemiretina occupy the caudal half of the tectum) This suggests that the contralateral nerve fibres may have been displaced forwards by competition for tectal sites with fibres arriving fom the ipsilateral nasal hemiretina

While it is clearly too early to draw any hard and fast conclusions, our observations indicate (1) that regenerating optic fibres may be able to distinguish between right and left tecta, and (2) if both optic nerves are forced into the same tectal field, each may have a tendency to exclude the other from the tectal zone it innervates

There is one further point worth noting Yoon[8] found that in certain conditions, goldfish optic fibre terminals would arrange themselves topographically in an anomalous region of the optic tectum Yoon attempted to reconcile his results with Sperry's original chemoaffinity hypothesis[3] by suggesting that respecification of tectal elements might have occurred after surgery Our study, however, makes this interpretation unlikely While only the nasal half of each retina was represented on the tectum, optic fibres from corresponding retinal loci deployed themselves topographically at different locations of the same unoperated tectum It is difficult to envisage how respecification of tectal elements could account for the development of a duplicate set of 'tectal markers' in an unoperated optic tectum

Evidence for two mechanisms of sclerotisation in insect cuticle

In many insects the cuticle changes drastically in properties soon after a moult When the insect emerges from the old cuticle the new one is soft, pale, and a major part of the proteins can easily be extracted Gradually the proteins become insoluble, the cuticle becomes harder, and in many cases it also becomes darker The colour may range from a very light amber to dark brown or even black It has been discussed repeatedly whether hardening and darkening are two independent processes or whether they are two results of the same chemical reaction, but no definitive conclusions have been reached[1–6]

During a study of cuticle sclerotisation I have obtained evidence which confirms an earlier suggestion[7] that two mechanisms for forming cross links exist in insect cuticle, one giving a colourless cuticle and the other a dark brown cuticle Both mechanisms can be active simultaneously in the same piece of cuticle and they can utilise the same substrate, N-acetyldopamine In the reaction resulting in a colourless cuticle the β position of the substrate is activated and becomes involved in cross linking of the proteins, while the aromatic ring is involved in the reaction giving rise to a brown cuticle

Both activities were assayed by means of tritiated N-acetyldopamine, for the former assay tritium was located on the β carbon atom of the sidechain and for the latter assay it was restricted to the aromatic ring of the substrate The two substrates were synthesised by treatment of 3,4-dihydroxyphenylethylamine (2^{3}H^{-} ethyl) and 3,4-dihydroxyphenylethylamine (^{3}H^{-} ring), respectively, with acetic anhydride in 10% potassium tetraborate[8] The purified products were diluted with unlabelled N-acetyldopamine to give 10 mM solutions which contained 2 μCi ml^{-1}

Samples of cuticle were obtained from the desert locust, *Schistocerca gregaria*, the silk moth, *Hyalophora cecropia*, and from meal worms, *Tenebrio molitor* All cuticles were carefully cleaned and washed in 1% potassium tetraborate and in distilled water They were divided into the appropriate parts which were incubated in 2 6 ml 0 2 M Na-acetate buffer, *p*H 5 5, 100 μl of either one or the other substrate was added, and the mixture was incubated for 18 h at room temperature The tritium which was split off during this period was determined after passing the supernatant through a small column (0 5 × 1 cm) of activated charcoal, which retains the aromatic substrate but not tritiated water[8] The first millilitre of the eluate was discarded, and from the rest of the eluate 1 ml was taken to be counted The non-enzymatic release of tritium from the substrates was determined in parallel experiments without any cuticle and was used to correct the experimental results The dry weight of the cuticular samples was determined after the incubations by drying them to constant weight at 100° C

Table 1 shows that all the cuticular samples will release tritium from both substrates and that the relative activities vary considerably The various types of locust cuticle which remain lightly coloured during sclerotisation show a much higher activity towards the sidechain of N-acetyldopamine than towards the ring, whereas the mandibles, which are a

Old pupae	Dark brown	4	10,225±1375	18,881±1331	0 54

The adult locusts were killed 1 d after the moult, their cuticle was thus well sclerotised, while the fifth instar larvae were caught while moulting The young *Tenebrio* adults were caught less than 12 h after the moult and were light brown in colour, whereas the old adults were about 2 week old and were very darkly coloured The young *Hyalophora* pupae had an uncoloured frontal part and a light brown abdomen, and the old pupae were dark brown all over

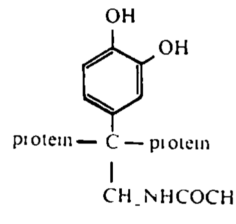
* Number of determinations

dark brown type of cuticle have a relatively higher activity towards the ring part of the substrate No significant differences are observed between those samples of locust cuticle which become melanised and those which do not

The pupal cuticle of *Hyalophora*, which becomes dark brown during hardening, contains high levels of both activities, whereas the enzyme active towards the sidechain of the substrate dominates in the colourless larval cuticle In young *Tenebrio*, where only little sclerotisation has occurred, the enzyme active towards the aromatic ring dominates slightly, but this activity disappears as the cuticle becomes fully sclerotised, and the sidechain directed activity remains

The results indicate that cuticles which become dark brown during sclerotisation contain relatively large amounts of an enzyme which is active towards the ring moiety of N-acetyldopamine, whereas cuticles which remain pale or colourless prefer the sidechain of the substrate

We have in some earlier publications reported on the sclerotisation of locust cuticle[7-9], and our results suggested that the cross links in hard, uncoloured cuticle are



It can be assumed that the enzyme which can remove tritium from the β position of N-acetyldopamine is also responsible for the formation of the cross links[8] The enzyme which removes tritium from the aromatic ring can be assumed to be an *o*-diphenoloxidase oxidising the substrate to an *o*-quinone which will combine with free amino groups with the simultaneous loss of tritium from the ring This enzyme would thus be responsible for the classical type of quinone tanning of insect cuticle first suggested by Prior[1]

The possibility that both enzyme activities reside in a single enzyme cannot be completely disregarded, although it seems difficult to explain how the ratio between the two activities can vary so much between the various types of cuticle if it is not two different enzymes The decrease of only one of the activities as sclerotisation progresses in *Tenebrio* cuticle also indicates that it is two enzymes It will, however, be necessary to obtain both activities in soluble form before this problem can be solved

The results reported here indicate that insect cuticle contains two enzyme activities, both involved in sclerotisation and both utilising the same substrate, but one of them resulting in a hard and colourless cuticle and the other giving rise to a hard and dark cuticle The intensity of the colour will presumably be determined by the relative amounts of the two enzymes in the cuticle and by the possible deposition of melanins, for which a third enzyme can be assumed to be responsible

Hepatic necrosis caused by furosemide

Furosemide (frusemide) is a diuretic drug frequently used in the treatment of many cardiovascular and renal diseases Its use is contraindicated in pregnancy because of its recognised teratogenic potential[1] The drug also has been reported to potentiate renal injury when used in combination with cephaloridine[2,3]. Here we report that this widely prescribed therapeutic agent is converted by microsomal enzymes in the liver of mice and humans to a reactive arylating metabolite that produces massive hepatic necrosis in mice.

Male, Swiss albino mice (20–25 g, National Institutes of Health stock) were given furosemide (400 mg kg^{-1}, intraperitoneally, in 0.9% saline solution) and killed at various intervals. Paraffin sections of the liver were prepared and stained with haematoxylin and eosin.

Within 3 h of furosemide administration, nucleolar changes were present in midzonal hepatocytes, and single cell necrosis with pyknotic hepatocytes showing eosinophilic degeneration was also occasionally present. By 6 h, necrosis of many hepatocytes was found in the midzonal and centrilobular areas, demonstrated by nuclear pyknosis, karyorrhexis and cytoplasmic eosinophilia (Fig. 1*a*). Early polymorphonuclear cell infiltration was often present in the less severely injured livers. By 12 h, severely damaged livers showed massive necrosis in both the midzonal and the centrilobular areas such that confluent zones of pyknotic, eosinophilic hepatocytes bridged adjacent lobules (Fig. 1*b*). The Küpffer cells, however, were generally normal. At later time intervals, the pattern of necrosis was usually centrilobular although occasional sections had entirely midzonal necrosis with a collar of viable parenchymal cells remaining around the centrilobular and periportal veins. Necrosis was greatest at 24–48 h; regeneration was evident by 48–72 h.

The histological slides were coded and the severity of the liver necrosis produced by furosemide was determined by two observers blind to the code, as previously described for other hepatotoxins[4]. Furosemide-induced hepatic necrosis was dose dependent (Table 1). After a single furosemide dose of 200 mg kg^{-1}, only slight necrosis (+) was observed in 16% of animals. After administration of 300 mg kg^{-1}, necrosis was present in 68% of mice and was more extensive (++ and +++). After 400 mg kg^{-1}, 92% of mice had necrotic livers and the severity was (++ to ++++) in 60% of the animals.

Table 1 Extent of hepatic necrosis in mice 24 h after various intraperitoneal doses of furosemide

Dose of furosemide (mg kg^{-1})	No. of animals	% Mortality	Extent of necrosis* O	+	++	+++	++++
			%	%	%	%	%
100	25	0	100	0	0	0	0
200	25	0	84	16	0	0	0
300	50	2	32	48	16	4	0
400	50	4	8	32	36	18	6
500	25	20	0	5	40	35	20

* Extent of necrosis (determined as previously described[4]): O, absent; +, necrosis of less than 6% of parenchymal hepatocytes; ++, necrosis of 6–25% of hepatocytes; +++, 26–50% of hepatocytes; ++++, greater than 50% of hepatocytes.

Alterations in hepatic blood flow with resulting hypoxia may play a role in the pathogenesis of centrilobular liver damage. Therefore, we considered the possibility that the hepatotoxicity produced by furosemide might have been caused by hypoxia resulting from massive diuresis with subsequent decrease in the vascular volume. Furosemide-treated mice were never in shock, however, nor showed respiratory depression during our studies, and other diuretics, such as chlorothiazide and ethacrynic acid, did not cause hepatic necrosis even after LD$_{50}$ doses. Moreover, the dose of furosemide required to produce necrosis was much greater than that which usually produces maximal diuresis[3] and post-treatment with Ringer's lactate in 5% glucose (12.5 ml kg^{-1}, intraperitoneally, at 1, 2, 3 and 4 h after administration of furosemide) did not prevent the lesion. In addition, the initial hepatic lesion occurred midzonally, not centrilobularly, and was present a few hours after drug administration. Finally, the liver damage is probably caused by a metabolite of furosemide rather than the parent drug, because necrosis was prevented when the metabolism of furosemide was inhibited by pretreatment of mice with three different types of cytochrome P–450 enzyme inhibitors: piperonyl butoxide, cobaltous chloride and α-naphthylisothiocyanate.

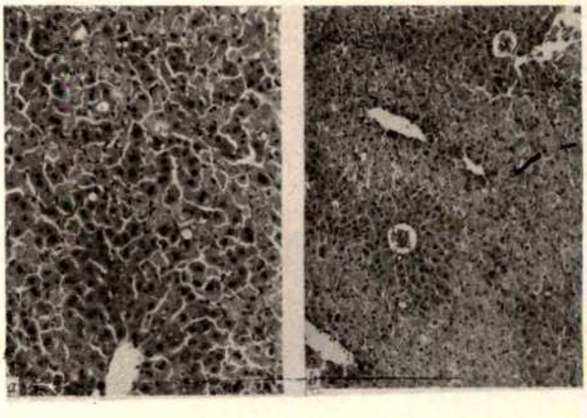

Fig. 1 Furosemide-induced liver necrosis in mice after an intraperitoneal injection of 400 mg kg^{-1} of furosemide. Sections of liver stained with haematoxylin and eosin. *a*, Midzonal hepatic nercosis 6 h after furosemide (×98); *b*, centrilobular-midzonal hepatic necrosis 12 h after furosemide (×44).

In a further series of experiments we studied the enzyme-dependent covalent binding of furosemide to hepatic macromolecules both *in vitro*[5] and *in vivo*[6]; this technique can be used as an index of the formation of an arylating metabolite of a drug[7,8]. Covalent binding *in vitro* of ^{3}H-furosemide (generally labelled) or ^{35}S-furosemide to hepatic microsomal protein required oxygen and a NADPH generating system and was inhibited by an antibody against NADPH-cytochrome *c* reductase and by a 9:1 carbon monoxide : oxygen atmosphere. Thus, the formation of an arylating metabolite of furosemide was mediated by a cytochrome P–450-dependent mixed-function oxidase in liver. We also found a furosemide metabolite bound to hepatic protein *in vivo* to about the same extent (1.5 nmol mg^{-1} protein) as we had previously found for the reactive, hepatotoxic metabolite of acetaminophen (paracetamol)[7].

Evidence of the covalent nature of the furosemide binding was obtained by hydrolysis with pronase of the solvent-extracted protein precipitate and isolation of the radiolabelled compound bound to single amino acids and peptide fragments. Pretreatment of mice with piperonyl butoxide, cobaltous chloride or α-naphthylisothiocyanate almost completely abolished both the *in vivo* covalent binding of furosemide and furosemide-induced hepatic necrosis. The covalent binding occurred a few hours before the onset of histologically recognisable necrosis and before biochemical changes in the hepatocytes (such as, decreased cytochrome P–450-dependent drug metabolism and decreased protein synthesis[8]). These findings lead us to conclude that the arylation of liver macromolecules by a reactive furosemide metabolite is causally related to the development of furosemide-induced hepatic necrosis.

Another important finding was the presence of a dose threshold for the covalent binding and liver necrosis produced by furosemide[8]. Only small amounts of covalent binding and no necrosis occurred until a dose of 100 mg kg^{-1} was exceeded. Studies on the metabolism, distribution and reversible plasma protein binding of furosemide after non-toxic and toxic doses suggest that this threshold may result from a saturation of the organic anion binding sites on plasma proteins after toxic doses of furosemide[8]. More free furosemide would then be available to the liver for metabolism. Unlike the dose threshold for acetaminophen-induced liver necrosis[10], the furosemide threshold is not the result of a protective role of glutathione since furosemide did not deplete hepatic glutathione.

The hepatic injury produced by furosemide (N-(2′-furylmethyl)-4-chloro-5-sulphamoylanthranilic acid) apparently results from the metabolic activation of the furan ring, possibly by an epoxidation similar to that proposed for the hepatocarcinogenic dihydrofuran aflatoxins[11]. For example, furosemide radiolabelled with tritium in its furan moiety was bound covalently to hepatic microsomes in the presence of oxygen and NADPH to the same extent as furosemide radiolabelled specifically with ^{35}S in its sulphonamide moiety, demonstrating that the bound metabolite contained both parts of the furosemide molecule. To determine where the binding occurred on the molecule, the metabolite-protein conjugates isolated from the liver were hydrolysed in mild acid conditions (*p*H 4.5) that split furosemide into its methylfuran and sulphamoylanthranilic acid portions. The binding of furan-radiolabelled furosemide to protein was unchanged whereas the binding of ^{35}S-labelled furosemide was lost. Thus, the metabolic activation of furosemide must have occurred on the furan ring.

Finally, we have compared the hepatotoxicity of structural analogues of furosemide and have shown that the hepatic lesion can be reproduced by such simple furans as 2-hydroxymethylfuran, 2-acetylfuran and even furan itself (Table 2). Moreover, pretreatment with phenobarbital shifts the zone of necrosis produced by furosemide and by other furan-containing compounds such as ngaione and 3-hydroxymethyl furan (N,N-diethyl)-carbamate[12,13] from a centrilobular to midzonal distribution in mice. Furosemide, furan, 2,3-benzofuran and certain other furano compounds cause toxic lesions in the kidney (Table 2) in addition to the liver, whereas ipomeanol and other furan analogues selectively produce lung damage and pulmonary oedema[14,15]. Thus, a variety of tissue lesions seen after furan-containing compounds may result from a metabolic activation similar to that proposed for furosemide. Extension of these studies to thiophene, an analogue of furan in which the oxygen atom in the five-membered ring is replaced with sulphur, has shown that several thiophene-containing compounds also produce massive hepatic or renal necroses in animals (J.R.M., W.Z.P., J.A.H. and D.J.J. unpublished). Studies are underway to determine whether the nephrotoxicity produced in humans by cephaloridine and cephalothin results from the metabolic activation of the thiophene nucleus in these antibiotic drugs.

The implications of the present findings for the clinical use of furosemide are uncertain. Extensive clinical experience with furosemide has not resulted in reports of liver damage; presumably therefore, the drug is not hepatotoxic at the usual therapeutic doses (40–600 mg d^{-1}). The enzyme pathway responsible for the formation of the toxic metabolite, however, is apparently present in humans because human cadaver microsomes, similar to mouse microsomes, can convert furosemide to an arylating metabolite (J.R.M., W.Z.P., J.A.H., and D.J.J., unpublished). The possibility arises, therefore, that the remarkable safety of furosemide after low therapeutic doses may result from the presence in humans of a dose-threshold phenomenon similar to that found in mice. If this is so, then tissue concentrations of furosemide in patients with renal failure probably are much greater in relation to the furosemide dose, since furosemide is eliminated from the body primarily by renal excretion of the unchanged drug[16]. In addition, patients with chronic renal failure often have decreased concentrations of plasma proteins, making more free (nonbound) furosemide available to the liver for metabolism. Since huge doses of furosemide (for example 2,000 mg by rapid intravenous injection) are currently used to treat patients with acute and chronic renal failure[17], the potential hepatotoxicity of this therapeutic regimen should be carefully evaluated. The possible consequences of the formation in humans of an arylating metabolite from furosemide should also be considered, because most compounds that arylate tissue macromolecules *in vivo* can produce neoplasia[18].

Table 2 Liver, kidney and lung toxicity in mice and rats after furan analogues, given intraperitoneally.

Liver*	Dose† (mmol kg^{-1})	Kidney*	Dose† (mmol kg^{-1})	Lung*

Red cell 2,3-diphosphoglycerate concentration in man decreases with age

So far there has been no report in the literature suggesting that the chemical composition of the red blood cell changes during the life of an adult healthy human. We have now obtained evidence that in a normal population the red cell concentration of 2,3-diphosphoglycerate (2,3-DPG) decreases with advancing age. 2,3-DPG is an intermediary metabolite in the Embden–Meyerhof glycolytic pathway in the red cells, which affects haemoglobin affinity for oxygen. Elevated concentration of 2,3-DPG decreases the affinity and thus increases the fraction of haemoglobin-bound oxygen available to the tissues, and decreased concentration of 2,3-DPG has the opposite effect[1,2]. In general, an increase in the red cell 2,3-DPG is found in response to hypoxia or anaemia and a decrease of 2,3-DPG is caused by acidosis[3,4].

Table 1 Relationship between age and concentrations of red cell 2,3-diphosphoglycerate (2,3-DPG) and haemoglobin in 'normal' population

Age (yr)	2,3-DPG* (μmol per g haemoglobin)		Haemoglobin (g per 100 ml)			
	All subjects			Males		Females
	No.	Mean±s.d.	No.	Mean±s.d.	No.	Mean±s.d.
18–24	26	14.9±1.6	36	15.0±1.0	17	13.5±0.8
25–34	35	14.4±1.3	36	15.4±0.6	8	14.0±0.9

85 and over	16	12.8±2.0†	4	15.1±0.8	12	14.1±1.1

* Regression equation for individual values of 2,3-DPG and age $y = -0.02x + 15.25$, $r = -0.2036$ ($P < 0.01$).
† Significantly lower than for Group 18–24 yr of age ($P < 0.05$, Student's *t* test).

None of the subjects were ill or seeking medical help at the time of investigation. There were no heavy smokers (more than 20 cigarettes in a day). None of the subjects were taking iron, folate or vitamin B_{12} supplements. Excluded from the study were the subjects in whom anaemia (haemoglobin concentration < 13.5 g per 100 ml for males and < 11.5 g per 100 ml for females) and/or deficiency of iron (serum iron concentration < 65 μg per 100 ml and TIBC > 410 μg per 100 ml), folate (serum and red cell folate concentrations < 4.0 ng ml^{-1} and < 160 ng ml^{-1}, respectively) or vitamin B_{12} (serum vitamin B_{12} concentration < 160 pg ml^{-1}) were found. Blood counts were determined using a Coulter Counter Model S. 2,3-DPG concentration was measured in 1:400 aqueous dilutions of heparinised or sequestrenated blood by a modified automated method of Grisolia *et al.*[14] using an Auto-Analyzer (Technicon). The concentrations of iron, folate and vitamin B_{12} in blood were determined using standard colorimetric and microbiological assays.

A total of 322 subjects (176 males and 146 females) from 18 to 97 yr of age were investigated. They were selected from the laboratory staff and the participants of the Nutritional Survey of the Elderly, carried out by the Department of Health and Social Security[5], by excluding those in whom anaemia and/or deficiency of iron, folate or vitamin B_{12} were found.

When subjects were grouped according to age a progressive decrease of 2,3-DPG concentration with advancing age was found (Table 1). The decrease from the mean 2,3-DPG of 14.9 μmol per g haemoglobin for the first group (18 to 24 yr) became statistically significant ($P < 0.05$) for the groups comprising subjects older than 65 yr. Furthermore, a significant ($P < 0.01$) inverse correlation between 2,3-DPG concentration and age was found when individual values were correlated by regression analysis. Within each group the mean 2,3-DPG concentrations in males and females were essentially the same, except in the age group 35 to 44 yr, where the difference between mean concentrations for males and females (13.6 and 15.2 μmol per g haemoglobin, respectively) was significant ($P < 0.05$). There was virtually no change in haemoglobin concentration with advancing age, and the difference in concentrations between males and females persisted in all age groups.

It is possible that the decrease of 2,3-DPG in the red cell is related to lower concentrations of plasma inorganic phosphate found in old age[6]. This is supported by observations that the red cell 2,3-DPG changes in parallel to the concentration of plasma inorganic phosphate in conditions with hyperphosphataemia[7] and hypophosphataemia[8,9]. Recently, increased concentrations of 2,3-DPG and plasma inorganic phosphate were found in children between 1 and 12 yr of age[10]. These children, however, had significantly lower than normal haemoglobin concentrations. Whether in children the 2,3-DPG concentration is increased in response to high plasma inorganic phosphate concentrations or to reduced haemoglobin is not clear.

The physiological significance of the decreased red cell 2,3-DPG in the elderly is uncertain. We calculated, on the basis of results obtained by other workers in transfused postoperative patients[11,12], that in the octogenarians studied by us the decreased 2,3-DPG would on average shift the p_{50} of the oxygen dissociation curve of haemoglobin 2 mm Hg to the left, the corresponding change in the delivery of oxygen to the tissues would only be slight. On the other hand, Birnstingl *et al.*[13] found considerably higher haemoglobin affinity for oxygen in normal men over 40 yr of age as compared to those younger than 40, when they measured oxyhaemoglobin dissociation at p_{O_2} of 9 and 13 mm Hg. Furthermore results from this laboratory indicate that in some anaemic subjects over 65 yr of age, the increase of 2,3-DPG was less than expected for the given degree of anaemia. Both latter studies would therefore indicate that at least in some elderly subjects decreased red cell 2,3-DPG may impair the mechanism of adaption to hypoxia or anaemia.

Glucose accumulation by rat small intestine during absorption *in vivo*

GLUCOSE is transported across the mammalian small intestine even when its concentration in the lumen is lower than that in the plasma According to the hypothesis of Crane[1], this 'active transport' is coupled to the movement of sodium ions, which are maintained at a lower concentration in the mucosal epithelium of the gut than in the lumen Glucose and sodium are thought to combine with a 'carrier' molecule at some external site on the brush border of the epithelial cells, the glucose then moving uphill into the cell at the expense of the movement of sodium down its electrochemical potential gradient[2] The concentration of glucose in the mucosa rises to a level above that in the blood capillaries at the base of the epithelium, so that the sugar can move downhill into the plasma The accumulation of glucose to give a tissue concentration higher than that in the bathing fluid has repeatedly been observed in a wide variety of *in vitro* intestinal preparations and is here extended to an *in vivo* situation

About 20 cm of jejunum from male Wistar rats (200–250 g) was exposed under ether anaesthesia, and the lumen gently rinsed with 10 ml ice cold 0 9% NaCl The segment was cannulated and the lumen perfused, *in situ* (that is, with intact mesentery), with Krebs-Ringer bicarbonate medium, in a gas lift, recirculation apparatus, similar to that described by Fisher and Parsons[3] The gas mixture was 95% O_2 and 5% CO_2 During perfusion, the gut was replaced inside the body wall, and the animal maintained continuously under ether (It is likely that the relatively high blood glucose levels shown in Table 1 were due to the deleterious effects of the ether anaesthesia) After 5 min perfusion, glucose was added to the luminal circuit, and the perfusion continued for a further 10 min After this time a sample of perfusion medium was taken, the gut re-exposed, and a portion, approximately 4 cm long, immediately clamped between aluminium tongs precooled in liquid nitrogen[4] The frozen segment was kept in liquid nitrogen while approximately 1 ml blood was withdrawn from the heart into heparinised tubes

The final (that is, 15 min) concentrations of glucose in the whole gut wall (after correction for contaminating luminal and blood glucose), in the luminal fluid, and in the blood plasma, are shown, for a variety of experimental conditions in Table 1 The tissue to lumen, and tissue to plasma final concentrations ratios of glucose are also included in Table 1

When the initial concentration of glucose in the lumen was 5 55 mM, there was an approximately two-fold uphill gradient of glucose from lumen to plasma In this situation, the gut wall concentrated the glucose to a level almost 1 5 times that in the plasma, and over three times that in the lumen, so that a downhill movement of glucose could take place from the tissue into the blood Phlorizin, a specific inhibitor of glucose active transport reduced the accumulation of glucose by the tissue (tissue plasma ratio 0 90) With an initial luminal glucose concentration of 28 mM, there was a downhill gradient of glucose from lumen to plasma, so that concentration of the glucose by the tissue to a level above that in the plasma was no longer necessary, and was not observed These findings are in accord with Crane's hypothesis, but they differ from that of Esposito *et al*[7] whose technique, however, perhaps allowed loss of

Three small (approximately 30–40 mg wt) and adjacent portions of the freeze-clamped tissue were chipped off and weighed on a torsion balance The first was ground to a paste in a ceramic mortar containing 6% (w/v) perchloric acid, the extract thawed at 4° C, centrifuged, the supernatant neutralised with 30% KOH and analysed for glucose[5] The samples of blood, and after centrifugation, plasma, withdrawn from the heart, and the luminal sample, were also deproteinised, and analysed for glucose by the same method The second tissue sample was ground with 1% (w/v) sodium citrate, to prevent blood clotting, and its absorption measured at 415 nm, since haemoglobin absorbs strongly at this wavelength A known volume of the whole blood collected from the heart was then added to the tissue extract and the increase in absorption at 415 nm used to calculate the blood volume of the frozen tissue This averaged 6 6% (in µl) of the wet weight of the tissue (in mg), which is reasonably close to published figures[6] The third portion of tissue was dried to constant weight at 110° C to determine the ratio of dry weight to wet weight of the frozen segment This was invariably less (usually around 0 16) than the true dry weight wet weight ratio of the tissue (0 215±0 0001 mean±s e) determined in separate experiments, on account of the layer of frozen medium sandwiched between the tissue layers, and could be used to calculate the amount of glucose contaminating the tissue from this source The values for tissue glucose concentration in the above table are therefore corrected for luminal glucose contamination, and for glucose contained in a space accessible to haemoglobin (The corrected values were about 30% higher than the uncorrected ones) The intracellular water associated with the tissue was assumed to be the same as the total tissue water, so that the figures for whole wall glucose concentration are probably an underestimate of the true intracellular glucose concentration Experimental diabetes was induced by the intravenous administration of streptozotocin, 65 mg kg^{-1}, 5 d before the experiment The ratio of dry weight to wet weight of frozen segments after perfusion from diabetic rats was 0 20±0 0001 and this value was used in the calculation of glucose contamination in these experiments All results are the mean ± s e m ND, Not determined

sugar from the mucosa during the time taken to sample the tissue

In the complete absence of glucose in the lumen, and in the presence of phlorizin (Table 1) a substantial amount of glucose was present in the gut wall probably in the mucosa (or possibly the intercellular spaces) If so, one has to postulate a backward movement of glucose from the plasma to the epithelial cells, and strong evidence in support of some form of mediated sugar movement across the basal and lateral surface of the epithelial cells has recently been reported[8-10] In the case of phlorizin inhibition, one has also to postulate some additional movement of glucose into the epithelial cells, insensitive to the action of this inhibitor

When experimental diabetes was induced by streptozotocin the plasma glucose rose to 30 mM and provided a sixfold uphill, lumen to plasma concentration gradient (Table 1) In spite of this extra load, the tissue responded by raising the intracellular glucose concentration to a level above that of the plasma, to bring about a downhill sugar gradient from tissue to plasma, suggesting that gut glucose concentrations during absorption are influenced more by the concentration of sugar in the plasma rather than that in the lumen

I thank Miss J Prendergast for technical assistance Streptozotocin was donated by Upjohn Ltd , Kalamazoo, Michigan

In vitro cultivation of *Trypanosoma vivax* isolated from cattle

IN West Africa, *Trypanosoma vivax* is responsible for the majority of trypanosome infections in cattle and other ruminants It is not readily established in laboratory animals, and research on pathogenic isolates has been hampered by the difficulty in its establishment *in vitro* Trager[1] reported a culture method for *T vivax* using tsetse fly tissues but this medium is complex and unsuitable for metabolic studies There is therefore a need for a medium which will support the *in vitro* growth of *T vivax* and other species of trypanosomes to give reproducible results The multiplication of *T vivax*, using mammalian tissue culture media buffered with 4-(2-hydroxyethyl)-1-piperazine-ethane-sulphonic acid (HEPES) is reported here

Three isolates were used Bodija 1, Bodija 2, and Vom 36/15 The first two were obtained from blood samples collected from cattle at the Ibadan slaughterhouse and the third was supplied as a stabilate from the Nigerian Institute for Trypanosomiasis Research (NITR) Vom The two local isolates were identified as *T vivax* by morphology and failure to infect rats Heparinised cattle blood containing approximately 19×10^6 trypanosomes was inoculated intraperitoneally into sheep obtained from the Jos Plateau, a tsetse-free area The stabilate, Vom 36/15 was injected into a sheep The parasitaemia, general health and haematology of the sheep were monitored daily

Trypanosomes for cultivation studies were isolated from whole blood by centrifugation, DEAE cellulose columns[2], or erythrocyte lysis[3] followed by DEAE cellulose columns The last method was found to be the most efficient, important with the low parasitaemias frequently associated with *T vivax*

Isolated trypanosomes were washed twice and resuspended in Hanks saline +5% foetal calf serum, and inoculated into culture media Some of the media and additives tried are included in Table 1 The number of trypanosomes inoculated into each ml of culture was $0\ 48 \times 10^6$ or $1\ 0 \times 10^6$ The number in culture at various times after inoculation was determined by dilution in a fixative-staining solution (0 5% toluidine blue, 1% sodium citrate, 10% formalin, in distilled water) and counting in a haemocytometer When trypanosomes numbered less than $0\ 03 \times 10^6$ ml^{-1} survival was monitored by evidence with phase microscopy of freely motile trypanosomes At each sampling, Giemsa stained smears were prepared after centrifugation and resuspending the trypanosomes in serum NADH diaphorase technique was used to demonstrate mitochondria[4]

Plasma from infected and uninfected animals was stored at −10° C before incorporation into culture media

As indicated in Fig 1, cultures of *T vivax* (Bodija-1 isolate) were made at parasitaemias of 11, 14, 17, 18, and 22 d after infection of sheep Table 1 presents the results of the cultures of the 22-d isolate of Bodija 1 Cultured in Medium 199 buffered by HEPES (Medium 199H) with foetal calf serum and homologous plasma (prepared the same day as the culture), and incubated at 25° C, organisms increased fourfold within 24 h *T vivax* from the same day isolated in Medium 199H and either γ-globulin free serum or foetal calf serum, increased in numbers 3 8 and 3 1-fold respectively within 24 h After the initial increase, numbers decreased at 48 h (1 95 to 1 55 ×

10^6 ml^{-1} and 1.5 to 1.05 × 10^6 ml^{-1} for example). From day 2 the number of trypanosomes continued to decrease. Throughout the period *in vitro*, however, but more noticeably after subculture every 72 h, there were groups of trypanosomes which appeared to be the result of division (early rosettes, later clumps). With Giemsa stained smears, forms which appeared to be dividing were present. Motile trypanosomes were present after 10 d *in vitro* when the cultures were terminated. In Trager's work as well as in long term cultures of primary lines with other species of trypanosomes, initial growth may be followed by a decrease or near disappearance of the line, later resumption of growth occurs from a very few competent organisms. Other media were less successful in supporting the growth of *T. vivax* (Table 1).

The populations of *T. vivax* isolated in Medium 199H and foetal calf serum at 25° C on days 11, 14, 17, and 18 after infection, survived 24, 96, 24, and 72 h, respectively.

The morphology of *T. vivax in vitro* during the growth period is similar to that of the forms seen in the whole blood when collected from the host, except that by 4 h *in vitro*, the kinetoplast moved 1–2 μm anteriorly. The mitochondrion as demonstrated by the NADH diaphorase technique did not seem to be significantly altered during the first 24 h period of growth *in vitro*.

Medium 199H with foetal calf serum and homologous plasma also supported growth at 25° C or 31° C of selected isolates of Bodija 2 and Vom 36/15.

Infectivity studies in ruminants were not carried out in this study as the volume of cultures was too small.

Our data indicate that trypanosomes taken at different times during the course of infection with *T. vivax* behaved differently in identical *in vitro* conditions. *T. vivax* is generally considered monomorphic, although evidence of morphological variation between strains has been reviewed recently[7]. We have observed considerable physiological pleomorphism within strains of *T. vivax*.

The optimum *p*H for the growth of pathogenic trypanosomes is considered to be 7.4. HEPES buffer[8] which has an efficient buffering capacity in the *p*H range 7.4–7.5 (*p*K 7.31 at 37° C and a *p*K$_a$ of 0.014) may therefore promote the multiplication of *T. vivax*. The use of homologous plasma seems to enhance growth.

Our method may be useful for the short term cultivation of *T. vivax* for metabolic, biochemical, immunological and pharmacological studies.

We thank the Rockefeller Foundation and the University of Ibadan Senate for financial support of this work. We also thank Dr D. G. Godfrey of the Lister Institute, London and Professor K. C. Sellers, Department of Veterinary Pathology, University of Ibadan for advice.

Neuraminidase treatment of adrenal cells increases their response to cholera enterotoxin

A PRIMARY action of cholera enterotoxin is to increase adenyl cyclase activity in the intestine and the elevated levels of cyclic AMP are thought to be responsible for the water loss and dehydration associated with cholera[1–4]. Enterotoxin also stimulates a variety of other tissues including cultured adrenal tumour cells[5,6]. In these instances the actions of the toxin are very similar to those hormones whose effects are mediated through regulation of intracellular cyclic AMP in their target tissues. A common characterisic of the hormonal responses, however, is that cyclic AMP levels are usually raised within a few seconds whereas the response to enterotoxin, in all the tissues tested, is always accompanied by a lag period of at least several minutes. We have shown previously that pretreatment of isolated rat adrenal cells with neuraminidase reduces the response to ACTH indicating that membrane sialic acid may be involved in stimulation of adenyl cyclase by this hormone[7,17]. We report here that in sharp contrast to the results obtained with ACTH, the response of adrenal cells to enterotoxin is markedly enhanced by treatment with neuraminidase.

Isolated rat adrenal cells prepared by collagenase-trypsin digestion[7] respond to enterotoxin with a characteristic lag period of between 30–45 min. Subsequently the rates of both cyclic AMP and corticosterone production are linear for at least 1 h. When the cells are treated with 20 mU ml^{-1} neuraminidase in conditions shown to liberate membrane sialic acid[7,17], the response to enterotoxin is increased. The results in Table 1 indicate that in neuraminidase treated cells, the production of both corticosterone and cyclic AMP is increased at all tested concentrations of enterotoxin, the increase is relatively greater for cyclic AMP than it is for corticosterone and the dose of enterotoxin required to produce maximum stimulation is similar for both corticosterone and cyclic AMP.

Figure 1 shows the time course of corticosterone synthesis by control and neuraminidase-treated cells in the presence of maximally stimulatory levels of enterotoxin. The maxi-

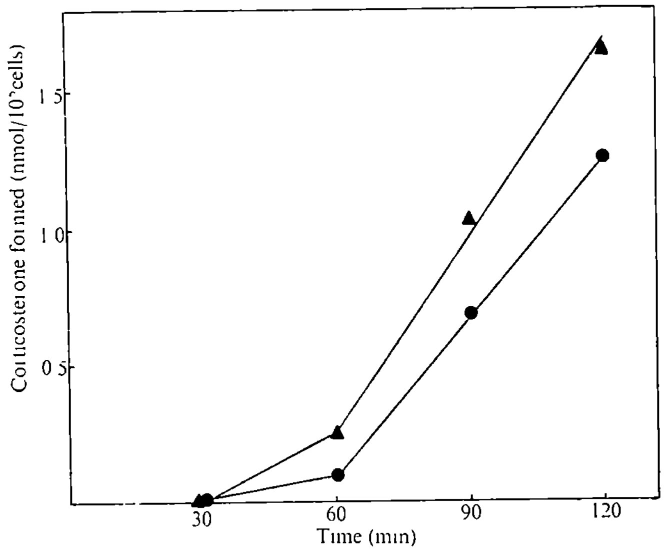

Fig 1 Time course of corticosterone synthesis by control (●) and neuraminidase-treated (▲) cells in response to enterotoxin In the absence of enterotoxin, corticosterone production was negligible (<0 05 nmol per 10^5 cells per 2 h) in both groups Concentration of enterotoxin was 1 μg ml^{-1}

mum rates for corticosterone production, attained after 60 min of incubation, are 1 17 and 1 45 nmol per 10^5 cells per h for control and neuraminidase-treated cells respectively Extrapolation of these curves indicates that the lag period is shortened by about 6–7 min in the neuraminidase-treated cells Thus, the increased response of neuraminidase-treated cells to enterotoxin may be the result of a combination of two effects first, the increased rate of synthesis and, second, the shortening of the lag period

It is not yet clear whether neuraminidase treatment simply 'unmasks' more enterotoxin receptors on the cell membrane or produces a change in the configuration of receptors Recent studies have indicated that the biological receptor for enterotoxin may be a ganglioside[8–12] King and van Heyningen[10] have shown that addition of neuraminidase-resistant monosialoylganglioside (G_{M1}) with enterotoxin can prevent the stimulation of intestinal adenyl cyclase by the latter Such an effect was not observed with neuraminidase-sensitive di- and trisialosylgangliosides The treatment of these gangliosides with neuraminidase, however, rendered them capable of abolishing the effect of enterotoxin—presumably by converting them to G_{M1} Cuatrecasas[11] has shown that among all the gangliosides tested, G_{M1} was the most effective in inhibiting the binding of enterotoxin to liver membranes In the same study it was found that digestion of liver membranes with neuraminidase resulted in a slight enhancement in the ability of the membranes to bind enterotoxin Thus, it is possible that increased sensitivity of the neuraminidase-treated cells to enterotoxin in our study was due to the conversion of complex di- and trisialosylgangliosides to monosialosylganglioside in the intact cell membrane Our studies also provide a plausible explanation for the presence and function of large amounts of neuraminidase found in *Vibrio cholerae*

Table 1 Effect of neuraminidase (Nase) treatment of adrenal cells on the formation of cyclic AMP and corticosterone in response to enterotoxin

Toxin ($ng\ ml^{-1}$)	Corticosterone formed nmol per 10^5 cells per 2 h Control cells	Corticosterone formed nmol per 10^5 cells per 2 h Nase treated cells	Cyclic AMP formed pmol per 10^5 cells per 2 h Control cells	Cyclic AMP formed pmol per 10^5 cells per 2 h Nase treated cells
0	<0 05	<0 05	0 5	1 4

Prostaglandin E_1 action on sinus pacemaker and adenylyl cyclase in kitten myocardium

A QUANTUM mechanical analysis of Kier *et al*[1,2] indicates that the amine group of the catecholamine isoprenaline may not be essential to produce pharmacological effects mediated through adrenergic β receptors Based on this and on conformational similarities between the ring, β-hydroxyl group and alkyl areas of N-*n*-propylnoradrenaline and prostaglandin (PG) E_1, these authors predicted that PGE_1 should be able to interact positively with adrenergic β receptors Isolated tissues from kitten heart are appropriate systems to investigate effects of drugs which are β-receptor dependent and we tested the predictions of Kier *et al* by investigating if PGE_1 produced positive inotropic and chronotropic effects and whether these effects are transmitted through the adrenergic β receptors

It is a general finding that dose response curves of positive inotropic and chronotropic effects of catecholamines are similar when obtained with driven left atrial strips and with

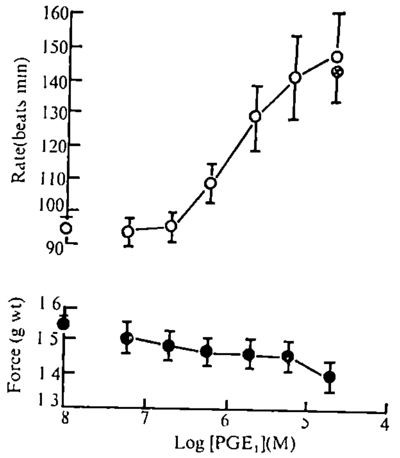

Fig 1 Nonadrenergic positive chronotropic effect of prostaglandin PGE_1 Tissues were from kittens (weight 350–800 g, either sex), pretreated with reserpine (5 mg kg^{-1} subcutaneously, 24 h) Cumulative concentration effect curves of PGE_1 on spontaneously beating right atria (○) and on left atrial strips driven at 2 s intervals with barely suprathreshold pulses of 5 ms duration (●) Values are mean ± s e m from four pairs of left and right atria in the same 50 ml organ bath containing gassed (95% O_2, 5% CO_2), warm (32 5° C) modified Krebs solution[3] 6×10^{-7} M (±)-propranolol was added for 65 min after 2×10^{-5} M PGE_1 had produced an equilibrium effect on right atria (±)-Propranolol did not influence the effect of PGE_1 (cross in circle) Open and closed circles on ordinate are values of basal rate and force, respectively, before PGE_1 was administered

spontaneously beating right atria[3] We found that PGE_1 selectively produced positive chronotropic effects but not positive inotropic effects (Fig 1) Similarly, on six driven papillary muscles (5 s intervals, 32 5° C, from kittens pretreated with reserpine), concentrations from 2×10^{-8} M to 4×10^{-5} M PGE_1 did not modify the strength of isometric contraction or the rates of contractions and relaxation This dissociation of positive chronotropic effects and lack of inotropic effects of PGE_1 is not characteristic for adrenergic agonists

To see whether the selective positive chronotropic effect of PGE_1 on right atria was mediated by adrenergic β receptors, β-receptor blocking agents were used Thus, if PGE_1 is a β agonist its activity should be antagonised by conventional β-blockers and greater concentrations of the prostaglandin should surmount the blockade allowing the estimation of an apparent dissociation equilibrium constant (K_B) for the blocker–receptor interaction If the blocker and the prostaglandin interact both with the same receptor this K_B should not differ from the K_B estimated from the antagonism of the blocker against a classical β agonist such as isoprenaline With this in mind, we first added 6×10^{-7}M (±)-propranolol to the atria under the influence of PGE_1 (±)-Propranolol did not modify the positive chronotropic effect of PGE_1 on four right atria (Fig 1) In two of these atria 1×10^{-7}M (−)-KL 255 was administered 65 min after (±)-propranolol and an additional 30 min incubation of (±)-propranolol plus KL 255 did not influence the positive chronotropic effect of PGE_1 Because the employed concentrations of both (±)-propranolol and (−)-KL 255 were at least 200 times greater than their respective K_Bs[3,4] they produced at least 99 5% β-receptor occupancy Since the positive chronotropic effect of PGE_1 persisted under these conditions, it must be ruled out that it is mediated through adrenergic β receptors[1,2,5]

PGE_1 presumably modifies the ion permeability of the membrane of sinus pacemaker cells in such a way that steeper prepotentials and tachycardia result If so, it may perhaps be related to an increase of adenylyl cyclase activity in the membrane of pacemaker cells and concomitant increase of intracellular cyclic 3′,5′-adenosine monophosphate (cyclic AMP) levels Based on the previous findings, activation of pacemaker cell adenylyl cyclase by PGE_1 should be independent of β-receptor action We therefore explored the possible effect of PGE_1 and isoprenaline on adenylyl cyclase activity in membranes of kitten atria In such membranes PGE_1 increases adenylyl cyclase activity by 50% (Fig 2) As expected, this effect of PGE_1 is unaffected by 10^{-7}M (±)-propranolol, indicating that it is not mediated by adrenergic β receptors To check whether these membranes preserved their β receptors, the action of (−)-isoprenaline was investigated (−)-Isoprenaline increased adenylyl cyclase activity about three times more than PGE_1 (±)-Propranolol (10^{-7}M) surmountably antagonised the action of (−)-isoprenaline (Fig 2)

We calculated an apparent K_B of about 3×10^{-9}M for (±)-propranolol from the concentration ratio of concentration-effect curves of (−)-isoprenaline obtained in the absence and the presence of the blocker according to equation K_B = (±)-propranolol/(concentration ratio — 1) This value of K_B for (±)-propranolol is the same as the K_B between the β blocker and receptors mediating positive inotropic and chronotropic responses of (−)-isoprenalaine[4], indicating that the β receptors are unchanged in cell-free membrane particles[6]

Concentration effect curves to PGE_1 on both intact right atria—positive chronotropic effect, and on atrial membrane particles—stimulation of adenylyl cyclase, seem to correlate This correlation does not however necessarily imply functional dependency If the enhanced adenylyl cyclase activity is a specific step between a hypothetical PGE_1 receptor and a site on the pacemaker cell where permeability changes lead to increased chronotropism, one would expect adenylyl cyclase in membrane particles from the ventricle not to respond to PGE_1 But PGE_1 was found to increase also the adenylyl cyclase activity in membranes from ventricular myocardium (Fig 3) This effect is only about 2/5 of the maximum increase of activity obtained with (−)-isoprenaline As in atrial membranes, the effect of PGE_1 is not modified by 1×10^{-7}M (±)-pro-

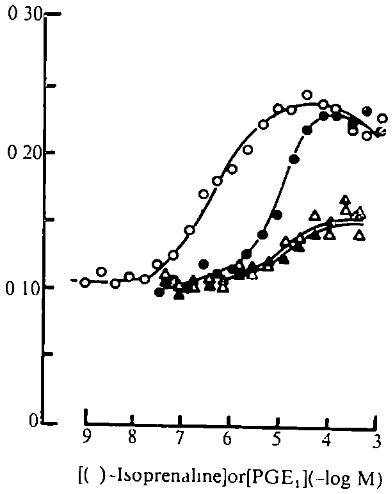

Fig 2 Nonadrenergic and adrenergic adenylyl cyclase stimulation by PGE_1 and (−)-isoprenaline, respectively 10,000*g* membrane particles of atria from kittens pretreated with reserpine were prepared as described elsewhere[12] Particles (78 µg protein) were preincubated in 20 µl of 0 5 mM $KHCO_3$, 2 5 mM EGTA, 25 mM Tris-HCl, *p*H 7 5, at 4° C, during 120 min with (solid symbols) or without (open symbols) 10^{-7} M (±)-propranolol, later 10 µl of 1 mM $KHCO_3$, 0 05 mM EGTA, *p*H 7 5, with or without (−)-isoprenaline (circles) or PGE_1 (triangles) were added and the mixture further preincubated for 90 min at 4° C Incubation was initiated by adding 20 µl containing ingredients to give in a final volume of 50 µl 2 0 mM α-^{32}P-ATP (1 5 × 10^6 c p m), 3 5 mM $MgCl_2$, 1 0 mM cyclic AMP, 20 mM creatine phosphate, 0 2 mg ml^{-1} creatine kinase and 25 mM Tris-HCl, *p*H 7 5 The incubation lasted 10 min at 32 5° C, it was stopped with 100 µl of 40 mM unlabelled ATP, 12 5 mM ^{3}H-cyclic AMP (about 10,000 c p m) and 1% sodium dodecyl sulphate followed by immediate boiling for 3 5 min The ^{32}P-cyclic AMP formed was determined by the method of Krishna *et al*[13]

pranolol and seems therefore not to be mediated by adrenergic β receptors In contrast, (±)-propranolol surmountably shifted the concentration-effect curve of (−)-isoprenaline towards greater amine concentrations (Fig 3) which allowed us to estimate a K_B of about 4 × 10^{-9}M for (±)-propranolol This K_B is the same as the K_B between (±)-propranolol and β receptors mediating inotropic effects in papillary muscles of kittens, indicating that the β receptors are preserved in ventricular membrane particles[6] The similarity of K_Bs of (±)-propranolol on membrane particles from atria and ventricles is evidence that the membranes from both tissues have similar β receptors

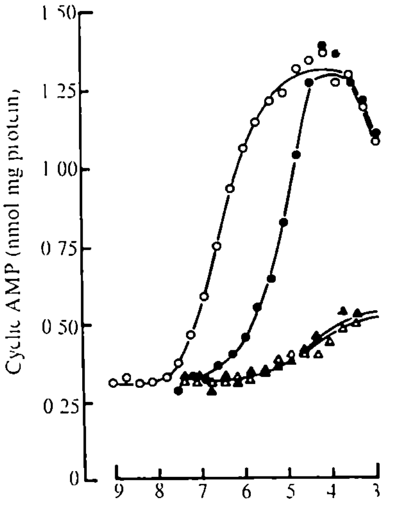

Fig 3 Comparison of adenylyl cyclase stimulation by PGE_1 (triangles) and by (−)-isoprenaline (circles) on membrane particles of ventricle For incubation medium and other conditions, see legend to Fig 2 Solid symbols with 10^{-7} M (±)-propranolol, open symbols without (±)-propranolol

Our results support the suggestion that PGE_1 would increase chronotropism through an increase of adenylyl cyclase activity in cardiac membranes Cyclic AMP has been shown to increase activity of pacemaker cells not only in atria, but also in Purkinje fibres The increase of heart cyclic AMP[8], and membrane adenylyl cyclase activity to PGE_1 seems to be of no consequence for inotropism and if PGE_1 promotes chronotropism through stimulation of adenylate cyclase activity, this effect is either restricted to intact pacemaker cells or does not affect mechanisms that lead to increased strength of contraction of myocardium The fact that PGE_1 stimulates adenylyl cyclase and chronotropism through receptors which are not adrenergic β receptors does not rule out the possibility that catecholamines perhaps catalyse the synthesis of endogenous prostaglandins This has been suggested for the action of cyclase stimulating hormones in the ovary[9], the thyroid[10], and stomach muscle [11]

We thank Dr John Pike (Upjohn Company, Kalamazoo, Michigan) for his generous gift of PGE_1 A J Kaumann is a career investigator of the Conicet of Argentina This research was supported in part by a project grant from the United States National Institute of Child Health and Human Development

Effect of foetal calf serum and epidermal growth factor on DNA synthesis in explants of chick embryo epidermis

THE epidermal growth factor (EGF) is a peptide hormone which has been isolated from the submaxillary glands of male mice[1,2] It enhances proliferation and keratinisation of embryonic and neonatal epidermis *in vivo* and *in vitro*[3,4] In spite of these morphologically well documented effects, attempts to demonstrate stimulation of epidermal DNA synthesis have failed[5] In this communication we report that EGF considerably enhances precursor incorporation into DNA of chick embryo epidermal explants and that the responsiveness of the tissue to the hormone is increased by foetal calf serum

Explants of epidermis of 9-d-old chick embryos were grown in Eagle's minimal essential medium in the presence of 15% foetal calf serum By means of pulse-labelling with tritiated thymidine a uniform rate of DNA synthesis was observed over the first 7 d of cultivation The DNA labelling was decreased if serum was omitted, but EGF strongly stimulated serum-free cultures (Table 1)

In the following experiments the explants were preincubated for one day before addition of the hormone Fig 1*a* shows the time course of the stimulatory effect of EGF on the labelling of DNA in the total absence of serum Maximal stimulation was observed with 2 μg ml^{-1} EGF whereas higher doses led to a decrease (Figs 1 and 2) When the explants were precultivated in the presence of 15% foetal calf serum for one day, the control level of DNA synthesis (without EGF) was found to be approximately twice as high as that achieved without serum (Fig 1*b*) Under these conditions an EGF dose as low as 0 02 μg ml^{-1} (3×10^{-9} M) was sufficient to induce the maximal response (Fig 1*b*) With higher concentrations an inhibition of DNA labelling was observed (Figs 1*b* and 2)

The response of the tissue to the hormone occurred after a certain lag phase which depended on the EGF dose In the absence of serum (Fig 1*a*) the lag phase was much longer than in serum-containing cultures where it was less than 2h, the time of the first measurement (Fig 1*b*) In order to decide whether the serum factor was identical with EGF, the explants were precultivated with 2 μg ml^{-1} EGF instead of serum One day later a further 2 μg ml^{-1} EGF were added and the incubation was continued for 24 h Marked labelling of the DNA was found (specific radioactivity of 1,880 ± 143 c p m $μg^{-1}$ in ten experiments) compared to a control in which the second addition of EGF was omitted (227 ± 42 c p m $μg^{-1}$) This is in clear contrast to the inhibition of DNA labelling by 2 μg ml^{-1} EGF in cultures preincubated with serum instead of EGF (Fig 1*b*) The serum effect is thus obviously not due to contamination by EGF

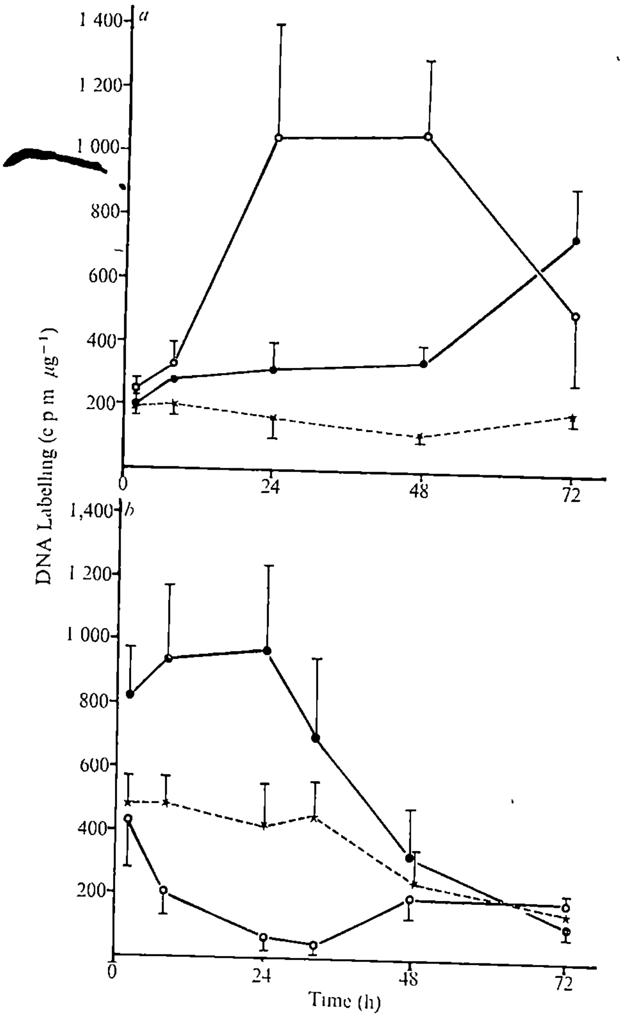

Fig 1 Effect of epidermal growth factor (EGF) on the pulse-labelling of DNA in chick embryo epidermal explants cultivated in the absence (*a*) or presence (*b*) of serum EGF was prepared from frozen submaxillary glands of male mice according to ref 2 The explants were dissected from the back-skin of 9-d-old chick embryos (White Leghorn) and epidermal sheets were separated from connective tissue by incubation with 0 1% collagenase (Boehringer Mannheim) in Dulbecco's phosphate-buffered saline (PBS) at 37° C for 25 min[4] The method used for tissue culture was based on that described by Cohen[4] Intact sheets of epidermis were layered on to pieces (0 5 × 0 5 cm) of Millipore filter (Solvinert, pore size 0 25 μm) with the peridermal side facing upwards The filters were placed on agar platforms[4] and incubated in plastic Petri dishes (Falcon, 3 5 cm diameter) with 1 ml Eagle's minimal essential medium (MEM) at 37° C in the presence of 5% CO_2 Each Petri dish contained 3 explants For DNA labelling three filters with explants were removed from the agar platforms, placed into an Eppendorf reaction vial containing 5 μCi ^{3}H-methyl thymidine (NEN, Boston, USA) in 1 ml medium and incubated at 37° C for 1 h The medium was then replaced by 1 ml ice-cold 0 4 M perchloric acid and the samples were allowed to stand in an ice-bath for 10 min After washing with 1 ml ethanol (twice) and 1 ml ether (twice) as well as with 1 ml ice-cold 0 4 M perchloric acid each, each filter was transferred into 0 4 ml 0 3 M NaOH and incubated at 30° C for 90 min During this procedure the epidermal sheet was solubilised The filter was removed and the solution was acidified with 0 1 ml 3 M perchloric acid After 60 min (0–4° C) the precipitate was collected by centrifugation, washed three times with 1 ml 0 4 M perchloric acid and finally dispersed in 0 3–0 4 ml 0 5 M perchloric acid and heated at 95° C for 20 min Aliquots of the clear supernatant were used for measuring radioactivity and DNA content[6] The explants were preincubated in MEM (without serum) for 24 h before the addition of EGF ★ controls (without EGF), ● 0 02 μg ml⁻¹ EGF, ○ 2 μg ml⁻¹ EGF Each point represents the mean of > 10 determinations (± s d)

Table 1 Pulse-labelling of DNA in chick embryo epidermal explants after 24 h cultivation in the absence and in the presence of foetal calf serum (15%) or epidermal growth factor

EGF (μg ml⁻¹)	Serum	Specific radioactivity of DNA (c p m μg⁻¹)
–	+	740 ± 240
–	–	348 ± 172
0 2	–	1294 ± 245
2	–	2830 ± 573

For experimental details see Fig 1 (± s d , *n* > 10)

These results show that EGF strongly induces DNA synthesis in explants of foetal epidermis and that foetal calf serum increases the tissue's responsiveness to the hormone approximately one hundredfold Since similar observations could not be made with epidermis of adult animals the stimulatory effect of EGF is apparently restricted to the foetal or embryonic tissue On the other hand, the healing of wounded corneal epithelium of adult rabbits is accelerated by the factor, although as soon as the regeneration is completed, the effect disappears completely[9]

We have recently proposed[7] that the proliferative compartment of foetal epidermis is built up by 'pluripotential' stem cells which are replaced by 'committed' stem cells during adolescence and that epidermal wound healing in adult animals is accompanied by a dedifferentiation of committed, or by an activation of residual 'pluripotential' stem cells (refs 10 and 11 and unpublished data)

Whereas a committed cell population may be considered to be a self-regulated system, in a pluripotential cell population the equilibrium between growth and specific tissue function must necessarily be controlled by exogenous factors Since EGF has been shown to induce cell proliferation as well as tissue function in interfollicular foetal epidermis[3,4], it may be such a factor

At present it is impossible to tell whether the primary activity of EGF is to induce growth or keratinisation, or whether it does both by controlling tissue homeostasis If EGF induces keratinisation and the stimulation of growth is due to compensatory proliferation of the remaining stem cells, the inhibitory effect of overdoses of EGF (see also ref 8) could be explained as the consequence of a rate of keratinisation too high for compensatory proliferation, so that the stem cell pool runs empty

The ontogeny of epidermis may include several stages of commitment One of the first might be the induction by specific

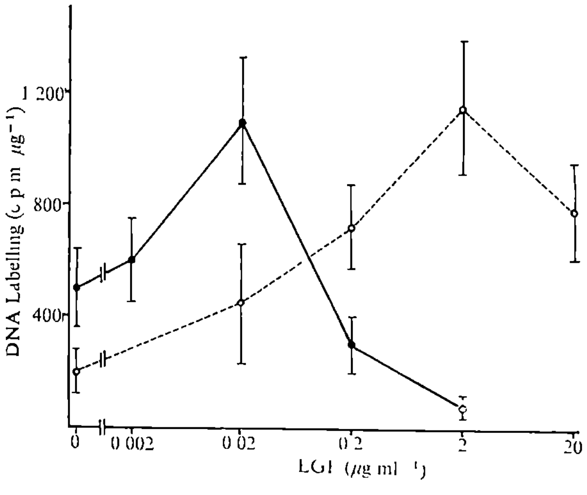

Fig 2 Dose-response relationship of the effect of EGF on pulse-labelling of DNA in chick embryo epidermal explants EGF was added after preincubation of the explants for 24 h The DNA was pulse-labelled after 48 h The experiment was done either in the absence (○) or in the presence (●) of 15% foetal calf serum Each point represents the mean of > 10 determinations (± s d) For details see Fig 1

serum factors of responsiveness to hormones capable of controlling tissue homeostasis, such as EGF. This stage, during which tissue function depends entirely on exogenous stimulation, is replaced by a second stage where the tissue's own regulation, such as the chalone mechanism[6-11], is established.

Heterogeneity of carcinoembryonic antigen and its fractionation by con A affinity chromatography

THE term carcinoembryonic antigen (CEA) was first used by Gold and Freedman to describe a tumour-associated antigen found in the cellular membrane of adenocarcinomas from endodermally derived digestive system epithelia[1]. It is conveniently prepared from liver metastases of primary colonic tumours by initial extraction with perchloric acid followed by Sepharose 4B and Sephadex G-200 chromatography[2,3]. Initial optimism about the specific occurrence of CEA in digestive tract tumours and in the serum of patients with such lesions has not been sustained and CEA is now known to occur in both normal colonic mucosa and other normal tissues[4] and in the sera of normal individuals, although in relatively low amounts[5]. Elevated levels of CEA have been found in a wide variety of neoplastic diseases and also in non-neoplastic disorders such as gastrointestinal polyps, alcohol cirrhosis, uraemia and inflammatory bowel disease[6-8].

It seems possible that the inadequate specificity of CEA radioimmunoassay, as used to detect certain types of human cancer, might result from heterogeneity in the CEA preparation used in the assay and to raise antisera. An associated glycoprotein CEX[9], separated from some batches of CEA by gel filtration, appears to be immunologically identical to NGP[10] and NCA[11] antigens originally reported. Other workers, however, using a variety of techniques[3,9,12,13], have demonstrated the heterogenous nature of CEA which had been separated from CEX. Charge heterogeneity and variation in electrophoretic mobility may reflect variability in sialic acid content although residual heterogeneity of CEA is still seen after neuraminidase treatment. Also, different batches of CEA are known to vary in terms of carbohydrate/protein ratio and their amino acid constitution and it is significant that the most marked variation occurs between preparations from tumours of different tissues[14].

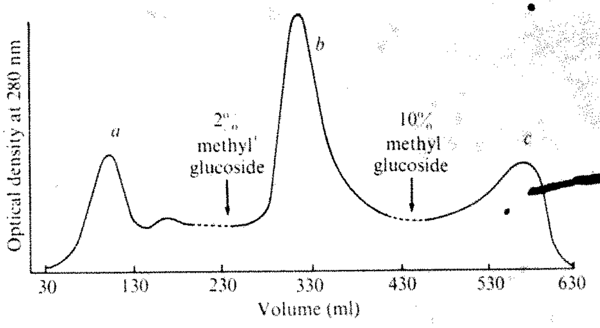

Fig. 1 Con A–Sepharose chromatography of CEA. 30 ml of purified CEA solution[2] containing 98 mg of CEA was dialysed against 0.1 M sodium acetate buffer (*p*H 6) containing 1 M NaCl, 10^{-3} M $CaCl_2$, 10^{-3} M $MgCl_2$ and 10^{-3} M $MnCl_2$. The solution was then applied to a column of con A–Sepharose (Pharmacia), bed volume 66 ml and eluted with the above buffer. After the unbound fraction 1 was collected, a 2% solution of methyl glucoside in the above buffer was applied and fraction 2 collected. The third fraction was eluted using 10% methyl glucoside solution. The column was finally washed with 20% methyl mannoside before reuse. The recovery of protein in each fraction, determined by optical density at 280 nm was 10%, 50% and 20% respectively.

Here we describe the use of con A immobilised on Sepharose 4B (ref. 15) to separate CEA into immunologically active fractions. Of particular relevance to our work are the results of Chu *et al.*[16] who have shown that CEA can be specifically bound to con A and the binding reversed by another saccharide. CEA used in the present study (M-12) was prepared by the method of Krupey *et al.*[2] from a large liver metastasis and separated on a column of con A–Sepharose into three fractions as illustrated in Fig. 1. To demonstrate that fraction 1 did not contain some fraction 2 because of overloading of the column, fraction 1 was reapplied to a new column; it was not absorbed and no detectable peak was eluted with 10% methyl glucoside. Each fraction was concentrated to approximately 1 mg ml^{-1} protein by ultrafiltration using an Amicon PM 10 membrane and tested by double diffusion against various anti-CEA antisera.

The preparation and comparison of the antisera formed the major part of this work. Antisera were prepared in rabbits by injecting 200 µg of a purified batch of CEA[2] in complete Freund's adjuvant, intradermally in the flank; a booster was given 40 d later. Antiserum 174, after extensive absorption with pooled normal colonic mucosa extract, normal human plasma and liver extract, produced a reaction of identity in double diffusion with fractions 1, 2 and 3 and an additional reaction with fraction 2 (Fig. 2*a*). The common antigenic determinant has been designated group A whereas the additional determinant in fraction 2 has been designated group B. Similar results have been obtained with a later CEA preparation (M-31). Anti-NCA (ref. 11) and anti-CEX (ref. 9) antisera on the other hand failed to react with fractions 1 and 2 but gave a strong reaction with fraction 3 identical to the reaction given by NCA previously prepared from a crude CEA extract (Fig. 2*b*).

These results are in contrast to those obtained with antiserum 224. After absorption, a sharp precipitin line was produced with fraction 1 but no reaction was given with fractions 2 and 3 (Fig. 2*c*). The determinant with which antiserum 224 reacts is quite distinct from the A group determinant (Fig. 2*d*), and has been tentatively designated the Y group, although it is not yet clear whether this is a widely occurring CEA component.

Various antisera, such as 'ace' 10, 22, 24 and 36, reacted similarly to antiserum 174 and gave a single line of identity between all three fractions. With the A-group specific line given by the latter antiserum (Figs 3*a* and 3*b*) 'ace' 24 antiserum gave an additional line with fraction 3, (cross-reacting with the A-group specific line), which has been shown to be identical with the line given by anti-CEX antiserum and the associated glycoprotein CEX. In addition, 'ace' 36 antiserum produces an additional line against fraction 2 (Fig. 3*c*) which is identical to the B group-specific line given by antiserum 174. It is not established whether the B group reported here is the same as the unique CEA determinant recently reported by Tomita *et al.*[17], or alternatively the β-E protein reported by Orjasaeter *et al.*[18] which was shown not to be identical to Gold's original CEA.

To exclude the possibility that our antisera may be reacting ~~strongly~~ with components in normal liver and colon, even after extensive absorption, we have tested the antisera against preparations containing up to 50 mg ml^{-1} of freeze-dried perchloric acid extract in double diffusion studies. Antiserum 224 and the B-group activity of antiserum 174 failed to produce a precipitin line in any case. Anti-NCA antiserum, however, produced a strong line with the extracts showing the presence of the associated glycoprotein. In addition, strong lines were given between anti-NCA antiserum and extracts (20 mg ml^{-1}) of normal lung and spleen in agreement with the original reports of Mach and Pasztaszeri[9] and von Kleist *et al.*[11]. Using antiserum 174 and the monospecific anti-CEA antisera of Todd (which react with the A-group) we have been able to demonstrate the presence of CEA in some normal colon and lung tissue extracts at concentrations of about 50 mg ml^{-1}. (Fig. 3*d*). The failure to detect both B and Y-group antigens on the other hand may be significant, although pending quantitative estimation by radioimmunoassay, their 'normal' level relative to that of CEA as measured by most anti-CEA antisera, is unknown.

Our results, reported here in preliminary form, show that CEA can be separated into at least two immunologically related fractions in addition to its separation from the well documented NCA. Also, we have shown that CEA fractions 1 and 2 contain determinants (which may be on separate molecules) which can be distinguished by appropriate antisera. These fractions, however, remain indistinguishable by anti-CEA antisera such as the Todd 'ace' antisera which appear to be reacting with a group common to each of the fractions.

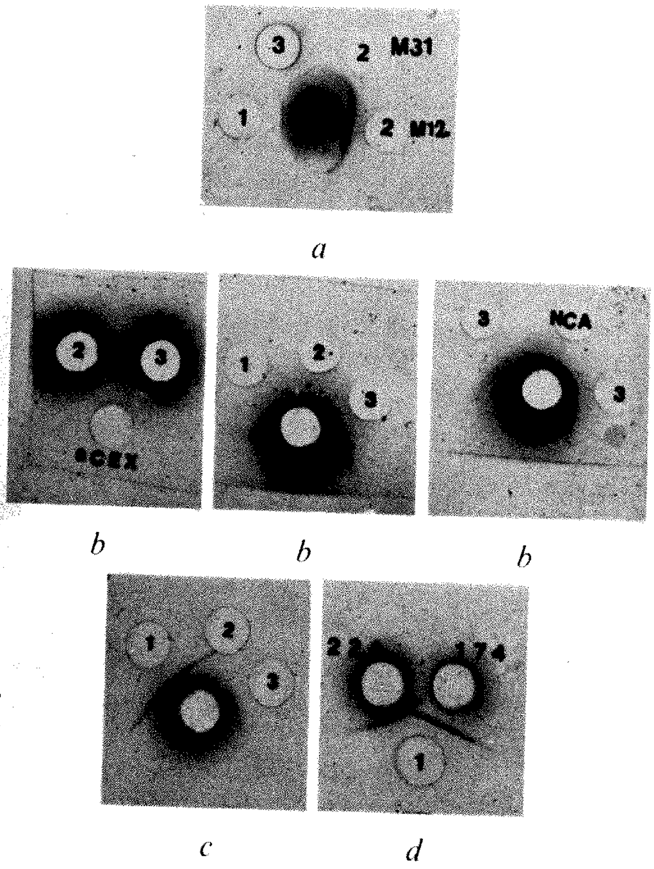

Fig. 2 *a*, Ouchterlony double-diffusion reactions between antiserum 174 (centre well) and fractions 1, 2 and 3 showing line of identity and an additional line produced by fraction 2 from CEA preparations M-12 and M-31. *b*, Reaction of anti-NCA and anti-CEX antisera (bottom wells) with fraction 3 and NCA showing an identical reaction. *c*, Reaction of antiserum 224 (centre well) with fraction 1 and, *d*, reaction showing dissimilar reactions of antisera 224 and 174 against fraction 1.

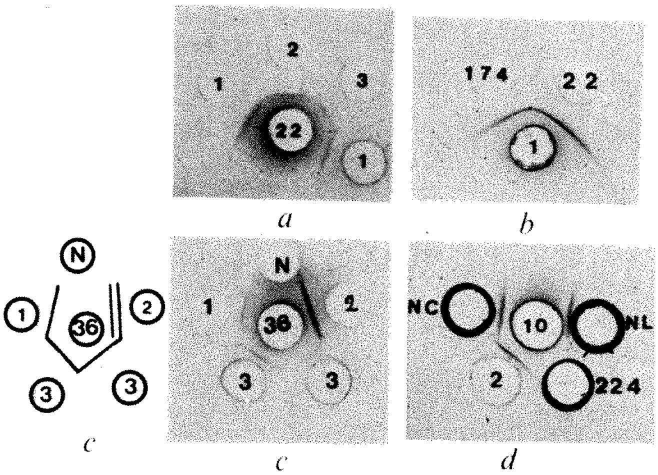

Fig. 3 *a*, Reaction of 'ace' 22 antiserum (centre well) with fractions 1, 2 and 3 showing line of identity. *b*, Reaction of identity between antiserum 174 and 'ace' 22 antiserum against fraction 1. *c*, Reaction showing additional line given by 'ace' 36 antiserum and fraction 2. *d*, Reaction using 'ace' 10 antiserum (centre well) to show the presence of CEA in normal colon (NC) and normal lung (NL); a line of identity with fraction 2 is obtained. Antiserum 224 fails to react.

The immunological differentiation between the con A bound and unbound CEA's raises fundamental questions about the chemical nature of CEA. It is necessary to know whether the A and Y and also the A and B groups are situated on different CEA-like molecules and whether further fractionation is possible. It is also important to know how sialic acid is distributed between the CEA fractions and how its removal will affect the binding properties of CEA to con A. In addition to these basic problems, further fractionation of CEA preparations may afford reagents for improving the specificity of the CEA assay and indicate whether circulating CEA shows a similar heterogeneity to preparations isolated from tumour tissue.

We thank Professor A. M. Neville for the anti-CEX antiserum and also a sample of CEX. We also thank Dr S. von Kleist for the anti-NCA antiserum and Dr C. W. Todd who supplied the 'ace' anti-CEA antisera. This work was carried out with the support of the Medical Research Council.

Combined hyperthermia and radiation suggest an alternative to heavy particle therapy for reduced oxygen enhancement ratios

THE American Cancer Society estimates that 250,000 people in the United States will die from cancer in 1974 and it has been speculated that 100,000 of them will die because of failure to control the primary tumour site[1]. In the report of a 1972 conference on particle accelerators in radiation therapy Bagshaw said: ". . . perhaps the most critical factor in determining success or failure in the sterilisation of a localised neoplasm with standard megavoltage radiation is the state of oxygenation of the cells being irradiated . . ."[2]. Cells which are poorly oxygenated when irradiated are more resistant to conventional X radiation than those which are well oxygenated. Many tumours are hypoxic and thus may be more resistant to radiation than the well oxygenated surrounding normal tissue. Considerable time and effort have been expended during the past decade in attempts to circumvent this problem. Efforts are currently focused on the use of heavy particles. We now have data suggesting that hyperthermia in conjunction with standard megavoltage radiation may present an alternative for circumventing the oxygen problem.

Our interest in the oxygen problem arose from *in vivo* studies of the effects of hyperthermia on the radiation sensitivity of normal and malignant tissues. These studies showed that the radiation sensitivity of C3H mammary tumours in mice was increased by a factor of 4.27 by treatment at 43.0° C, whereas the sensitivity of normal mouse skin was increased by a much smaller factor—2.06 (ref. 3). Since this tumour is considered to be poorly oxygenated, the data suggested a differential effect of hyperthermal treatment on the radiation sensitivity of hypoxic and well oxygenated cells. We present here data that show a selective hyperthermal radiation sensitisation of anoxic cells.

Our biological test system was the spleen-colony bone marrow system of Till and McCulloch[4]. Receptor mice were given a whole body dose of 800 rad which eliminated endogeneous haematopoetic cells from the spleen. On the next day, marrow cells were collected from donor mice, counted, subjected to the experimental treatment and then injected into the tail vein of receptor mice. A fraction of these cells lodged in the spleen and grew to form cell aggregates, grossly visible as nodules in the otherwise radiation-depleted spleen. The number of colonies in the spleen 10 d after injection was used as a relative measure of cell survival.

Properly diluted suspensions of bone marrow cells were placed in siliconised test tubes in water baths for 1 h at 37.5°, 42.5° or 43.0° C. This hyperthermal treatment was initiated before irradiation, maintained during irradiation and continued after irradiation, with the heating time equally divided between before and after. This treatment regimen was chosen to allow direct comparison with parallel studies of tumour therapy already in progress. Cells were irradiated with approximately 100 rad min^{-1} from a conventional 100 KVP X-ray unit.

Hypoxia was produced by causing high purity nitrogen containing 5% carbon dioxide (specified by the manufacturer as having oxygen contamination of less than 2 p.p.m.) to flow over the cell suspensions, which were agitated periodically to assure gas equilibrium. The effluent gas was monitored continuously and the degree of hypoxia was considered adequate when less than 10 p.p.m. of oxygen was detected, although the gas flow was continued for the full hour of thermal treatment. Gas treatment was identical for the oxygenated group, except that air with 5% carbon dioxide replaced the nitrogen–CO_2 mixture. Cells rendered anoxic in this manner and well-oxygenated controls were irradiated, using an appropriate dose range, to determine radiation survival curves at each of the hyperthermal temperatures. Data were obtained for both the anoxic and oxygenated groups during the same period of treatment and at least two independent treatments were carried out at each temperature. Regression analysis was carried out on the survival data to yield the survival curve slopes shown in Table 1.

Table 1 Calculated best fit slopes and associated standard deviations, obtained with hyperthermal treatment

Temperature (° C)	Survival curve slope (10^2 per rad)		OER
	Oxygenated	Anoxic	
37.5	0.94 ± .05	0.38 ± .02	2.47 ± .19
42.5	1.81 ± .18	1.07 ± .06	1.69 ± .19
43.0	2.66 ± .09	1.93 ± .09	1.38 ± .08

OER, oxygen enhancement ratio. This describes the relative radiation sensitivity of the oxygenated and anoxic cells, and was calculated from the ratios of the slopes of the anoxic to oxygenated cells at each temperature.

Although there was a marked increase in the radiation sensitivity of both oxygenated and anoxic cells with increasing temperature of treatment, it was appreciably greater for the latter. Anoxic cells subjected to the hyperthermal treatment at 43.0° C were more sensitive to radiation by a factor of 5.07 (1.93/0.38) and oxygenated cells by a factor of 2.83 (2.66/0.94) than their controls at 37.5° C. This selective radiation sensitisation brings about a reduction in the oxygen enhancement ratio (OER) from a value of 2.47 at 37.5° C to 1.38 at 43.0° C.

To place these data in perspective, Table 2 lists some representative and recently reported OER values from studies with heavy particle beams produced by an accelerator. They range from approximately 1.5 to 2.2. Since the OER of 1.38 which we have obtained through hyperthermal treatment at 43.0° C seems to compare well with those reported from heavy particle studies, our data suggest that the use of hyperthermia as an adjunct to radiation therapy might well be a way to circumvent the oxygen problem. The production of thermal fields necessary for the treatment of patients will require considerable research and engineering. If a technology for producing suitably controlled and localised thermal fields can be evolved, hyperthermia in conjunction with readily available radiation sources (such as cobalt teletherapy units, linear accelerators or betatrons) might provide some of the same advantages as heavy particle therapy.

Table 2 Recently reported OER values obtained with heavy particle beams under conditions suitable for patient treatment

Functional identification of three components which mediate tissue-type specific embryonic cell adhesion

VARIOUS hypotheses have been suggested to explain *in vitro* reconstruction of tissues from populations of dispersed embryonic cells[1-5], all asserting that it is based on selective adhesion. Although selective adhesion has been amply demonstrated[6-8], its molecular basis as well as the identity and number of components involved remains to be defined. Supernatant solutions from cell and tissue cultures have been reported to yield a component(s) apparently involved in the enhancement of cell aggregation[9-11]. In addition a component(s) in the supernatant binds at the cell surface and is specific to the cell type from which the supernatant is prepared[11]. These results suggested the existence of specific receptors at the cell surface that are complementary to the aggregation promoting molecules (APM). We have now found that the binding factor participates directly in adhesion and that another component must be present for adhesion to be complete.

Collection of ^{3}H-glucosamine-labelled aggregation-promoting supernatant solutions (APMs; retina aggregation promoting material (RAPM) and cerebral lobe aggregation promoting material (CLAPM, called BAPM in ref. 11)), preparation of single cells and binding of APMs to the cell surface was achieved as before[11]. After binding (20×10^6 cells per ml of RAPM and 5×10^6 cells per ml of CLAPM), cells with APM or control cells were pelleted and resuspended in 1% glutaraldehyde in phosphate-buffered saline at *p*H 7.2 for 30 min at room temperature. The fixed dead cells were washed in the cold with six changes of Tyrode solution for 48 h before use.

After glutaraldehyde fixation, neither control cells nor those fixed with APM adhered to one another, even when brought into contact on a gyratory shaker. Cells fixed after binding of ^{3}H-APM retained approximately 50% of bound radioactivity and lost no more label during either washing or a subsequent 24 h incubation at 37° C. Thus fixation bound the APM permanently to the cells and caused no generalised stickiness which could complicate later experiments.

When added to freshly dispersed live cells of the same type, control fixed cells (no bound APM) had no effect on aggregation while APM-fixed cells enhanced the size of the aggregates formed (Figs 1 and 2). A minimum of one APM-fixed cell for each nine freshly dispersed live cells was required for maximal enhancement of retina cell aggregation while for cerebral cells the ratio was one in five. When, using these ratios of cells, the assay was carried out in the presence of 5 μg ml^{-1} cycloheximide (a concentration that inhibits 98% of ^{14}C-leucine incorporation within 10 min and 100% of aggregation of embryonic cells, our unpublished observations), fixed cells did not mediate any aggregation. This suggests that fixed cells alone do not mediate adhesion of live cells but that live cells must contribute some essential component(s), which was synthesised during our experiment. If this component were newly synthesised APM, addition of APM alone to APM-fixed cells should have caused adhesion or agglutination. This was not the case, further suggesting that the component(s) contributed by the live cells differs from the active factors in APM preparations.

Table 1 shows that fewer single cells remained in homologous combinations of live cells after 24 h with APM fixed cells than with control fixed cells. Thus APM-fixed cells interact with live cells in enhancing aggregation. We have evidence (manuscript in preparation) that APM is bound to the cell surface through the carbohydrate moiety of a macromolecule containing both carbohydrate and protein; for exhaustive pronase digestion does not affect binding of ^{3}H-glucosamine-labelled APM. To further characterise the role of the protein moiety of the surface-bound APM, APM preparation was digested with pronase before binding and fixation. As with whole APM, bound radioactivity was not removed during washing or culture. After washing, fixed cells were combined with live cells at ratios of 1:1 to 1:10. No live cells were promoted to aggregate (Fig. 1*d*). Results were similar when 10-d embryonic chick neural retina (Fig. 1) and 10-d cerebral lobe cells (Fig. 2) were combined in the appropriate combinations with fixed cells.

Taken together these results suggest that the live cells contribute a component(s) to the adhesive mechanism which differs from APM, and that its activity is mediated through the protein portion of the APM molecule. We have obtained further support

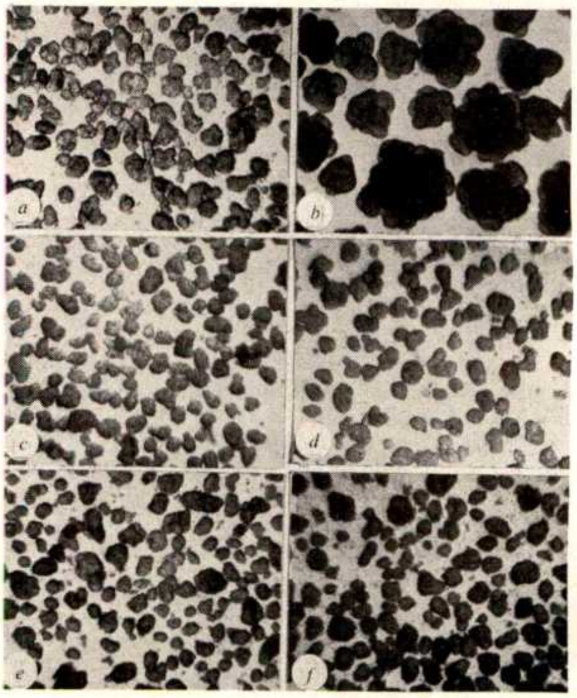

Fig. 1 Aggregation of 18×10^6 10-d retina cells in 3 ml of Eagle's basal medium under an atmosphere of 10% CO_2 in air on a gyratory shaker for 24 h. There were 2×10^6 fixed cells in in each case. *a*, No fixed cells; *b*, RAPM-fixed retina cells; *c*, control fixed retina cells; *d*, pronase-digested-RAPM-fixed retina cells; *e*, CLAPM-fixed cerebral cells; *f*, control fixed cerebral cells. (× 15).

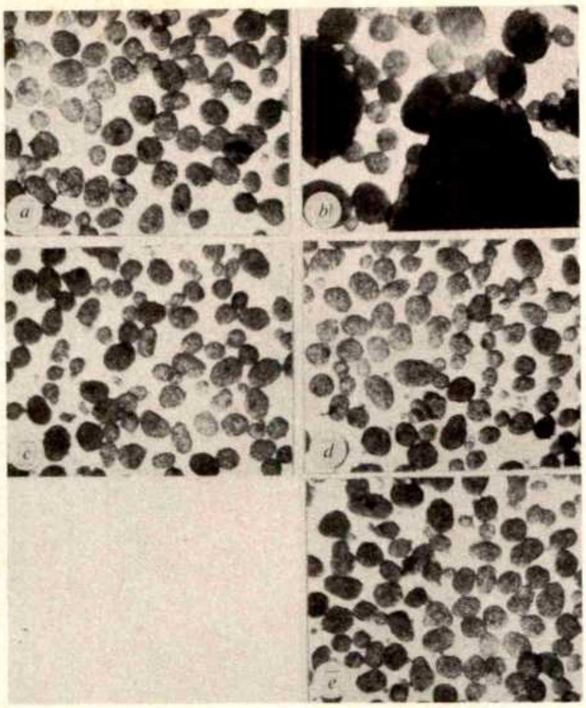

Fig. 2 Aggregation of 4 × 10^6 cerebral cells as in Fig. 1. *b–e*, 1 × 10^6 fixed cells; *a*, no fixed cells; *b*, CLAPM-fixed cerebral cells; *c*, control fixed cerebral cells; *d*, RAPM-fixed retina cells; *e*, control fixed retina cells. (× 15).

for the existence of this third component (we consider APM and its receptor to be separate components). If cells are synthesising a third type of molecule which mediates aggregation, monolayer cultures should synthesise and release it into the medium. APM-fixed cells in rotation culture on top of monolayers should thus be agglutinated in the medium above the monolayer. (Agglutinated here distinguishes loose clusters of dead cells from the formation of tissue-like aggregates of live cells. Fixed dead cells, although their adhesive mechanism may be reconstituted, would be unable to undergo further histotypic organisation.)

Monolayer cultures were prepared in Eagle's basal medium without serum; after incubation for 24 h at 37° C they were washed twice with warm serum-free culture medium, and control fixed (no APM) or APM-fixed cells were added. Incubation continued at 37° C on a gyratory shaker for 24 h (Fig. 3). APM-fixed cells were agglutinated maximally (Fig. 3*b* and *f*) while controls showed little or no agglutination (Fig. 3*c* and *g*). These results are not due to monolayer cells which were loosened from the substrate as few if any were released (Fig. 3*a* and *e*). Thus our third component can be active in a form unattached to live cells.

To test the specificity of the component(s) we prepared heterologous combinations between APM-fixed cells and live cells. Aggregation assays revealed little or no ability of APM-fixed cells to enhance aggregation even at high ratios of fixed to live cells (Fig. 1*e* and *f*, Fig. 2*d* and *e*). Rotation culture of APM-fixed cells on top of heterologous monolayers gave essentially the same results (Fig. 3*d* and *h*). Agglutination was always greatest with homologous combinations but some occurred with heterologous combinations. Counts of single cells remaining after 24 h also reflect the specificity of the proposed third component (Table 1). This is evident since in heterologous combinations the number of single cells remaining is the same for APM-fixed and control cultures, while in homologous combinations more single cells remain in control cultures than in APM-fixed cultures.

Table 1 Effect of APM-fixed cells on the number of single cells remaining in suspension after 24 h of rotation culture

Live cells	Fixed cells	Single cells remaining after 24 h	Control fixed-APM-fixed
Retina cells 18 × 10^6	RAPM-retina 2 × 10^6	2.2 × 10^6 ± 0.3 × 10^6	1.2 × 10^6
	Control retina 2 × 10^6	3.4 × 10^6 ± 0.3 × 10^6	
	CLAPM-cerebral 2 × 10^6	1.4 × 10^6 ± 0.2 × 10^6	−0.1 × 10^6
	Control cerebral 2 × 10^6	1.3 × 10^6 ± 0.3 × 10^6	
Cerebral cells 4 × 10^6	CLAPM-cerebral 1 × 10^6	0.9 × 10^6 ± 0.1 × 10^6	0.5 × 10^6
	Control cerebral 1 × 10^6	1.4 × 10^6 ± 0.1 × 10^6	
	RAMP-retina 2 × 10^6	2.8 × 10^6 ± 0.1 × 10^6	0
	Control retina 2 × 10^6	2.8 × 10^6 ± 0.3 × 10^6	

Single cells were counted on a Coulter model B particle size analyser at the appropriate settings for each cell type. These results are each the average of six experiments.

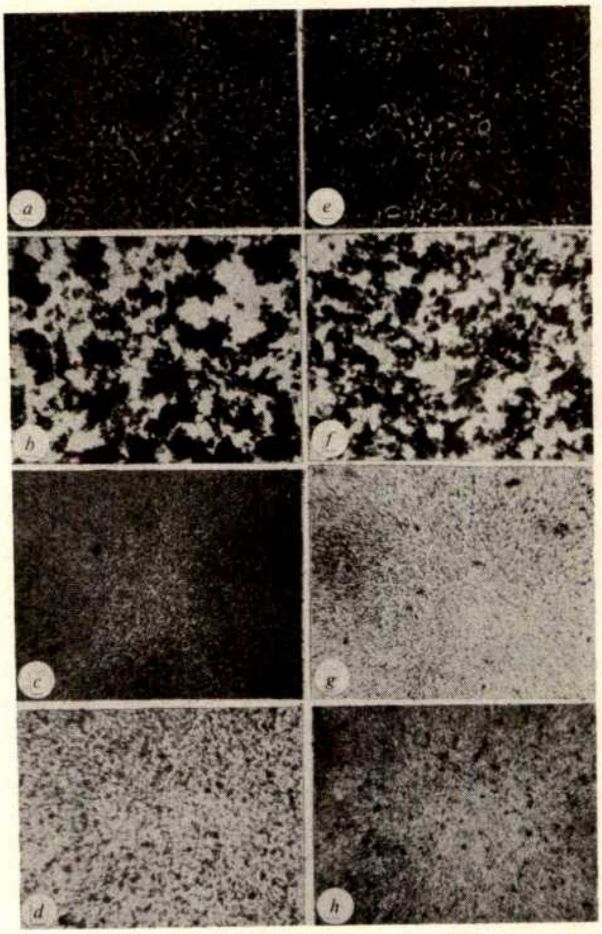

Fig. 3 Agglutination of fixed cells (2 × 10^6 retina cells or 1 × 10^6 cerebral cells) in rotation culture on monolayer cultures of retina cells (*a–d*) or cerebral cells (*e–h*) for 24 h. *a,e*, No fixed cells; *b,f*, homologous APM-fixed cells; *c,g*, homologous control fixed cells; *d,h*, heterologous APM-fixed cells. (*a,e*, × 96, focused at plane of monolayer; *b–d* and *f–h*, × 15, focused above monolayer.)

Various models are consistent with our results. For example, the third component may modify APM in some way to make it capable of forming a functional adhesion, or APM may modify the cell surface, thus allowing third component alone to form a functional adhesion. Or the third component may act as a ligator (Fig. 4). According to this model APM interacts specifically through its carbohydrate moiety with a cell surface receptor. The third component(s) interacts with the protein moiety of APM, again specifically, to effect a bridge between the cells. In this model the third component appears to be functionally

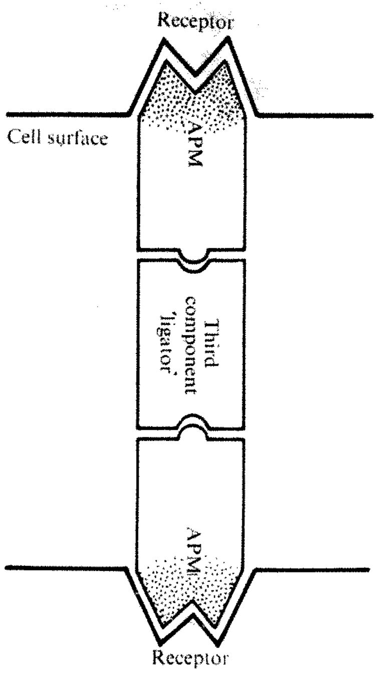

Fig. 4 Model showing the role of each of the proposed components in forming a complete specific adhesive bond. The stippled area is carbohydrate.

analogous to the sponge aggregation factor[12,13]. The aggregation-promoting factor, or APM as we term it, seems to be functionally analogous to the base plate molecule[14], in that APM and baseplate mediate the effect of the ligator molecule. Although no component analogous to our specific receptor has been identified in the sponge system, Weinbaum and Burger[14] found that once baseplate is removed from cells by hypotonic shock it can be added back to the cells, effecting a functional union.

The existence of the third component(s) may explain the necessity for biosynthetic activity even when APM is supplied to the cells[9]. Immediately after trypsinisation both APM and the third component are removed from the cell surface, for control fixed cells can neither enhance the aggregation of live cells nor be agglutinated when placed on a monolayer of live cells. Aggregation thus requires the replacement of both APM and third component. When APM is supplied a complete adhesive bond is still not formed; the third component is now the limiting factor. Our preliminary observations suggest that this third component is extremely labile. This observation may bear on the need for continued biosynthetic activity during aggregation. If this component is continuously destroyed during aggregation then its continued synthesis would be necessary.

TRH potentiates behavioural changes following increased brain 5-hydroxytryptamine accumulation in rats

WHEN tryptophan is administered to rats pretreated with a monoamine oxidase (MAO) inhibitor there results a characteristic syndrome of hyperactivity. This syndrome seems to be due to the increased synthesis and accumulation of the putative neurotransmitter 5-hydroxytryptamine (5-HT) and its 'spill-over' into functional activity which is presumably dependent on the stimulation of postsynaptic 5-HT receptors[1]. A qualitatively similar syndrome is produced by the administration of 5-methoxyN,N-dimethyltryptamine which, it has been suggested, directly stimulates 5-HT postsynaptic receptors[2]. This hyperactivity syndrome has been used to investigate the functional organisation of brain 5-hydroxytryptamine, the action of drugs such as chlorpromazine[2], reserpine[1] and lithium[3] and to investigate the role of brain catecholamines[4] in the mediation of brain 5-HT function.

Recently a report[5] has suggested that thyrotrophin releasing hormone (TRH) produced a rapid, though transient, improvement in depression when given intravenously. Because the combination of tryptophan plus a monoamine oxidase inhibitor has antidepressant properties[6] and because reserpine[7] and lithium[8,9] also affect mood in man, we investigated the effect of TRH on the hyperactivity syndrome.

Rats were pretreated intraperitoneally with 2 mg kg^{-1} TRH (Calbiochem, London) 3 h before the administration of 20 mg kg^{-1} tranylcypromine (Tcp), 30 min after which L-tryptophan was given. As shown in Fig. 1*a*, TRH caused an increase in the degree of hyperactivity[1]. There was no potentiation with a TRH dose of 0.25 mg kg^{-1}, perceptible potentiation with 0.5 mg kg^{-1}, a maximum potentiation at 1 mg kg^{-1} and 2 mg kg^{-1} but no potentiation when the dose was increased to 10 mg kg^{-1}. With a dose of 1 mg kg^{-1} it was observed that there was some potentiation of hyperactivity when TRH was given 1 h before Tcp and tryptophan, a marked response after 3 h and 6 h, but no effect at 24 h. A 1 mg kg^{-1} dose of an equimolar solution of proline, histidine and glutamic acid injected instead of TRH (pyroglutamyl histidyl prolylamide) failed to produce potentiation, showing that the constituent amino acids in combination were ineffective. No hyperactivity occurred after TRH pretreatment when either Tcp or tryptophan alone were administered.

Pretreatment with either thyroid stimulating hormine (TSH, 1 mg kg^{-1}) or L-thyroxine (1 mg kg^{-1}) (both from Sigma, London) 3 h before the Tcp, with L-tryptophan after a further 30 min failed to produce potentiation of the hyperactivity suggesting that TRH was not producing its effect by its action on pituitary secretion of TSH by a TSH-mediated effect on thyroid function. This was confirmed by the observation that TRH still potentiated the hyperactivity in rats hypophysectomised 48 h previously.

TRH alone had no effect on brain tryptophan or 5-HT concentrations nor did it affect brain tryptophan concentrations, 5-HT concentrations or the rate of brain 5-HT accumulation after the administration of Tcp and L-tryptophan. The effect of TRH on the hyperactivity produced by 5-methoxy N,N-dimethyltryptamine (5-MeODMT) was therefore examined to see whether TRH was effecting the postsynaptic response to activation of 5-HT receptor sites.

Rats were pretreated with TRH (1 mg kg^{-1}) followed 3 h later by Tcp (20 mg kg^{-1}) with 5-MeODMT (2 mg kg^{-1}) after a further 30 min TRH pretreatment consistently increased the degree of hyperactivity which was prolonged following 5-MeODMT (Fig 1*b*) This suggested that TRH was altering either 5-HT receptor sensitivity or the postsynaptic responses to increased 5-HT release When rats were pretreated with TRH (10 mg kg^{-1}) and subsequently challenged with Tcp and 5-MeODMT as above no potentiation was seen This is consistent with the observation that this higher dose of TRH does not potentiate the hyperactivity following Tcp and L-tryptophan

Previous experiments have shown the importance of brain dopamine in the production of the hyperactivity following increased 5HT synthesis or 5-MeODMT The results were tentatively interpreted as indicating that there may be a group of dopaminergic neurones lying between the 5-HT neurones initiating the response and those mechanisms responsible for the expression of the syndrome[4] Furthermore, Plotnikoff *et al*[10] showed that TRH potentiates the hyperactivity resulting from administration of a MAO inhibitor and L-dopa, a syndrome which is nevertheless qualitatively different from that produced by increasing 5-HT synthesis It was possible therefore that TRH might affect the 5-HT induced hyperactivity by an action on the postsynaptic dopaminergic system postulated We therefore attempted to confirm the visual scoring of Plotnikoff *et al*[10] by activity meter measurements

Pretreatment with TRH 3 h before the Tcp and L-dopa potentiated the hyperactivity, both at a TRH dose of 1 mg kg^{-1} and 0 25 mg kg^{-1} (Fig 2) This lower dose had been ineffective in enhancing Tcp/L-tryptophan hyperactivity This dose, however, did potentiate hyperactivity following Tcp and DL-5-hydroxytryptophan (50 mg kg^{-1}) We are unable, at present, to suggest reasons for these dose-response differences

There was no alteration in whole brain concentrations of dopamine and noradrenaline 3 h after TRH administration or after a further 90 min when Tcp and L-tryptophan had also been administered

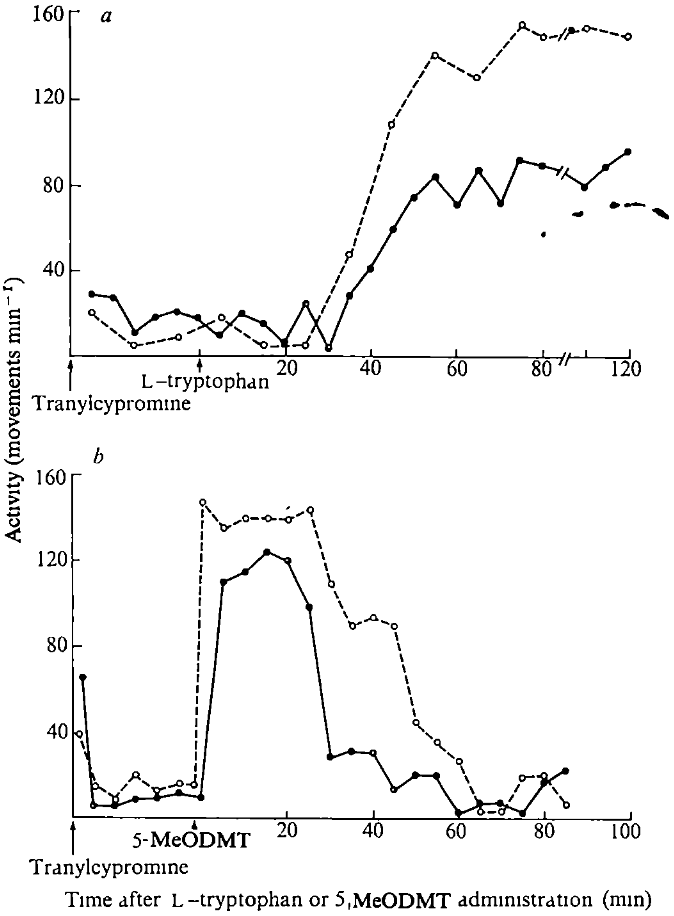

Fig 2 Hyperactivity response to L-dopa following TRH Rats pretreated with 1 mg kg^{-1} TRH (○), 0 25 mg kg^{-1} (△) or saline (●) 3 h later all groups were injected with tranylcypromine (20 mg kg^{-1}) with L-dopa (50 mg kg^{-1}) administered 30 min later

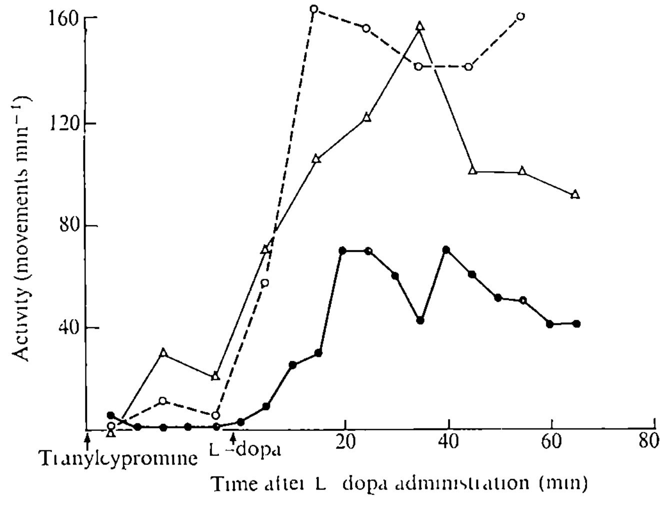

Fig 1 Hyperactivity response to, *a*, L-tryptophan and, *b*, 5-methoxyN,N-dimethyltryptamine (5-MeODMT) following TRH Male Wistar rats (150–200 g) were used in all experiments and were pretreated with either TRH 2 mg kg^{-1} (○) or saline (●) 3 h later both groups were given tranylcypromine (20 mg kg^{-1}) with L-tryptophan (50 mg kg^{-1}) or 5-MeODMT (2 mg kg^{-1}) 30 min later Activity was measured in groups of three rats on Animex activity meters (sensitivity and tuning setting 30 μA) with total movements recorded each minute Results are plotted against time after tranylcypromine administration and show typical results of experiments performed at least three times

There have now been several reports of alterations in behavioural responses to released central neurotransmitters following administration of hypothalamic hormones Plotnikoff *et al*[10] reported that TRH enhanced the hyperactivity following MAO inhibition and L-dopa and the same group[12] found similar enhancement when rats were pretreated with melanocyte stimulating hormone inhibitory factor (MIF) another hypothalamic hormone with suggested antidepressant properties[13] MIF also elicits stereotyped behaviour in cats indistinguishable from that following L-dopa or amphetamine[14] Since amphetamine effects dopaminergic systems in the brain[15], MIF may thus be altering the function of dopaminergic neurones This may also be the case with TRH since we have found that the hyperactivity resulting from injection of 4-methoxyamphetamine (10 mg kg^{-1}) 30 min after Tcp (20 mg kg^{-1}) was also potentiated by pretreatment 3 h previously with TRH (1 mg kg^{-1})

Another possibility examined was that TRH might increase the overall sensitivity of neurones to excitatory stimuli We therefore pretreated groups of mice with TRH (1 mg kg^{-1}) or saline and 3 h later pentylenetetrazol (Leptazol, 70 mg kg^{-1}) was given intraperitoneally In the animals which had received TRH, convulsions occurred with a shorter latent period than those receiving saline (Fig 3) At present, however, it is not possible to exclude the possibility that this effect of TRH is mediated by some change in the function of brain monoamines

Recently it has been reported[16] that TRH increased the turnover of cerebral noradrenaline No change in the brain content of 5-HT, noradrenaline, dopamine, homovanillic acid or 5-hydroxyindoleacetic acid was found in this study The TRH dose used, however (10 mg kg^{-1}) caused no potentiation of the hyperactivity following Tcp and either L-tryptophan or

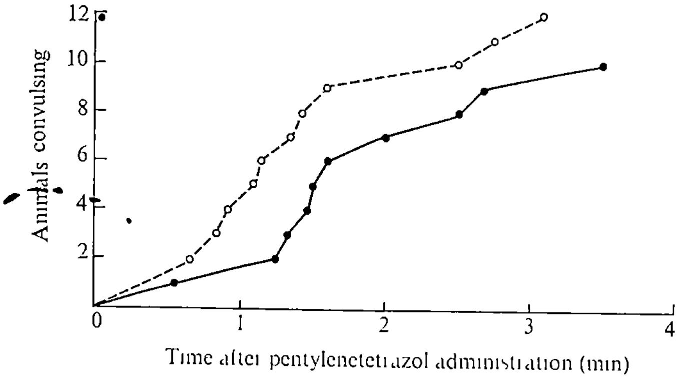

Fig 3 Time taken for a group of 24 mice given either 1 mg kg^{-1} TRH (○) or saline (●) to convulse following injection of pentylenetetrazol (70 mg kg^{-1}) 3 h later All 12 animals injected with TRH convulsed whereas only 10 of the 12 saline injected animals convulsed Therefore nonparametric statistics (Mann-Whitney test[11]) were used for analysis TRH-treated mice convulsed with a significantly shorter latent period than control mice ($T<0$ 01)

5 MeODMT and we have so far been unable to definitely incriminate noradrenaline in the hyperactivity response to increased 5-HT accumulation[4]

These results show that TRH, in a curiously restricted dose range, causes potentiation of the hyperactivity response to stimulation of 5-HT receptors in the brain Whether this is due to some effect of TRH to alter neuronal sensitivity generally, as might be inferred from the potentiation of the various effects of L-dopa and Tcp, 4-methoxyamphetamine and pentylenetetrazol—or more specifically through an effect on a system common to all these stimuli—cannot at present be concluded

These experiments and those of others show conclusively, however, that TRH has actions on brain function quite independent from its effects on TSH and therefore thyroid function

γ-Aminobutyric acid synthesised in the olfactory nerve

WE have found the candidate neurotransmitter γ-aminobutyric acid (GABA) and its biosynthetic enzyme in the olfactory nerve of two fish In the light of these findings current concepts of GABA as an exclusively inhibitory transmitter may have to be reconsidered The olfactory nerve is a component of the rhinencephalon, a phylogenetically primitive part of the central nervous system (CNS) In addition to its receptive sensory function, the olfactory nerve conducts impulses Fish have either short olfactory nerves and long olfactory tracts, as do most vertebrates, or long nerves and short tracts, as found in the gar fish (*Lepisosteus osseus*) and the pike (*Esox estor*)[1] The olfactory cilia and nerve cell body are in the olfactory mucosa, from where the nerve action potentials are propagated to the olfactory bulb, 3 cm (pike) to 15 cm (gar) away, depending on the size of the animal The primary synapse occurs within the olfactory bulb with the mitral cells The olfactory nerve in the gar and the pike contains no motor nor other known sensory fibres[2,3] Furthermore, it is neurally homogeneous, sensory, unmyelinated and is of a reasonable size for biochemical study (50–150 mg per nerve per fish)

Fish were caught by net in the Mississippi River, stored and transported to the laboratory in small pools and used as needed The general methodology of Hildebrand *et al*[4] was used to test for the biosynthesis of acetylcholine, dopamine, noradrenaline, adrenaline, serotonin and γ-aminobutyric acid Gar nerve explants or brain slices (20 mg) were incubated in 500 µl gar Ringer (112 mM NaCl, 3 5 mM KCl, 3 mM $CaCl_2$, 24 mM glucose and 4 mM N Tris (hydroxymethyl)methyl-2-amino-ethane sulphonic acid) containing 5 µCi of either ^{14}C-L-tyrosine, ^{14}C-L-tryptophan, ^{14}C-choline or ^{14}C-L-glutamate (each 50 Ci mol^{-1}) After 3 h at ambient temperature (23° C), tissues were blotted, homogenised (glass-to-glass) in 120 µl 0 5 N formic acid containing carrier and subjected to paper electrophoresis to resolve the possible neurotransmitter from the labelled precursor There was no detectable incorporation of tyrosine into dopamine, noradrenaline or adrenaline, of tryptophan into serotonin, nor of choline into acetylcholine in the olfactory nerve On the other hand, there was substantial incorporation of L-glutamate into a substance which comigrated with GABA on paper electrophoresis Labelled dopamine, noradrenaline, serotonin, acetylcholine and GABA were formed in the brain slices from their precursors The demonstration of GABA formation in gar olfactory nerve prompted an investigation of its metabolism *in vitro*

GABA is an established inhibitory neurotransmitter acting at the crustacean neuromuscular junction and a probable neurotransmitter in the vertebrate CNS[5,6] The biosynthesis of GABA from L-glutamate is catalysed by glutamate decarboxylase (EC 4 1 1 15) and the concentration of GABA parallels that of its biosynthetic enzyme[5] We found glutamate decarboxylase activity in homogenates of olfactory nerve (Table 1) at 25% of the level found in the brain, although the specific activity in the pike (per unit weight of tissue) was about half that in the gar Enzyme activity in other tissues was very low or not detected (<5 nmol min^{-1} g^{-1}) Glutamate decarboxylase activity was also present in the gut homogenate from the pike, but not the gar Roberts *et al* have reported that a second glutamate decarboxylase (GAD II) is present in non-nervous tissue[8,9] The activity might also represent enzyme present in bacterial flora although we removed the flora from the tissue by extensive rinsing before homogenisation

When we measured GABA as described before[10] (Table 2) we found that nerves contained 65% and 75% of the amount found in the brain of the pike and gar, respectively None was found in several other tissues (Table 2) except for the gut of the pike The GABA content thus parallels that of glutamate decarboxylase (Table 1) The level of GABA in the fish brains was about 50–60% that of rat brain[11] It was similar to that found in the mammalian CNS[12] but not that in the inhibitory

Table 1 Glutamate decarboxylase activity

Tissue	Gar (nmol min^{-1} g^{-1})	Pike (nmol min^{-1} g^{-1})
Olfactory nerve	80 1	40 9
Brain (whole)	320	162
Gill	<5	<5
Visceral fat	<5	<5
Gut	<5	17 4
Skeletal muscle	<5	NS

A 1 10 tissue homogenate was made in 5 mM potassium phosphate (*p*H 7 4)-0 1 mM EDTA (buffer *A*) Then 10 µl of extract was added to 10 µl of solution so that the final incubation mixture contained 2 0 mM ^{14}C-L-glutamate (20 Ci mol^{-1}), 0 1 mM pyridoxal phosphate and 50 mM potassium phosphate (*p*H 7 4) After incubation for 5 min at 37° C, 10 µl of 0 5 N formic acid-25 mM GABA was added to stop the reaction Then 10 µl aliquots were taken for paper electrophoresis[7] After drying at 100° C for 15 min, the GABA zones were developed with ninhydrin spray and cut out for radioactivity measurement by liquid scintillation counting[7]

NS, not studied

motor neurones of the peripheral nervous system of the lobster (about 100 µmol g^{-1}) (ref 13)

Two mitochondrial enzymes are required for GABA catabolism The first, GABA-α-oxoglutarate transaminase, and the second, succinate semialdehyde dehydrogenase, catalyse reactions 1 and 2, respectively.

$$\text{(1)}\quad \begin{matrix}\text{GABA} & & \text{succinate semialdehyde}\\ + & \leftrightharpoons & +\\ \alpha\text{-oxoglutarate} & & \text{L-glutamate}\end{matrix}$$

$$\text{(2)}\quad \begin{matrix}\text{succinate semialdehyde} & & \text{succinate}\\ + & \leftrightharpoons & +\\ \text{NAD} & & \text{NADH}\end{matrix}$$

These enzymes are ubiquitous in tissue, although they are most active in nervous tissue[14] The activity of GABA transaminase was highest in brain and olfactory nerve, but present in all tissues assayed (Table 2)

Glutamate decarboxylase is often considered a marker for neurones for which GABA is the neurotransmitter[5], and so we characterised it in the olfactory nerve In gar and pike olfactory nerve homogenates, the time course of GABA biosynthesis was linear for more than 20 min at 37° C (see legend to Table 1) In each case, activity was proportional to protein concentration up to 5 5 mg protein per ml of incubation medium (higher protein concentrations were not tested)

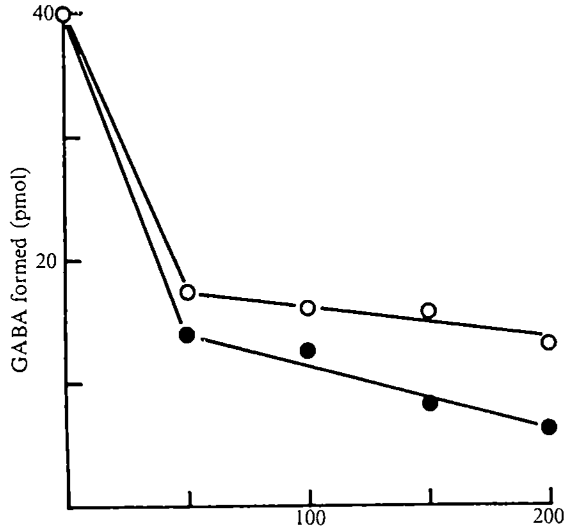

Fig 1 Inhibition of pike olfactory nerve glutamate decarboxylase by salt Assays were carried out as described in Table 3 using the specified concentration of KCl (●) or NaCl (○)

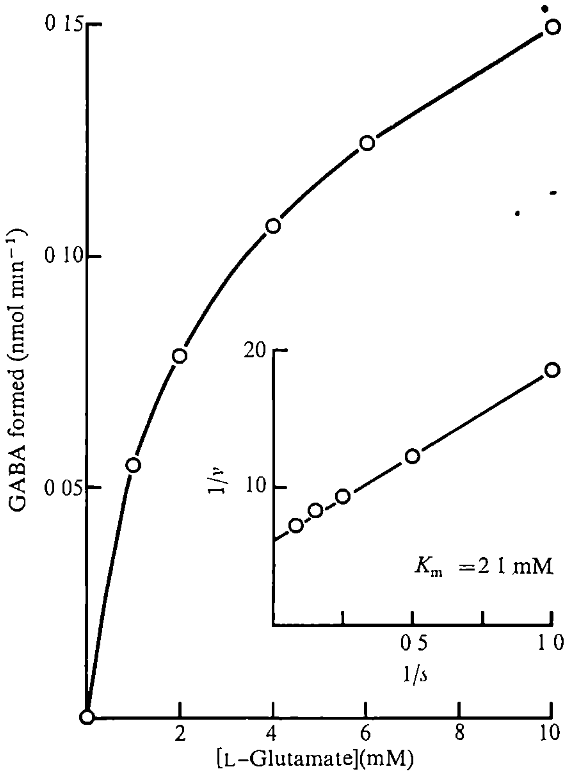

Fig 2 GABA biosynthesis in pike olfactory nerve as a function of glutamate concentration Assays were carried out as described in Table 4 using the specified concentration of glutamate

The mammalian and lobster glutamate decarboxylase enzymes, which require pyridoxal phosphate as a cofactor, are inhibited by carbonyl-trapping reagents[15] Table 3 shows that glutamate decarboxylase activity in the olfactory nerve extract of the pike is inhibited markedly by hydroxylamine Semicarbazide, thiosemicarbazide and isoniazid are also inhibitory Results were similar with the gar olfactory nerve (not shown) These studies support the hypothesis that the glutamate decarboxylase of the olfactory nerve requires a carbonyl-containing group for activity After dialysis overnight against 2,000 volumes of buffer, pyridoxal phosphate stimulated GABA biosynthesis by 20% As in the case of the mammalian and lobster enzymes[15], the data suggest that the pyridoxal phosphate is rather tightly bound to the enzyme

Mouse brain glutamate decarboxylase is inhibited by chloride[16], while the mouse kidney enzyme[9] (GAD II) and the lobster inhibitory nerve enzyme are not[17] The data from Fig 1

Table 2 Levels of GABA and its transaminase in tissues of gar and pike

Tissue	GABA Gar (nmol g^{-1})	GABA Pike (nmol g^{-1})	GABA transaminase Gar (nmol min^{-1} g^{-1})	GABA transaminase Pike (nmol min^{-1} g^{-1})
Olfactory nerve	0 55	0 49	46 3	24 1
Brain	0 74	0 75	87 9	50 3
Gill	<0 02	<0 02	34 4	7 6
Visceral fat	<0 02	0 03	11 0	9 8
Gut	<0 02	0 26	25 1	11 6
Skeletal muscle	NS	NS	22 1	NS

To assay GABA transaminase, tissues were homogenised in buffer *A* To remove low molecular weight endogenous substrates, the extracts were dialysed against 100 volumes of buffer *A* for 1 h, against buffer *A* containing 100 mM KCl for 4 h and 12 h and against buffer *A* again for 1 h (all at 4° C) before assay The GABA dependent conversion of labelled α-oxoglutarate into glutamate was measured[14] and the labelled glutamate was resolved from precursor by paper electrophoresis

NS, not studied

Table 3 Inhibition of pike olfactory nerve glutamate decarboxylase by carbonyl-trapping reagents

Addition	Activity (pmol ^{14}C-GABA formed)
Control	35.9
Hydroxylamine, 0.2 mM	0.2
Isoniazid, 50 mM	4.8
Thiosemicarbazide, 12.5 mM	10.8
Semicarbazide, 50 mM	1.5

The assays were carried out as described in Table 1 using 10 µl extract (11 mg protein ml^{-1}) for a 15 min incubation at 37° C in the presence of the specified reagent.

show that sodium and potassium chloride inhibit the decarboxylase activity of the olfactory nerve. The KCl consistently inhibited activity more than NaCl, and parallel results were obtained with the gar olfactory nerve homogenate (not shown).

The olfactory nerve decarboxylase activity exhibits saturation kinetics (Fig. 2). The apparent K_m for the pike decarboxylase is 2.1 mM (Fig. 2) and that for the gar, 2.6 mM. Because crude dialysed homogenates were used, these values are not significantly different. The *p*H optimum for both the pike and gar enzymes, using 50 mM potassium phosphate buffer, is between 7.0 and 7.4.

In vertebrate neurones, the activity of the enzymes which catalyse neurotransmitter biosynthesis, and the neurotransmitter content is greatest in the synaptic region. Subcellular fractionation has shown that the biosynthetic enzyme activity and the content of acetylcholine[18-20], GABA[21] and noradrenaline[22,23] is greatest in the pinched off nerve ending, or synaptosome fraction. GABA and glutamate decarboxylase were measured in segments of the gar and pike olfactory nerves, cut progressively from the rostral to caudal ends. The enzyme activity, and the GABA content, show a rostral-to-caudal gradient with the greatest quantity nearest the synaptic region. To avoid adventitious contamination by non-olfactory nerve neurones, the synaptic region itself was not included for assay in the most caudal segment.

In the olfactory nerve of the gar and pike, GABA has several possible, and not necessarily mutually exclusive, functions. First, it might be a substrate for oxidative metabolism[15]. For example, conversion to succinate semialdehyde followed by oxidation to succinate yields 3 ATP equivalents. This GABA-shunt pathway accounts for about 10% of O_2 consumption in rat brain[15]. Second, GABA and its biosynthetic enzyme might be associated with the non-neuronal Schwann cells of the olfactory nerve. GABA and glutamate decarboxylase are found in mammalian glial cells grown in tissue culture[24]. Unlike the olfactory nerve decarboxylase, however, the glutamate decarboxylase found in gliomas (GAD II) is not inhibited by salt or by carbonyl trapping reagents[8]. Third, GABA might be taken up by the olfactory nerve from synapses in the olfactory bulb region as part of a GABA-inactivating mechanism such as for the Schwann cell and connective tissue in the lobster neuromuscular junction.

Although very unlikely, based on current concepts of its function, GABA might be a sensory excitatory neurotransmitter. It has been implicated so far exclusively as an inhibitory transmitter agent. Iontophoresis of GABA on to cerebellar and cerebral neurones[26], neurones in the dorsal Dieter's nucleus[17] and in the lobster neuromuscular junction[28], all produce inhibition. Furthermore, experiments with the olfactory bulb of the cat and rabbit are consistent with the notion that granular cell inhibition of the mitral cell is mediated by GABA[29,30]. On the other hand, the olfactory nerve in these preparations excites the mitral cells.

The presence of GABA, and its biosynthetic enzyme, in an axonal-to-synaptic gradient in the olfactory nerve of two fishes (Table 4) makes it a neurotransmitter candidate at the synapse between the nerve and the post-junctional cell in these species. Further experiments showing that GABA is released during neuronal activity and that it has the same effect on the post-synaptic cells as the natural transmitter are required before this compound can be considered a neurotransmitter substance. Until such time as the function is established, GABA and glutamate decarboxylase activity cannot be used to map inhibitory pathways in the vertebrate central nervous system.

Since this report was submitted, Flock and Lam, using methodology similar to our own, reported GABA synthesis in the sensory hair cells of amphibian and fish inner ear sense organs and fish lateral line organs[31]. The proposed function of GABA in these sensory transducing hair cells parallels that considered here for the olfactory nerve. On the other hand, Margolis suggested that carnosine may be related to olfactory nerve transmission in mouse[32].

This work was supported by grants from the US Public Health Service and the US National Science Foundation. We thank Bruce Stavens for advice about gar olfactory nerve dissections.

Regulation of striatal acetylcholine concentration by dopamine receptors

IMPAIRMENT of the coordinated activities of cholinergic and dopaminergic neurones in the brain has been implicated in the pathophysiology of Huntington's chorea, drug-induced dyskinesias, Parkinsonism, schizophrenia and manic-depressive psychosis[1-6] Physostigmine, a drug which increases brain acetylcholine by inhibiting acetylcholinesterase, has been reported to improve the neurological status of patients with Huntington's chorea, tardive dyskinesias and L-dopa-induced dyskinesia[7-9] The hyperkinetic involuntary movements in these disorders are thought to be related to a denervation hypersensitivity of dopamine receptors in the striatum[10] On the other hand, in diseases with decreased dopaminergic activity, such as idiopathic and phenothiazine-induced Parkinsonism, intravenous injection of small doses of physostigmine exacerbated rigidity and tremors[11,12] A similar aggravation of Parkinsonian-like symptoms by physostigmine can be observed in rats pretreated with phenothiazines or reserpine and in dogs pretreated with intracisternal 6-hydroxydopamine[13 14] L-Dopa blocks the adverse neurological effects of physostigmine in Parkinsonian patients and in animals pretreated with reserpine or 6-hydroxydopamine[11-14] These observations suggest that the response to central cholinergic stimulation depends on the functional activity of inhibitory dopamine receptors in the striatum The diminished striatal dopamine receptor stimulation in Parkinsonism[15] may secondarily produce cholinergic hyperactivity in the striatum, the converse may exist in dyskinetic and choreiform disorders Striatal dopamine receptors could regulate cholinergic activity by modulating intrastriatal acetylcholine synthesis and release by cholinergic neurones We have now tested this hypothesis by investigating the effect of dopamine receptor agonists and antagonists on striatal acetylcholine concentration

Male Sprague Dawley rats (180–200 g) were kept under constant diurnal lighting and temperature conditions for at least one week before use Animals were killed at approximately the same time (0900–1200h) of day All drugs were administered intraperitoneally Control rats received an equal volume of vehicle Rats were decapitated at various times (Table 1) after the injection of apomorphine (10 mg kg^{-1}), trivastal (10 mg kg^{-1}), *d*-amphetamine (10 mg kg^{-1}), chlorpromazine (15 mg kg^{-1}), haloperidol (10 mg kg^{-1}) and pimozide (10 mg kg^{-1}) L-Dopa (100, 300, 600 mg kg^{-1}) was administered 1 h after MK 486 (α-methyl dopa hydrazide, 25 mg kg^{-1}) and the rats were killed 1 h after the second injection

The brains were removed from the skull and placed immediately in cold pentane (−5° C) The striatum was dissected by the method of Glowinski and Iverson[16] Bilateral striata from two rats were homogenised together in 0 4 N perchloric acid (4° C) containing propionylcholine iodide as an internal standard Acetylcholine was extracted and assayed by gas-chromatography[17,18], modified as described previously[19]

The concentration of acetylcholine in the striatum had increased significantly 0 25, 0 5 and 1 h after the administration of apomorphine, trivastal and *d*-amphetamine (all $P < 0\ 001$, Table 1) The maximum increase with apomorphine and trivastal was 49% and 83% respectively after 0 5 h and for *d*-amphetamine 33 6% after 1 h Chlorpromazine, haloperidol and pimozide significantly (all $P < 0\ 001$) decreased striatal acetylcholine concentration 0 25, 0 5 and 1 h after injection The maximum reduction with chlorpromazine and pimozide was 43% and 51 2%, respectively, after 0 25 h and with haloperidol 57 9% after 30 min A significant reduction in acetylcholine concentration persisted for 4 h after injection of pimozide and for 16 h after injection of haloperidol (Table 1) L-Dopa (100, 300 and 600 mg kg^{-1}) significantly ($P < 0\ 001$) increased acetylcholine concentration in the striatum of rats pretreated with the peripheral dopa decarboxylase inhibitor MK 486 (Fig 1) MK 486 or L-dopa, when administered alone had no significant effect on striatal acetylcholine concentration

Dopamine, released from nigro-striatal nerve endings, reduced striatal neuronal discharge frequency[20 21] Since the striatum contains the highest concentration of acetylcholine[22] in the brain it is possible that intrastriatal cholinergic neurones which contain dopamine receptor sites are inhibited by dopamine Our results support this hypothesis Dopamine receptor agonists like apomorphine, trivastal, *d*-amphetamine and MK 486+L-dopa (which increases brain dopamine) may inhibit striatal cholinergic activity, which would reduce the release of acetylcholine from cholinergic neurones and produce the observed increase in striatal acetylcholine concentration In contrast, dopamine receptor antagonists such as chlorpromazine, haloperidol and pimozide would increase discharge frequency of striatal cholinergic neurones, increase the release of striatal acetylcholine and produce the observed decrease in striatal acetylcholine concentration The decrease in striatal acetylcholine concentration is not likely to be due to a central anticholinergic action of these neuroleptic drugs since chlorpromazine actually enhances the tremorigenic effect of physostigmine both in man and animals[12,13] Anticholinergic drugs which decrease brain acetylcholine also reduce the tremorigenic action of physostigmine[23] Furthermore, we have observed that pretreatment with L-dopa (300 mg kg^{-1}) significantly blocked the chlorpromazine-induced

Table 1 Effects of drugs on concentration of acetylcholine in the striatum

Drug	Dose (mg kg^{-1})	Time after injection						
		0 h	0 25 h	0 5 h	1 h	4 h	16 h	24 h

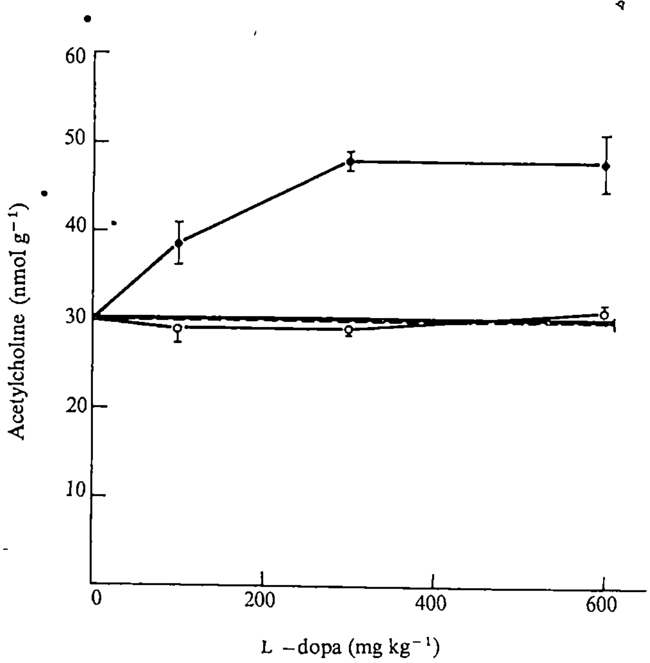

Fig. 1 Effect of various doses of L-dopa on striatal acetylcholine concentration in control and MK 486-treated rats Each point is the mean ±s e of four to twelve determinations — — —, Control, ———, MK 486, O, L-dopa, ●, MK 486 +L-dopa

decrease in striatal acetylcholine concentration, indicating that the changes in acetylcholine concentration are mediated by functional changes in the dopamine receptors

Our results are consistent with the demonstration by Stadler *et al* [24] that chlorpromazine increased acetylcholine release from the caudate nucleus of the cat, and that this release was blocked by apomorphine However, Jones *et al* [25] found no alterations in acetylcholine release during superfusions of the ventricular surface of the caudate nucleus in cats treated with either L-dopa or amphetamine Reserpine, a drug which decreases brain dopamine, also lowers striatal acetylcholine and this effect is reversed by pretreatment with L-dopa[26]

In idiopathic and phenothiazine-induced Parkinsonism there is a decrease in striatal dopaminergic activity and an apparent increase in cholinergic activity Further enhancement of cholinergic activity by the injection of acetylcholine into the basal ganglia of Parkinsonian patients was found to increase tremor on the contralateral side, while anticholinergic drugs reduced the tremor[27] Excessive discharge frequency of striatal cholinergic neurones associated with increased release of acetylcholine and decreased acetylcholine concentration may be causally related to the Parkinsonian side effects of the neuroleptic drugs This mechanism would account for the therapeutic effectiveness of anticholinergic drugs in drug-induced Parkinsonism

A stimulatory effect of neuroleptic drugs on cholinergic neurones could also be relevant to their therapeutic effectiveness in schizophrenia Several clinical studies have demonstrated that drugs which stimulate central cholinergic neurones improve schizophrenic symptomatology Cholinomimetic compounds like arecoline and physostigmine have been observed to produce symptomatic improvement in schizophrenic patients[28,29] On the other hand, anticholinergic drugs, L-dopa and methylphenidate aggravate the symptoms of schizophrenia[30-32] Physostigmine reversed the intensification of the schizophrenic psychosis produced by methylphenidate[33] The anti-schizophrenic action of phenothiazine drugs, haloperidol and pimozide could be related to their ability to block an excessive dopaminergic inhibition of cholinergic neurones in the brain

We thank the following for compounds Les Laboratories Servier, trivastal, Smith Kline and French Laboratories, amphetamine and chlorpromazine, Merck Sharp and Dohme Research Laboratories, MK 486, McNeil Laboratories, haloperidol and pimozide This work was supported by grants from the US Public Health Service

Quantitation of adrenaline in rat brain nuclei and areas by mass fragmentography

THE existence of adrenaline (A) in the mammalian central nervous system (CNS) was first demonstrated by von Euler[1] and Holtz[2] Subsequently, many reports have documented the presence of whole brain A in mammals and amphibia In amphibia adrenaline is the major CNS catecholamine[3], being about four times greater than noradrenaline[4], while in mammals, adrenaline is only a small fraction (4–22%) of the total noradrenaline content[5 6] These data in mammals could indicate either adrenaline uptake from the periphery or a very discrete adrenaline pathway possibly with a high turnover rate We have quantitatively measured adrenaline in some specific nuclei of the rat brain, using the highly sensitive and specific technique of gas chromatography–mass spectrometry (GC–MS)[7]

In our preliminary experiments, 15 brain nuclei were dissected and assayed for their catecholamine content Male rats (125–175 g) were killed by cervical fracture and the brain rapidly removed and frozen in powdered dry ice The frozen brains were serially sectioned (400 μm, knife angle 30° to the brain axis) in a microtome cryostat (−5° C) and the nuclei located and punched out with a hollow steel tube (0 5–1 2 mm internal diameter), using the atlases of Konig and Klippel[8], Zeman *et al*[9], and Wunscher *et al*[10] as a guide The catecholamines were extracted into 100 μl 0 1 M formic acid 50 mM ascorbic acid, 60 μl was taken to dryness in the presence of internal standards and the dry residue reacted with pentafluoropropionic anhydride[7] After 30 min reaction at 60° C, the excess acylating reagent was removed, and the acylated catecholamines redissolved in 10 μl ethylacetate and 2 μl of this solution was analysed by GC–MS (LKB 9000) using a column packed with 3% SE 54 on Chromasorb G By using the combined instrumentation of GC-MS it is possible to quantitatively measure the catecholamines without having any interference from other compounds The catecholamines are initially resolved on the GC, for example, the retention times for noradrenaline, adrenaline, dopamine and epinine are 370, 425, 510 and 600 s respectively At the retention time for adrenaline (425 s) the MS is focused at m/e 190 which is the base peak (100%) for adrenaline Since the fragment m/e 190 is approximately 60% of the total ions produced, the sensitivity of the detection is extremely high, less than 10 fmol (10×10^{-15}) adrenaline can be measured

Fifteen different rat brain nuclei were initially (triplicate determinations) analysed individually for their catecholamine content Of these regions all contained noradrenaline while only five contained adrenaline The five regions which contained adrenaline were the ventral lateral N reticularis (A_1), the cerebellum at the level of the genu N facialis, including the region from the lateral edges of the iv ventricle, juxtaposed to and possibly including the N superior and N principalis vestibularis and fibrae vestibulo cerebellares, the N locus coeruleus, the habenulu region and the periventricular area of the anterior hypothalamus including the nuclei and regions listed in Table 1 In these five regions (Table 2) the percentage adrenaline ranged from 1 0 to 6 5 of the noradrenaline The highest concentration of adrenaline, 5 7 pmol mg^{-1} protein was found in the periventricular area of the hypothalamus, while the highest adrenaline concentration (as % noradrenaline) was found in the cerebellum

The periventricular areas of the hypothalamus were further dissected into four subregions and assayed for adrenaline Adrenaline was found in all four regions with the highest concentrations being found in the N periventricularis hypothalami, and the area infundibulum and nucleus arcuatus (Table 1)

Table 1 Adrenaline concentrations in the periventricular areas of the hypothalamus

	Adrenaline (pmol mg^{-1} protein)
N Paraventricularis (filiformis) pars magnocellular	2 0 ± 0 24
N Paraventricularis (filiformis) pars parvocellularis	1 6 ± 0 18
N Periventricularis (hypothalami)	4 0 ± 0 40
Area Infundibulum + N Arcuatus	3 4 ± 0 95

*Mean ± s e of three determinations

Table 2 Adrenaline concentrations of five rat brain nuclei and areas*

Area or nuclei	Adrenaline (pmol mg^{-1} protein)	Noradrenaline (pmol mg^{-1} protein)	$\frac{\text{Adrenaline}}{\text{Noradrenaline}} \times 100$
N Reticularis lat (A_1)	1 3 ± 0 33	75 ± 15	1 7
Cerebellum	1 1 ± 0 03	17 ± 4 4	6 5
N Locus coeruleus	1 4 ± 0 16	140 ± 20	1 0
Habenulu	1 2 ± 0 16	57 ± 3 1	2 1
Periventricular area of the hypothalamus	5 7 ± 1 1	160 ± 23	3 6

*Mean ± s e of four determinations

These preliminary data support the proposal of Hokfelt *et al*[11] that a neuronal network containing adrenaline is present in rat brain They base this conclusion on their immunocytochemical localisation of phenylethanolamine-N-methyltransferse (PNMT) in neurones They reported a total of 17 areas or nuclei in rat brain which gave a positive PNMT reaction We have not examined all of these areas as yet but some of our preliminary findings reported here agree with the results of the PNMT reaction, N reticularis lat (A_1) contains cell bodies reacting to PNMT and the locus coeruleus and periventricular areas of the hypothalamus contained PNMT positive terminals Saavedra *et al*[12] have recently reported on the biochemical measurement of PNMT activity in rat brain nuclei The PNMT activity was unevenly distributed and the biochemical localisation of the enzyme agreed well with the histological data of Hokfelt *et al* There does not, however, seem to be good agreement between the PNMT activity and adrenaline concentrations, that is A_1 region 41 5, and N paraventricularis 15 0, PNMT activity against adrenaline concentration of 1 3 and 4 0 pmol mg^{-1} protein, respectively

In these preliminary experiments adrenaline has been measured in a few discrete areas of the rat brain, and found to be present in only certain regions At this point we cannot postulate that the adrenaline is confined to the PNMT neuronal network, additional studies are presently being done to test this hypothesis It is likely, however, that adrenaline is contained in neurons which presumably function independently of the noradrenaline and dopamine neuronal systems

Effect of reserpine on cationic contents of rat brain

PREPARATIONS of the plant *Rauwolfia serpentina* have been used in India for centuries as a calming drug Reserpine is the principal alkaloid of this plant and its effect on the central nervous system (CNS) has been studied extensively The most important biochemical effect of reserpine on the CNS found *in vivo* is the release of noradrenaline, 5-hydroxytryptamine and dopamine from the amine storage sites in brain so that they are more susceptible to degradation by monoamine oxidase[1] In synaptosomal preparations, reserpine has been shown to inhibit the uptake of noradrenaline and 5-hydroxytryptamine[2] Prolonged reserpine treatment depletes these amines from the brain[1] Amine depletion is thought to be due to changes in the permeability of neuronal membranes[3]

Tetrodotoxin and local anaesthetics increase the glycolysis of cerebral cortex slices[4] and this prompted us to investigate a number of neurotropic agents including reserpine Studies with reserpine revealed that this drug can cause an increase in the potassium content of cerebral tissue both *in vitro* and *in vivo* In view of the important role played by cations in the regulation of brain metabolism[5], the effect of reserpine on the potassium contents is of great interest and we are surprised that such measurements have not been made previously

Rat cerebral cortex slices were prepared and incubated as described earlier[4,5] and anaerobic glycolysis, cationic contents, ^{22}Na transport and respiration were measured For the *in vivo* experiments rats were given reserpine (2 mg kg^{-1}, Ciba) or saline intraperitoneally for 5 d after which they were killed, the brains quickly removed, weighed and protein-free extracts prepared for cation analysis by a Coleman flame photometer

The *in vitro* experiments, details of which will be published elsewhere, showed that during anaerobic conditions, 12-120 μM reserpine greatly enhances the rate of glycolysis by adult rat and guinea pig cerebral cortex slices The maximum effects observed were up to 3–4 times the normal rate It was thought possible that reserpine may exert this effect indirectly by amine release Experiments carried out with biogenic amines showed that unlike reserpine, these amines have no significant effect on anaerobic glycolysis It was therefore concluded that reserpine may also exert its effect on the anaerobic glycolysis by increasing K$^+$/Na$^+$ ratio, as is the case with tetrodotoxin and local anaesthetics This was found to be true and reserpine had a significant effect in increasing the K$^+$ contents of the cerebral cortex slices incubated under anoxic conditions, the increase being up to 34 μeq per g initial wet weight of the tissue as compared to 17 μeq per g initial wet weight for the controls

Other experiments further demonstrated that 12 μM reserpine may affect the cationic movements It was found that the respiration of rat cerebral cortex slices, stimulated by 10 μM protoveratrine, was suppressed by 12 μM reserpine These effects were much more evident in a Ca^{2+}-free Krebs–Ringer phosphate medium ^{22}Na movement was also suppressed by reserpine in these conditions

A most interesting effect of reserpine was observed *in vivo* (Table 1) It was found that chronic reserpine administrations results in an increase in the K$^+$ contents of brain of more than 25% while the Na$^+$ contents are not affected The cationic contents described here were determined in the whole brain It is possible that most of the K$^+$ increase occurs intracellularly (and primarily in the neurones as compared to the glia), since very little extracellular space is present in brain

Table 1 Effect of chronic reserpine administration on the Na$^+$ and K$^+$ contents of rat brain

Treatment	K$^+$ (μeq per g fresh weight)	Na$^+$ (μeq per g fresh weight)
Control (12)	122 7 ± 5 7	48 5 ± 3 0
Experimental (12) (Reserpine, 2 mg kg^{-1} d^{-1} for 5 d)	157* ± 4 7	49 3† ± 2 5

K$^+$ and Na$^+$ contents were determined as given in the text Values obtained, and their standard deviations are given Number of observations are shown in parentheses

*P < 0 001, highly significant

†P > 0 4, not significant

The effect of reserpine on the amine uptake presumably results from changes in the permeability of neuronal membrane with a concomitant increase in the steady state level of K$^+$ Our results have wide implications Sedation induced by reserpine is thought to result from a decrease in the quantity of monoamines[1] High cerebral potassium in reserpinised animals may cause neuronal hyperpolarisation resulting in the potentiation of sedative effects It has been argued that barbiturates and other sedatives may primarily act by inhibiting impulse conduction rather than amine metabolism[7]

Our observations also raise the question whether an increase in the level of cerebral K$^+$ is the primary effect of reserpine or is caused indirectly due to other central effects The former possibility seems to be true The uptake of amines by nerve encings is dependent on the presence of Na$^+$ (ref 8), and the mechanism is activated by excitation and thus depolarisation[10] Membrane affinity for neurotransmitters is affected by nervous stimulation[9] Moreover, K$^+$ has been shown to compete with Na$^+$ for the Na$^+$-dependent uptake of monoamines[10,11] Almost 80% of noradrenaline released at the synapse is inactivated by the uptake mechanism[9] It seems that the increase in neuronal K$^+$ affects the uptake of amine by storage granules, presumably by competing with Na$^+$ (refs 10 and 11) Modulation of membrane affinity to neurotransmitters, therefore, seems to be involved in the action of reserpine Further investigations are in progress to examine these possibilities

S-100 protein in synapses of the central nervous system

THE brain-specific S-100 protein[1] is predominantly localised in glial cells in the central nervous system and is synthesised by glial cells in tissue culture[2-5] S-100 is, however, also present in neurones[6-9], located in both the neuronal perikaryon and the nucleus[6,9-11] It has been proposed that the protein is transported along the axon[10] although the presence of S-100 in the Schwann cell[12,13] calls for confirmation of an intra-axonal localisation of the protein Approximately 90% of the S-100 in the brain is easily soluble and extracted by water[14-15], but an additional small amount can be extracted from the particulate matter with *n*-pentanol. Rusca *et al.*[14] showed a further release 5–7% of the S-100 from whole beef brain, and Haglid *et al.*[13] extracted 7% from human grey matter and 3% from white matter with n-pentanol. The percentage of total S-100 which remained bound to the particulate matter after water extraction was considerably higher in neuronal perikarya than in glial cells (manuscript in preparation). We have investigated the ultrastructural location of the relatively large amounts of membrane-bound neuronal S-100.

White albino rabbits, weighing 1.5–2 kg, were killed after mebumal anaesthesia and decapitated. Parts of the CNS were dissected fresh, immersed in ice-cold 0.1 M cacodylate buffer, *p*H 7.4, and cut to 10–20 μm thick sections on a Vibratom (Oxford Instrument). In other experiments, the brains were fixed by intra-aortal perfusion with 2% formaldehyde in 0.1 M cacodylate buffer, *p*H 7.4, and rinsed in the same buffer after a fixation time of 5 min. All solutions in contact with the tissue slices contained 2.5 mM EDTA or EGTA. The fresh and prefixed sections were incubated for 30 min in 0.1 M cacodylate buffer, containing antiserum against S-100 coupled with peroxidase. They were then extensively rinsed, and thereafter fixed in 2.5% glutaraldehyde and 2% formaldehyde in cacodylate buffer.

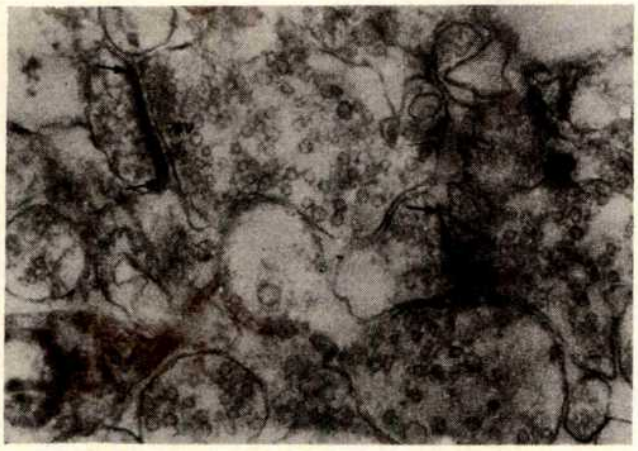

Fig. 1 Electron micrograph of synapses in the frontal cortex of an adult albino rabbit. The tissue piece was treated with rabbit antiserum to beef S-100 protein coupled to peroxidase as described in the text. The postsynaptic membranes (arrow) show a strong peroxidase activity. No activity is seen in the synaptic cleft or in the synaptic vesicles. The activity of the presynaptic membrane is about the same as in other neuronal membranes. × 42,750.

Cerebellar glomerular complexes were isolated by Ficoll gradient centrifugation according to A.H., H.-A.H., and Å. Sellström (in preparation). The glomerular suspension was incubated at room temperature for 10 or 30 min with the peroxidase-coupled antiserum against S-100, sedimented and treated like the tissue sections. All material was then thoroughly rinsed and incubated in a cacodylate buffered solution of 3.3-diaminobenzidine and hydrogen peroxide[16]. The samples were rinsed, postfixed in osmium tetroxide, dehydrated and embedded in Epon. Thick sections were cut on an ultramicrotome (LKB Ultrotome III) and examined in a phase contrast microscope. Selected areas were sectioned for examination in an electron microscope (Siemens 1 A). They were either unstained or double-stained with uranyl acetate and lead citrate. The purification of beef S-100 and the production of anti-beef S-100 rabbit antiserum, as well as the monospecificity of the antibodies in the serum were tested by microcomplement fixation, immunoelectrophoresis and other electrophoretic methods[13,15]. The peroxidase (Sigma Type VI) was coupled to the antiserum according to Avrameas[17]. The peroxidase-coupled anti-beef S-100 rabbit serum was separated from free peroxidase by G-75 Sephadex column chromatography. The specificity of the peroxidase-coupled anti-beef S-100 rabbit serum reactions was checked by the use of a control antiserum which had been repeatedly (12 times) absorbed with purified beef S-100 protein. Test and control antisera were diluted and treated in an identical manner. The completeness of the absorption was tested by microcomplement fixation against the original antigen. The final dilution of antiserum was titrated by chessboard until maximal test–control difference in peroxidase activity was observed.

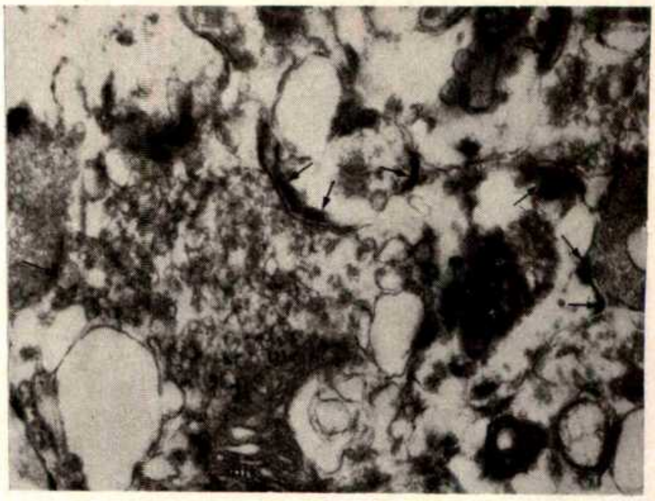

Fig. 2 Electron micrograph of an isolated cerebellar glomerulus after treatment with rabbit antiserum to beef S-100 protein coupled with peroxidase. Note the dark reaction products indicating peroxidase activity, that is, localisation of S-100 protein at the postsynaptic membrane (arrow). The other neuronal membranes have a lower level of activity than the postsynaptic membrane. The mitochondria (mit) may show nonspecific activity. × 31,950.

Specific peroxidase activity was seen in most synaptic regions of the cerebral and cerebellar cortex. Heavy precipitates were localised exclusively on, and immediately interior to, the postsynaptic membrane (Fig. 1). No activity was seen in the synaptic cleft. All other parts of the neuronal membrane—including the presynaptic membrane —had a low or moderate but specific peroxidase activity. The synaptic vesicles, endoplasmic reticulum, filaments, microtubules and nuclei did not show any significant peroxidase activity. Some mitochondria showed peroxidase activity also after treatment with antisera absorbed repeatedly with the antigen protein S-100. Such nonspecific peroxidase activity has previously been described[17]. Neither peroxidase-coupled rabbit antisera directed against other soluble or particulate brain proteins, nor free peroxidase showed any localisation to the postsynaptic membrane.

In order to investigate whether the distribution of peroxidase activity was affected by penetration barriers, we examined suspensions of isolated cerebellar glomeruli, which consist of clusters of synaptic contacts. Again, intense peroxidase activity was observed at the postsynaptic membrane (Fig. 2). A different pattern was observed in the synaptic terminals of the rods and some bipolar nerve cells in the rabbit retina (Fig. 3). An intense reaction was seen in the synaptic ribbon and in both the pre- and postsynaptic membranes in these composite synaptic terminals. In retinal synapses of more conventional type the peroxidase reaction was confined to the postsynaptic region, as in the cerebral and cerebellar synapses.

The S-100 protein visualised by peroxidase-coupled anti-beef S-100 rabbit serum is presumably particulate bound, as fixed and fresh slices gave a similar picture—the fresh slices were subjected to buffer solution in multifold excess which makes the soluble S-100 protein easily diffusable. The

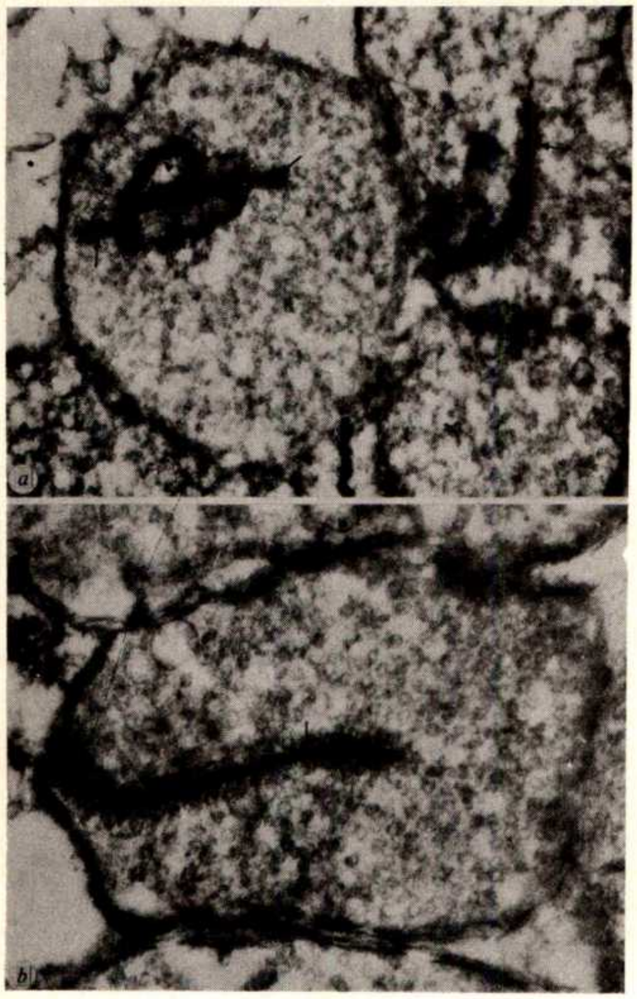

Fig. 3 Electron micrograph of synaptic terminals in the outer plexiform layer of the rabbit retina treated as in Fig. 1. Dark deposits, indicating peroxidase activity, are seen in the synaptic ribbon (arrow) and at the synaptic contacts with bipolar nerve cells (arrowhead) and also, although at a lower level, in the neuronal membrane. The synaptic vesicles show mainly background activity. *a*, × 21,300; *b*, × 22,720.

soluble form of S-100 does not bind the subcellular particulate material in the presence of EDTA (B. W. Moore, communicated at NATO Advanced Study Institute meeting in Cortona, Italy, 1971).

The functional role of the S-100 protein is so far unknown. Its interaction with Ca^{2+} ions[18] and with the passage of monovalent and divalent cations across artificial lipid membranes[19] may lead to speculations about its function. We here present data which indicate a specialised synaptic localisation of the S-100 protein. This might imply a functional interrelation between a glial brain-specific protein and synaptic function, since so far there is no evidence that this protein is synthesised in neurones.

Dihydrostreptomycin accumulation in *E. coli*

DIHYDROSTREPTOMYCIN is an antibiotic composed of streptidine, dihydrostreptose and N-methyl-L-glucosamine joined by two glycosidic bonds. It differs from streptomycin only in that the aldehyde group on the middle residue (streptose) is reduced. Both compounds have similar biological actions[1,2] but their accumulation by bacterial cells has been little studied. Passive diffusion is often assumed to be responsible, although Mitchell thought it improbable that a molecule such as streptomycin passes through a lipid layer[3]. Anand *et al.* proposed a mechanism in two phases[4]. First, a small amount of antibiotic would enter by passive diffusion regardless of an intact lipid layer and affect protein synthesis so as to cause deterioration of membrane integrity. Then more rapid accumulation would follow by passive diffusion through the disrupted lipid barrier. Alternatively, Hurwitz *et al.* showed streptomycin accumulation to be sensitive to chloramphenicol during initial exposure and insensitive after several minutes of exposure. They suggested facilitated diffusion, with entry of the antibiotic depending on a streptomycin-induced protein[5].

Carlson and Bockrath found dihydrostreptomycin accumulation to vary depending on whether bacterial cells grew in a glucose-defined medium or in nutrient broth[6]. Accumulation was roughly fifty times more efficient in nutrient broth cultures or with cells recently transferred from nutrient broth in the defined medium. After an apparent lag of a few minutes, the kinetics of accumulation were generally linear with time for at least 30 min. Anand *et al.* used cells growing in defined medium and Hurwitz *et al.* used cells growing in nutrient broth. We have repeated the observation of a chloramphenicol-insensitive phase of accumulation and have found that cells growing in nutrient broth accumulate antibiotic during this phase by a transport mechanism involving a positive contribution from cellular metabolism.

A culture of *Escherichia coli* **B** growing exponentially

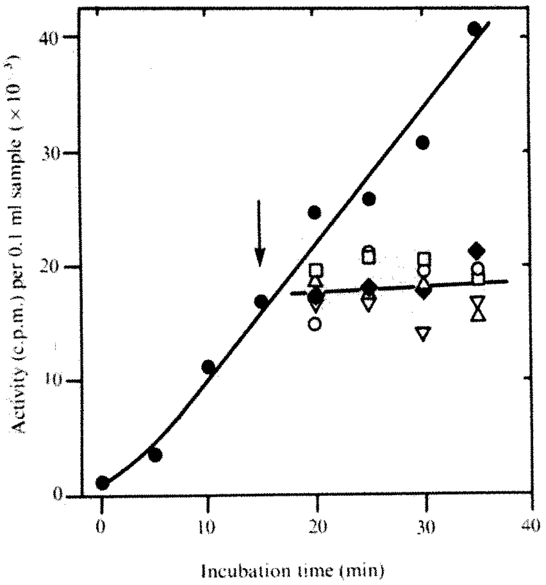

Fig. 1 Inhibition of ^{3}H-dihydrostreptomycin accumulation. ^{3}H-dihydrostreptomycin sesquisulphate (2 μg ml^{-1}, Amersham/Searle, specific activity 2.1 mCi mg^{-1}) was added at zero time to an exponentially growing culture of *E. coli* B in Difco nutrient broth (4.8×10^7 bacteria ml^{-1}). At 15 min (arrow) aliquots were removed to separate cultures for specific perturbations during continued incubation: ▽, transferred to ice bath; ◆, potassium arsenate (10 mM); △, mercuric chloride (0.2 mM); □, N-ethyl maleimide (1 mM); and ○, iodoacetate (2 mM). All incubations were at 37° C (except ▽) with aeration. Accumulated radiolabelled antibiotic was determined during incubation time: 0.1 ml samples were diluted × 100 into buffer[6] at room temperature, filtered on to glass fibre filters, rinsed twice with 10 ml of buffer, dried and quantitated by liquid scintillation counting.

in Difco nutrient broth was challenged at zero time with ^{3}H-dihydrostreptomycin (^{3}H-dhSm, 2 μg ml^{-1}). Chloramphenicol (20 or 200 μg ml^{-1}) inhibted ^{3}H-dhSm accumulation when added at zero time but had little effect if added 10 min later. The rate of accumulation when chloramphenicol was added at zero time (just before the addition of ^{3}H-dhSm) was very small and showed no tendency to increase. Repeated experiments found chloramphenicol to be a good inhibitor if added at zero time, a moderate to good inhibitor of accumulation if added 5 min after the initial exposure to ^{3}H-dhSm, and moderate to poor if added after 10 min. Therefore, it seems that protein synthesis is of marginal importance to the accumulation of ^{3}H-dhSm by *E. coli* B once the cells have been exposed to dihydrostreptomycin for a period of 10 min.

Table 1 Perturbations of ^{3}H-dihydrostreptomycin accumulation

Challenge	Concentration (mM)	Accumulation (%)
Ice bath	—	0
Dinitrofluorobenzene	0.5	0
2,4-Dinitrophenol	2.0	0
Potassium cyanide	0.5	5
Mercuric chloride	0.2	8
Potassium arsenate	10.0	8
Iodoacetate	2.0	12
N-ethyl maleimide	1.0	21
Phenalzine methyl sulphate	0.1	22
Potassium fluoride	5.0	47
Sodium fluoride	5.0	58
Amytal	0.1	58
Rotenone	0.1	79
Oxamic acid	0.5	114

Perturbations of ^{3}H-dihydrostreptomycin accumulation were determined as described in Fig. 1. In each case the indicated challenge was introduced after 10 or 15 min of accumulation. The effect is recorded as the slope of accumulation after the challenge relative to the slope of accumulation in the control.

Dramatic inhibition of accumulation may, however, be produced by cold and by several anti-metabolites added 10 or 15 min after the initial exposure to ^{3}H-dhSm. Figure 1 shows several examples of an abrupt cessation of ^{3}H-dhSm accumulation. The perturbations are not introduced until 15 min after initiation of exposure. The results of these experiments and several others are summarised in Table 1. Clearly they suggest a metabolism-dependent mechanism of ^{3}H-dhSm accumulation. Several inhibitors of metabolism can cause accumulation to stop and plateau regardless of a hypothetical deterioration of membrane integrity or a physiological development obviating the requirement for protein synthesis.

Anand *et al.*, who rinsed their samples with water, found toluene treatment of cells to cause an apparent influx of streptomycin (with an exogenous antibiotic concentration of 40 μg ml^{-1}). In our experiments cells growing in nutrient broth accumulated large amounts of ^{3}H-dhSm (from an exogenous concentration of 2 μg ml^{-1}); we rinsed individual samples with a buffer[6] and found the addition of toluene then caused an apparent efflux of the antibiotic (Fig. 2). To ensure that the toluene treatment did not totally dissociate the cell structure or alter the filtration system to allow cells to pass through the filter, cells prelabelled with ^{3}H-uracil were also treated. In Fig. 2 the open symbols show this activity (labelled ribosomes and nucleic acid) to remain on the filter unless the cells were further treated with lysozyme.

An integral cellular membrane is therefore essential in our assay for accumulated ^{3}H-dhSm. Apparently antibiotic molecules which have already entered the cell do not

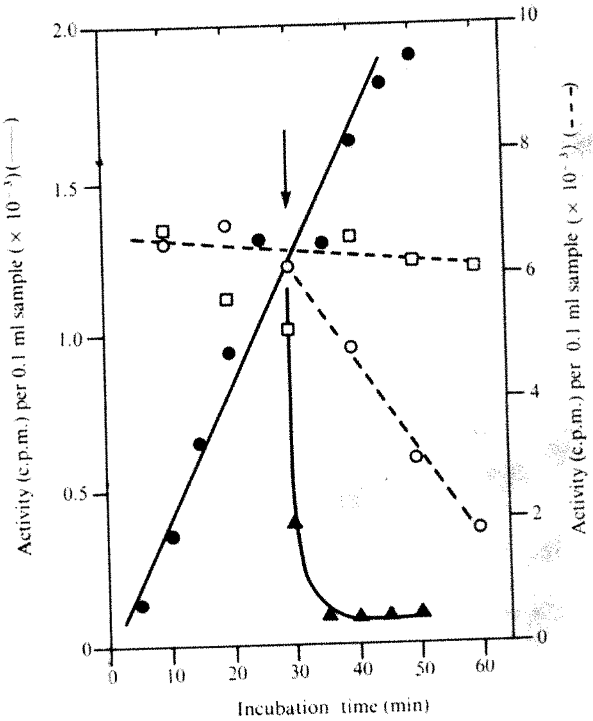

Fig. 2 Effects of toluene on the accumulation assay. ^{3}H-dihydrostreptomycin (2 μg ml^{-1}, Mallinckrodt, specific activity, 0.25 mCi mg^{-1}) was added at zero time to an expo-nentially growing culture of *E. coli* B in Difco nutrient broth (6×10^7 bacteria ml^{-1}). After 30 min 0.02 ml ml^{-1} toluene was added to one aliquot (-▲-), with the remaining culture serving as a control (-●-). A nutrient broth culture of *E. coli* B was also grown with ^{3}H-uracil (1.5 μCi ml^{-1}) for several generations and divided into two aliquots at zero time. Dihydrostreptomycin (unlabelled), 2 μg ml^{-1}, was added to both; one (- -□- -) was treated with toluene, 0.02 ml ml^{-1}, at 30 min, and the other (- -○- -) was treated with toluene after 15 min and lysozyme, 0.4 mg ml^{-1}, after 30 min.

equilibrate rapidly with the rinse buffer unless the membrane is altered by an agent such as toluene. In consequence, it seems the normal membrane is not transparent to ^{3}H-dhSm and a brief period of exposure to ^{3}H-dhSm does not open the membrane.

Plotz *et al.* have shown that when normal cells are held in a water rinse apparent uptake is increased[7]. We found toluene-treated cells, similarly held in a water rinse containing a representative amount of ^{3}H-dhSm, to yield an even larger apparent uptake. We therefore doubt that toluene treatment of cells in culture necessarily allows ^{3}H-dhSm to rush in. More likely, the equilibrium of ^{3}H-dhSm between the medium and the cell volume is principally a function of the cation-exchange capacity of cell biomass[8] and the intracellular concentration of competing cations. The apparent accumulation of antibiotic in toluene-treated cells would vary with the ionic composition of the rinse solution.

In summary, after a period of potentiation during which cellular uptake of ^{3}H-dhSm becomes refractory to inhibition by chloramphenicol, the accumulation of ^{3}H-dhSm is still sensitive to inhibitors of metabolism. Our assay for accumulation of antibiotic uses a buffer rinse which does not seem to remove accumulated ^{3}H-dhSm unless the integrity of the cell membrane is disrupted. These findings are consistent with an accumulation mechanism in *E. coli* for dihydrostreptomycin that involves either active transport or group translocation.

Maternal inheritance of mammalian mitochondrial DNA

EUKARYOTIC cells contain a class of cytoplasmic DNA molecules which are found only within the mitochondria, where they replicate and are transcribed (for a general review see ref. 1). This mitochondrial DNA (mtDNA) constitutes the 'mitochondrial genome' and carries genetic information essential to mitochondrial function. In view of its extranuclear location, it is not surprising that inheritance of the mitochondrial genome is not governed by the same rules that apply to chromosomal genes. For fungi[2-7] and amphibians[8] there is evidence that the mitochondrial genome of an individual is derived solely from the maternal parent (in contrast to chromosomal genes, which are inherited biparentally). We present here evidence that the mitochondrial genome is inherited maternally in mammals too.

This problem is not readily approachable by the standard techniques of genetic analysis, because mutations in the mammalian mitochondrial genome have not been identified. We have, therefore, used specific cleavage by a restriction endonuclease to look directly at the inheritance of mtDNA nucleotide sequences. When any homogeneous DNA preparation is digested to completion by a site-specific restriction endonuclease, a characteristic set of fragments is produced. If the DNA is of low complexity, as in the case of simple viruses[9,10] or mammalian mtDNA[11], separation of the restriction fragments on the basis of molecular weight by gel electrophoresis produces a characteristic 'fragment pattern' (Fig. 1). This pattern is characteristic of the original DNA molecule in much the same way that the tryptic fingerprint of a protein is characteristic of that particular protein.

We have studied the inheritance of mtDNA by isolating pure mtDNA from hybrids between two closely related mammalian species. The two parental mtDNAs are readily distinguishable by restriction enzyme cleavage analysis; analysis of the mtDNA from the hybrid animals yielded a fragment pattern characteristic of the maternal species. None of the DNA fragments specific for the paternal species were observed.

We obtained our material from common equine species: the horse (*Equus caballus*), the donkey (*E. asinus*), and the two reciprocal hybrids between them, the mule and the hinny. The two hybrids are defined as (1) ♀ horse × ♂ donkey → mule and (2) ♀ donkey × ♂ horse → hinny. Mules and hinnies may be of either sex but are generally sterile.

Mitochondria were partially purified from liver or heart tissue, and the DNA extracted from such preparations was centrifuged in CsCl-ethidium bromide gradients[12]. Pure mtDNA was isolated from the supercoil band in such gradients. The purified mtDNAs were then digested with a restriction endonuclease isolated from *Haemophilus aegyptius*, endonuclease Z[13] (endonuclease R·Hae III in the nomenclature of ref. 14), and the resulting digests were analysed by electrophoresis in 3.5% polyacrylamide gels. The DNA-containing bands were demonstrated by fluorescence after staining with ethidium bromide[15].

The fragment patterns obtained from horse and donkey mtDNAs are clearly distinguishable (Fig. 1). We examined DNA from six horses, two full-sized (one of each sex) and four ponies. Their mtDNA cleavage patterns were almost identical. The two horse patterns were indistinguishable, and the pony patterns differed in the position of one or two of the lower molecular weight fragments. These minor intraspecies variations in the fragment pattern seem to be significant and will be discussed elsewhere (manuscript in preparation). mtDNA from two male donkeys yielded fragment patterns indistinguishable from each other, but clearly different from the characteristic horse pattern. But although the two species yield readily distinguishable fragment patterns, there appears to be considerable homology between the two patterns.

Cleavage analysis of mule mtDNA gives the maternal (horse) fragment pattern (Fig. 1). All three animals that we have examined (one male, two females) yielded the standard horse pattern. This could be explained in terms of a general phenomenon of maternal inheritance of the mtDNA. Alternatively, however, it could be a result of a species-specific loss of donkey mtDNA in horse–donkey hybrid cells. To distinguish between these possibilities we have analysed the mtDNA from a hinny. Again the maternal pattern was observed (a donkey pattern in this case, see Fig. 1). The liver of this female hinny contained predominantly horse glucose-6-phosphate dehydrogenase (G6PD), but only donkey mtDNA (Fig. 2). This proved that the animal contained horse chromosomes (G6PD is X linked), and verified the word of the breeder that the animal was, in fact, a hinny. The preponderance of horse G6PD in this hybrid suggests the preferential inactivation of the maternal donkey X chromosome in this animal and is consistent with certain published reports of non-random X-chromosome inactivation in mules and hinnies (ref. 16 and review in ref. 17). It should be noted that a model consisting of an X-linked template for mtDNA synthesis, which is non-randomly inactivated in the hybrid animals, is not a reasonable explanation for the observed maternal inheritance of mtDNA since in this hinny it is the

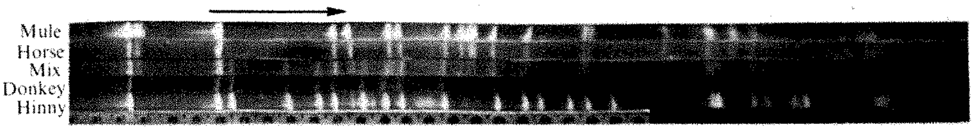

Fig. 1 Polyacrylamide gel electrophoresis of restriction fragments of equine mtDNAs. The arrow indicates the direction of electrophoresis. Reading from the ruler, the samples are: (1) hinny heart; (2) donkey liver; (3) mixture of donkey liver and horse liver; (4) horse liver; (5) mule liver. Analysis of liver mtDNA from the hinny gave a pattern the same as shown here for heart mtDNA. Our preparation of mtDNA will be described in detail elsewhere (manuscript in preparation). Tissue was homogenised to disrupt cells, then nuclei and debris were sedimented in the presence of 0.25 M sucrose at 500*g* for 10 min. After recentrifuging the supernatant at 500*g*, the mitochondria were pelleted twice at 10,000*g* for 10 min. The pellet was suspended in 0.15 M NaCl, 0.05 M EDTA, 0.01 M Tris, *p*H 7.4, lysed by the addition of 2% sodium dodecyl sulphate (SDS), phenol extracted twice, and then dialysed against SSC. About 20 ml of this mitochondrial nucleic acid preparation was then sedimented into an 18 ml preformed CsCl-ethidium bromide gradient (ρ = 1.4 to 1.7; 100 μg ml^{-1} ethidium bromide) poured in a 1 × 3.5 inch cellulose nitrate tube. The gradient was centrifuged 18–24 h at 22,000 r.p.m. in a SW27 rotor. DNA bands were demonstrated by fluorescence in ultraviolet light, and the bottom (supercoil) band was collected, freed of ethidium bromide by isopropanol extraction, then dialysed against SSC. The mtDNA was pelleted at 33,000 r.p.m. for 10 h in a SW50.1 rotor, the supernatant was discarded, and the mtDNA was dissolved in 0.15 M NaCl, 0.01 M Tris, *p*H 7.5. Yields from this type of preparation range from about 0.1 to 1.0 μg of supercoiled mtDNA per gram of tissue. To 45 μl of mtDNA solution (containing 10–20 μg DNA) were added 10 μl 0.13 M $MgCl_2$, 5 μl 0.02 M β-mercaptoethanol, and 5 μl endonuclease Z (enough enzyme to give a limit digest of 50 μg of SV40 DNA). Digestion was carried out at 37° C for 10 h, solid sucrose was added to 20% and the sample was layered on top of a cylindrical 3.5% polyacrylamide gel (gel composition as in ref. 9 except that agarose was omitted) 7 mm in diameter and about 50 cm in length. Electrophoresis was carried out for about 18 h at 310V, at which time bromophenol blue added to the sample is near the bottom of the gel. Gels were removed gently from the plastic tubes by air pressure into electrode buffer[9] containing 1 μg ml^{-1} ethidium bromide, and stained at room temperature for 2 h. Gels were placed against a black background, illuminated at a distance of a few inches with a Sylvania type BLB fluorescent black-light bulb and photographed at *f*4.7 for 60 to 120 s on Polaroid type 55 P/N film. An ultraviolet filter and an orange filter approximating the colour of the DNA-ethidium fluorescence were placed in front of the camera lens. These fragment patterns are interpretable in terms of a single type of mtDNA molecule of approximately 1 × 10^7 daltons for each of the two equine species. A quantitative analysis and comparison of these patterns will be presented elsewhere.

paternal X which is active. In summary, the evidence presented here demonstrates that the mtDNA of both mules and hinnies is maternally derived. We believe that as little as 5% paternal mtDNA would have been detectable in our experiments; however, we cannot exclude the presence of smaller amounts of paternal mtDNA. It seems reasonable to assume that the experiments look directly at inheritance of the primary nucleotide sequence of the mtDNA, however, we cannot logically exclude the possibility that factors which modify cleavage sites on the mtDNA differ between the two species and are maternally inherited.

Since the mtDNA is maternally inherited in both reciprocal hybrids, it seems reasonable to conclude that mtDNA is maternally inherited in each of these equine species. It would be surprising if this phenomenon were restricted to equine mammals. These experiments support the idea that the mitochondrial genome consists of cytoplasmically replicating mtDNA which is not the product of any chromosomal template.

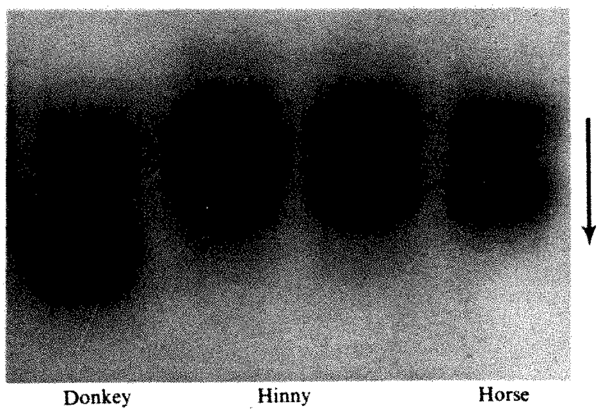

Fig. 2 Starch gel electrophoresis of equine G6PDs. Liver extracts were electrophoresed by the Tris-EDTA-borate method and stained for G6PD activity[25]. The left channel contains donkey G6PD, the two middle channels are identical samples of female hinny G6PD, and the right hand channel is horse G6PD. An arrow indicates the direction of electrophoresis. It has been suggested[26] that the slower moving (minor) components in both horse and donkey G6PD represent degradation products. The hinny samples are clearly predominantly horse G6PD, but appear possibly to contain a trace of the faster moving donkey enzyme.

Although it is not surprising that mtDNA is inherited maternally in mammals it could not be predicted *a priori* since the middle piece of the mammalian spermatozoon, containing the mitochondria, usually enters the egg[18]. In the mouse, mitochondria from the sperm have been observed to scatter in the cytoplasm of the egg[19,20]. In the light of these observations at least two mechanisms for maternal inheritance can be proposed: (1) the paternal (spermatozoon) mitochondria may be incapable of replication during development of the fertilised eggs, (2) maternal inheritance may result from a quantitative preponderance of maternal (egg) mitochondria in the zygote. It is amusing to consider some numerological consequences of the second type of mechanism. It has been estimated that a bull sperm contains 72 mitochondria[21]. Mammalian eggs are known to be rich in mitochondria[18,22], and if the concentration of mtDNA is similar to that found in the cytoplasm of echinoderm eggs[23,24], an equine egg would contain about 10^6 molecules of mtDNA. This would imply that if paternal and maternal mitochondria replicate at equal rates, then only about 10^{-4} of the mtDNA in a mammal would be paternally derived. This would be below the limit of detection of our experiments. Furthermore, the sperm mitochondria could be partitioned into cells during the formation of the blastocyst, before the onset of mitochondrial replication. As a consequence, many clones of cells in the developing embryo may be completely free of paternal mtDNA, even if paternal mitochondria are viable. It therefore seems unnecessary to postulate any replicational defect in the paternal mitochondria to account for the observed maternal inheritance of mtDNA. The possibility still exists that paternal mitochondrial genomes are present in very small numbers in mammalian tissues, and that sufficiently sensitive experiments could detect their presence.

We thank Dr H. N. Kirkman for help with the electrophoretic separation of G6PD species. Drs R. Penniall and N. M. Davidian gave helpful advice on the preparation of mammalian mitochondria. We also thank Mr Fred Cockerill for technical assistance and Drs D. P. Costello and J. Lucchesi for discussions. This work was supported by grants from the US Public Health Service and the American Cancer Society.

T3 x T7 phage crosses leading to recombinant RNA polymerases

THE related virulent bacteriophages T3 and T7 code for RNA polymerases which are specific for promoters located on the DNA of these phages[1,2]. These single peptide chain polymerases—the products of gene 1 (refs 1 and 3)—are genetically homologous but can be distinguished by their template specificity and their molecular weight. The T3 RNA polymerase transcribes T7 DNA at only about 10% of the rate at which T3 DNA is transcribed, and the T7 RNA polymerase transcribes T3 DNA at about 60% the homologous rate[2]; and, by direct comparison with the T7 polymerase, the molecular weight of the T3 polymerase was found to be about 5% lower than that of the corresponding T7 protein[4,5] (whose molecular weight has been estimated at 107,000 (ref. 1), 110,000 (ref. 2), 100,000 (ref. 6), and 108,000 (ref. 4). Since phages T3 and T7 can be crossed[7], the differences between the T3 and T7 RNA polymerases provide a model system for studies on the correlation between genetic constitution and functional specificity. Here we report some initial experiments in this direction.

The procedure was to isolate genetic recombinants within gene 1 of T3 and T7, and to analyse the corresponding gene 1 products with regard to template specificity and molecular weight. Since the recombination frequency in crosses between T3 and T7 is very low[7,8], parental types carrying two amber mutants were chosen to avoid *am*+ revertants. One parent was T7 *am*H13.*am*H280 (with both *am* markers within gene 1) and the other was T3 *am*H222.*am*H283 (a gene 1–gene 3 double mutant). The exact locations of the mutational sites are shown in Fig. 3. The proportion of *am*+ recombinants among the progeny of such crosses was $1-4\times10^{-5}$; that is, about a thousand times less than in corresponding crosses with homologous phage. From such a T3×T7 cross we picked ten *am*+ plaques for further analysis.

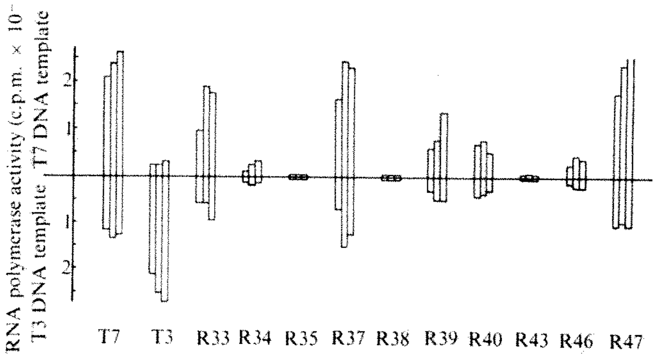

Fig. 1 RNA polymerase activity in cell-free extracts of phage-infected host bacteria, assayed with T3 or T7 template DNA. Exponentially growing cells of *E. coli* B (2×10^8 cells ml^{-1}) in casaminoacids medium[8] (37° C) were infected with T7, T3 or various genetic recombinants between T3 and T7 (multiplicity: 10 PFU/cell). At 5, 7 and 9 min after infection (first, second and third column, respectively), sample (10 ml) of each culture was poured on ice with chloramphenicol (300 μg ml^{-1}, final concentration) and centrifuged immediately. The pellets were resuspended in 0.5 ml buffer (0.05 M Tris-Cl, *p*H 8; 0.01 M 2-mercaptoethanol; 2 mg ml^{-1} bovine serum albumin) and the cells were disrupted by low intensity ultrasound (Branson sonifier B-12, microtip, 0° C). The extracts were centrifuged and the supernatant fluid was assayed at 37° C for rifampicin-resistant RNA polymerase activity as described by Chamberlin *et al.*[1], except, that first, 100 μl of assay mixture contained 7 μg of T3 or T7 DNA and second, 20 μl of cell extract were added to 100 μl of assay mixture. The RNA polymerase activity is here given as c.p.m. of ^{14}C-UTP (500 c.p.m. nmol^{-1}) incorporated into acid precipitable material, per assay.

The first step in this analysis aimed at ascertaining the recombinatorial origin of these *am*+ stocks. For this, two non-selected markers were checked: first, the ability to code for an active *S*-adenosylmethionine-cleaving enzyme (AdoMet-ase), which depends on the T3-specific *sam*+ gene (ref. 3), and second, the specificity towards T3 and T7 antiserum, determined by the product of gene 17 (serum blocking protein)[9]. (The *sam*+ gene is located at the 'left' end of the genetic map[3] and gene 17 lies at about 0.9 genome length, that is, near the 'right' end of the map[10].) The assay techniques for these markers were described elsewhere (refs 11 and 9). All the ten *am*+ stocks were *sam*+ and had the antiserum specificity of T7. Thus, these phages were undoubtedly recombinants between T3 and T7.

These T3×T7 recombinants were then analysed with regard to the activity and template specificity of the phage RNA polymerase they induce after infection of *Escherichia coli* B. As shown in Fig. 1, all the recombinant RNA polymerases either had a preference for T7 DNA or had virtually no measurable *in vitro* activity. The recombinants with no activity at 37° C (R35, R38, R43) were also grown and tested at 25° C, with the same result. Since the phage RNA polymerase is essential for phage growth, as evidenced by the fact that amber mutants in gene 1 cannot grow on su^- hosts, it must be concluded that the RNA polymerases coded by these recombinants are functionally active *in vivo* but are so unstable that they become inactive in the process of extraction. The recombinant RNA polymerases active *in vitro* were also less stable than the wild type enzymes, as shown by a higher temperature sensitivity.

Next, the recombinant RNA polymerases were characterised with regard to their molecular weights. This was done by polyacrylamide gel electrophoresis, in the presence of SDS, of extracts of host cells infected with phage and supplemented with ^{35}S-methionine, followed by autoradiography of the dried gels. This method (successfully used to characterise the T7-coded intracellular proteins[6,12]) revealed that the RNA polymerases of three of the tested recombinants had the molecular weight of the T3 RNA polymerase while the others—with one exception—had the molecular weight of the corresponding T7 enzyme (Fig. 2). The one exception, R43, coded for a gene 1 product with a molecular weight intermediate to those of the RNA polymerases of T3 and T7 (Fig. 2). It is especially noteworthy that the RNA polymerases of R33, R39 and R47 showed a preference for the T7 DNA template, although they had the molecular weight of the T3 RNA polymerase.

Our main interpretations of the results are as follows. First, the higher molecular weight of the T7 RNA polymerase is probably not due to a single deletion which occurred in a T3 ancestor or a single insertion in a T7 ancestor. Rather, there seem to be at least two regions ('loops') of about equal size within gene 1 of T7, which have no homologous counterpart in gene 1 of T3. Otherwise, a recombination event leading to a gene 1 of a size intermediate between that of T3 and of T7 would be highly unlikely to occur. These loops (Fig. 3) comprise about 150–200 base pairs each, as judged by the physical length of gene 1, and may correspond to the region of nonhomology between T3 and T7, seen at about 0.15 genome length through electron microscopy of heteroduplex T3-T7 DNA (ref. 10). Second, gene 1 polypeptides whose primary structure over a large extent is that of the T3 enzyme but which carry the amino acid sequence encoded by one or both loops of T7 gene 1 are likely to fold into unstable tertiary structures; therefore the *in vitro* inactivity or temperature sensitivity of the recombinant enzymes. Third, the gene 1 segment which imparts the template specificity (either a preference for the DNA of T3 or T7) to the RNA polymerase is located at the 'right', that is the carboxyl end of gene 1. Thus, recombination events occurring distal to the loops of T7 gene 1 may lead to recombinant genes coding for RNA polymerases with a molecular weight characteristic of T3 but a template specificity characteristic of T7.

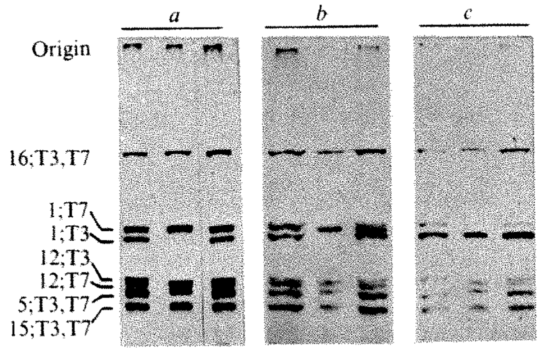

Fig. 2 Comparison of the molecular weight of recombinant RNA polymerases with that of T3 and T7 polymerase. Phage-directed proteins were continuously labelled by adding ^{35}S-methionine (40 μCi ml^{-1}, final concentration) together with the phage (multiplicity: 10 PFU per cell) to a sample (0.2 ml) of ultraviolet-irradiated *E. coli* B bacteria (3×10^8 cells ml^{-1}). After 15 min at 37° C the infected cells were collected by centrifugation and resuspended in 20μl of buffer (0.15 M Tris-Cl; 1.5 M 2-mercaptoethanol; 5% sodium dodecyl sulphate; 10% glycerin). After 2 h of incubation at 50° C, followed by 2 min at 100° C, the samples were placed on 8% polyacrylamide slab gels and subjected to electrophoresis for 5 h at 150 V. The dried gels were then autoradiographed for 2 d. Further details of the method are as described by Studier[12]. In this figure the results for three of the tested recombinants are given: *a* is an example of recombinant RNA polymerases with the molecular weight of the T7 polymerase (here: R34); *b* refers to R43, with a gene 1 product of intermediate molecular weight; and *c* represents the recombinant RNA polymerases with the molecular weight of the T3 enzyme (here: R47). For each recombinant tested, three parallel runs were made: at left is a reference frame which is a mixture of T3-coded and T7-coded proteins (the numbers at left refer to the corresponding genes[4,6]); the middle column is that of the recombinant proteins and at the right a mixture of T3, T7 and recombinant proteins was applied.

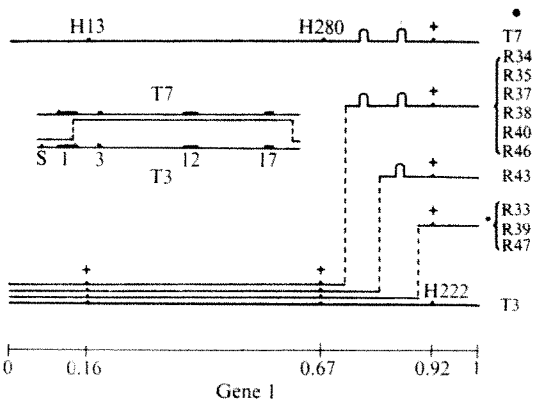

Fig. 3 Scheme of the presumptive genetic constitution of T3–T7 recombinants within gene 1. These recombinants were picked as am^+ plaques after plating the progeny of the cross T7*am*H13·*am*H280 × T3*am*H222·*am*H283 on the su^- host *E. coli* B. For the crossing procedure see ref. 3. The T7 parent carries two amber markers within gene 1 and the T3 parent is a gene 1–gene 3 double mutant. The position of the *am* markers within gene 1 was determined by estimating the molecular weights of the gene 1 amber peptides with the gel electrophoresis–autoradiography method[12]. The inset represents the length of the complete genomes of the parental phages[3,10] and the probable overall genetic constitution of the recombinants. The specified genes are those for which this constitution has been checked (S = *sam*). The presumed crossover at the right end of the genome is to satisfy the need for identical terminal redundancies[10] at the ends of recombinant phages; alternatively, such a crossover could have taken place to the left of the *sam* gene.

DNA purified from naked intranuclear particles of human liver infected with hepatitis B virus

DANE *et al.*[1] observed a particle 42 nm in diameter with a double shell and an inner core resembling a viral nucleoid in the sera of some patients with hepatitis B antigenemia. They postulated that this particle was the complete hepatitis B virion. Almeida *et al.*[2] showed that an internal core particle, 27 nm in diameter, could be released by treating the 42 nm Dane particle with Tween-80 (polysorbate) and that this core particle contained an antigen different from hepatitis B antigen (HBAg). Almeida[3] suggested that these core particles were identical to naked particles, also 27 nm in diameter, observed by electron microscopy in the nuclei of hepatocytes of human livers infected with hepatitis B virus (HBV)[4,5]. Cores isolated from Dane particles in human sera[6] seem to be similar in morphology to the 27 nm naked particles visualised in homogenates of HBV-infected human livers[7]. We recently reported methods for isolation and purification of concentrated preparations of naked intranuclear particles of hepatocytes of HBV infected liver[8]. The ultraviolet absorption spectrum of these particles suspended in 0.05 M Tris-HCl, 40 mM KCl, 0.1% β-mercaptoethanol (BME), 10 mM $MgCl_2$, *p*H 7.5 buffer showed a peak at 264 nm and a shoulder at 280 nm indicating the presence of both nucleic acid and protein[8]. We now report the isolation of double-stranded DNA from these particles and describe the spectral properties of the isolated DNA.

The naked intranuclear particles of the hepatocytes of an HBV-infected human liver obtained at necropsy from a patient with chronic HBV infection were purified as previously described[8]. The purification procedure entailed the isolation of the liver nuclei, the subsequent release of the naked intranuclear particles from the nuclei by sonication, and the purification of the particles on CsCl density gradients[8]. The purified particles obtained from the CsCl gradients at a density of 1.30–1.31 gm ml^{-1} (ref. 8), and visualised by electron microscopy[8], were dialysed against 0.01 M NaCl, 0.01 M PO_4, 10^{-3} M EDTA, 1% BME, *p*H 7.2 buffer. The particle preparation was made up to a concentration of 1% of sodium dodecyl sulphate (SDS), allowed to stand at room temperature for 10 min, and then extracted four times at room temperature with distilled phenol previously equilibrated with buffer. The aqueous portion was dialysed exhaustively against two changes of 0.01 M NaCl, 0.01 M PO_4, 10^{-3} M EDTA, *p*H 7.2 buffer and then against four changes of 0.01 M NaCl, 0.01 M PO_4, *p*H 7.2 buffer at 5° C.

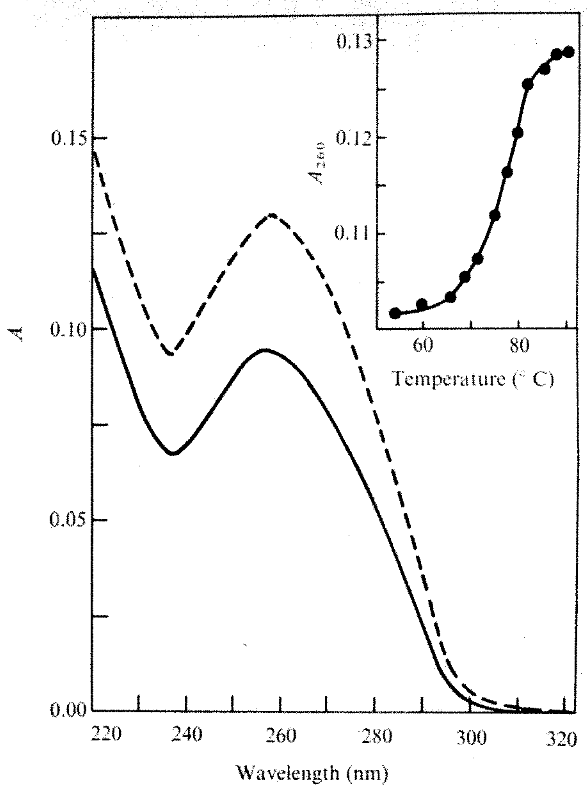

Fig. 1 Ultraviolet absorption spectra of DNA purified from naked intranuclear particles of hepatocytes of HBV-infected human liver. Solid line: native spectrum at 33.6° C; dashed line: denatured spectrum at 87° C. Insert shows the thermal denaturation profile at 260 nm. DNA was dissolved in 0.01 M NaCl, 0.01 M PO_4, *p*H 7.2 buffer. 100 μl microcuvettes of 1 cm pathlength contained 0.35 ml DNA solution to preclude meniscus effects on the absorbance values. The microcells were fitted with Teflon stoppers and sealed with RTV-60 compound. Temperature was controlled with a Laude K-2R circulation bath (Brinkmann Instruments) containing 50% ethylene glycol and measured by a platinum probe in a 3 ml sealed quartz cuvette filled with 1 ml buffer in the Beckman Acta V spectrophotometer. Temperature equilibrium was reached within 20 min at each point. The temperature was raised by 5° C increments until 50° C and then by 1–2° C until denaturation was complete. Absorbance values read by digital display at each temperature were corrected to 4° C for the expansion of water[13].

The ultraviolet absorption spectrum of the resulting dialysate suggested a solution of nucleic acid (Fig. 1). The nucleic acid was identified originally as double-stranded DNA by means of the following reactions: (1) a positive diphenylamine[9] but negative orcinol[10] reaction; (2) immediate increase in ultraviolet (220–290 nm) absorbance (+12% at 260 nm) when material of 0.1 absorbance at 260 nm was treated with pancreatic DNase (20 μg ml^{-1}; Sigma; double-stranded calf thymus and *Bacillus subtilis* DNAs gave comparable immediate increases in ultraviolet absorbance when treated with DNase under similar conditions, the immediate

Table 1 Properties of DNA purified from naked HBV particles determined by spectral analysis

	Hyperchromic spectra	Denatured spectra	
Mole fraction A–T	0.434±0.012 (s.d.)	0.374±0.023 (s.d.)	Average 0.404±0.036 (s.d.)
Concentration (mol nucleotide l^{-1})	1.35×10^{-5}	1.41×10^{-5}	DNA in native state (%), 95.7
Molar extinction at 260 nm (l mol^{-1} cm^{-1})	6,926	6,631	Average 6,779
Randomness (δ) parameter	0.012	0.124	

See text and legend to Fig. 1 for experimental details. Calculations were based upon data taken at 5 nm intervals between 220 and 290 nm for the hyperchromic spectra and at 240 nm, 250 nm, 260 nm, 270 nm and 280 nm for the denatured spectra using the three term analyses given by Hirschman and Felsenfeld[14]. A program written for a Wang 700B computer was used for the calculations.

increase in absorbance representing incomplete digestion of double-stranded DNA) and no change in absorbance when treated with pancreatic RNase (20 μg ml^{-1}, Sigma), (3) no reaction when neutralised formaldehyde was added to a concentration of 1 8% (ref 11), (4) a very slow increase in ultraviolet absorbance of the heat-denatured material treated with pancreatic DNase but no reaction when treated with pancreatic RNase, and (5) a slow increase (single-stranded RNA reacts immediately) in ultraviolet absorbance (~15% at 260 nm in 4 h) when the heat-denatured material was treated with neutralised formaldehyde (1 8%) Electron microscopic observation[12] of the material showed linear strands consistent with double-stranded DNA

First estimates from the absorbance at 260 nm indicated that the yield of double-stranded DNA from naked particles purified from 60 g of HBV infected liver was 15 μg It was considered that the properties of such modest amounts of DNA could well be studied by spectral analysis[13-15] adapted to microdeterminations Ultraviolet spectra were recorded with a Beckman Acta V spectrophotometer in the single beam mode using 100 μl microcuvettes and microapertures DNA of known base composition in 0 01 M NaCl, 0 01 M PO_4, *p*H 7 2 buffer also was analysed to determine the accuracy of the micromethods The microcells were fitted with Teflon stoppers and sealed with RTV silicone rubber compound (General Electric) for DNA melting experiments[13,14] Analysis of DNA of known base composition (*B subtilis* and calf thymus DNAs, 0 665 and 0 585 mole fraction A–T, respectively) adjusted to 0 1 absorbance at 260 nm at room temperature showed (1) accurate determination of the blank values of the microcuvettes was imperative, (2) correct assessment of the first temperature of complete denaturation[13] was critical, especially when deriving data from the denatured spectra, because the small changes in absorbance produced by depurination upon further heating[13] led to large errors in values of mole fraction A–T, (3) analyses of the denatured spectra gave lower values of A–T mole fraction, that showed greater scatter, than those derived from the hyperchromic spectra, (4) the low initial absorbance values required precise measurement of the temperature at each point because of the relatively greater contribution to the total absorbance values by the corrections for the expansion of water at each temperature, and (5) the microanalyses of DNA of known base composition were accurate to ±0 040 and ±0 055 mole fraction A–T using the hyperchromic and denatured spectra, respectively These values compare well with the macromethods[14] The native spectra were not used in these studies because of the greater inaccuracy of the derived values of mole fraction A–T[14] Only three-term analyses[14] were used to derive data from the spectra

The ultraviolet absorption spectrum of the purified native DNA showed a peak at 257 nm and a trough at 237 nm (Fig 1) When heated to 90° C the DNA gave a sharp rise in hyperchromism of 33% at 260 nm (Fig 1, insert), the melting temperature (T_m) in 0 01 M NaCl, 0 01 M PO_4, *p*H 7 2 buffer was 77° C, characteristic of DNA of 0 44 mol fraction A–T (S Z Hirschman, unpublished data)

The mol fraction A–T derived from the hyperchromic spectra (Fig 1) was 0 434±0 012 (standard deviation, s d) and from the denatured spectra 0 374 ± 0 023, the average value from both spectra was 0 404 ± 0 036 (Table 1) Analysis of the hyperchromic and denatured spectra yielded DNA concentrations of 1 35 × 10^{-5} and 1 41 × 10^{-5} mol nucleotide l^{-1}, respectively, indicating that 95 7% of the DNA was in native (double-stranded) state[14] (Table 1) The average molar extinction coefficient at 260 nm was 6,779 l mol^{-1} cm^{-1} (Table 1) The values of the 'randomness' (δ) parameters[13,14] were 0 012 and 0 124 for the hyperchromic and denatured spectra, respectively

Preliminary comparisons of the fraction of all A–T pairs (F_{AT}) against the fraction of all G–C (F_{GC}) pairs melted at each temperature[14,15] indicated that 60% of the DNA had a mol fraction A–T of 0 48 and 40% had a mol fraction A–T of 0 32 But because of the small changes in absorbance at each wavelength at each temperature throughout the melting these data will require substantiation by studies with much higher concentrations of DNA

Lower values of mol fraction A–T derived from the denatured spectra were found also with DNAs of known base composition (see above) The value of mol fraction A–T derived from the hyperchromic spectra agreed with the value obtained from the T_m at 260 nm The average extinction coefficient at 260 nm of 6,779 l mol^{-1} cm^{-1} compares to the extinction coefficient of 6,710 l mol^{-1} cm^{-1} previously reported for bacterial DNAs of 0 43 mol fraction A–T[13] The very low values of the 'randomness' (δ) parameter[13,14] suggested that the DNA did not contain abnormal bases

Thus, double-stranded DNA of unique base composition has been isolated from the putative HBV nucleoid, the naked intranuclear particle of hepatocytes of human liver infected with HBV Unfortunately, electron microscopic observation of the DNA showed the strands to be heterogeneous in size with a highest molecular weight of about 1 × 10^6 We assume that the DNA strands were broken either by liver nucleases or the sonication to release the particles from the nuclei of the hepatocytes during particle preparations[8] Various methods of particle preparation are under investigation to allow determination of the true molecular weight of the DNA

The small HBV nucleoid could accommodate a DNA of about 2 × 10^6 molecular weight Other small mammalian DNA-containing viruses, such as parvo[16] and adeno associated viruses (AAV)[17], contain single stranded DNA in the virion and may require a helper virus for replication The DNA of AAV may be packaged as separate plus and minus strands that can reassociate to a double-stranded form after extraction of the DNA[17] Whether HBV DNA is actually double stranded in the virion may still be open to some question But this question and the possibility that HBV may require a helper virus for replication can be subjected to experimental investigation now that concentrated naked particle preparations are available[8]

We thank Dr Anthony Garro for gifts of distilled phenol and purified *Bacillus subtilis* DNA, Drs Gary Felsenfeld and Julius Marmur for discussions, and Dr Hajo Delius for the electron microscopic observation of the DNA The study was supported by a grant from the United States Public Health Service

Immunological destruction of herpes simplex virus I infected cells

THERE are clearly two levels at which the immune response may intervene to induce protection against viral infection Neutralising antibodies effectively limit spread of free virus in many situations, thus preventing reinfection In a number of viral diseases, however, it is often not possible to cure the infection by even high titres of neutralising antibodies[1,2] In such situations, recovery from infection may require the intervention of a cell-mediated immune response directed at the infected cell Selective impairment of the host's immunity, for example, by thymectomy or by antilymphocyte serum, markedly increased mortality of mice infected with ectromelia[3], and herpes simplex[4,5] Macrophage suppression has had a similar effect[6] In these cases recovery could be conferred by transfer of immune lymphoid cells (ref 7 and B R-Z, and A C Allison, unpublished) But the nature of the cells involved, and the mechanisms by which they act remain problematic Our experiments were undertaken to evaluate the contribution of various types of cells to immune reactivity to cells infected with herpes simplex virus I *in vitro*

Adult C57Bl/6J mice were infected intraperitoneally with 10^6 plaque-forming units (PFU) of the HFEM strain of herpes simplex virus I, (HSV), grown in chick embryo fibroblasts, and immune lymphoid cells were collected at various times after immunisation The ability of these cells to destroy HSV infected Chang human liver cells, was assessed by measuring the release of ^{51}Cr from labelled HSV-infected Chang cells 16 h after treatment with various immune or normal lymphoid cells In this system, Chang cells in suspension were infected at an input multiplicity of 10 Twenty hours after infection, when lymphoid cell preparations were added, 80% of the cells exhibited viral specific membrane fluorescence Infected cells were labelled for 45 min at 37° C with 100 μCi ^{51}CrO$_4$ (Amersham) washed three times, and 5 × 10^4 cells were distributed to plastic test tubes Lymphoid cells were added at a ratio of 40 1 and the cells were cultured in Eagle's medium containing 6% foetal calf serum Spontaneous ^{51}Cr leakage was approximately 15–20%

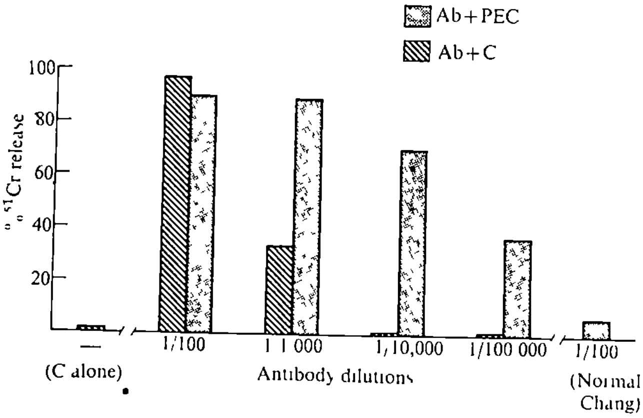

Fig 1 Comparative efficiency of cytolysis of HSV-infected Chang cells by Ab-dependent cell-mediated lysis and complement (C)- mediated lysis Target cells were treated with dilutions of rabbit anti-HSV serum before the addition of effector cells or complement The neutralisation titre of the anti-HSV serum was 1 640 Complement was used at a 1 12 dilution of fresh guinea pig serum The ratio of PEC to target cells was 40 1

Table 1 Cytolysis of HSV-infected Chang cells by immune or nonimmune mouse lymphoid cells

Target cells	Effector cells	% Specific ^{51}Cr release
HSV-infected Chang	Nonimmune spleen cells	0
	Immune spleen cells	4 5
	Nonimmune spleen cells + anti-HSV mouse serum (1/100)	4 5
	Immune peritoneal exudate cells	46 0
	Nonimmune peritoneal exudate cells + normal mouse serum (1/100)	0
	Immune spleen cells + nonimmune peritoneal exudate cells (20 1)	30 0
	Nonimmune peritoneal exudate cells + anti-HSV mouse serum (1/100)	90 0
	Anti-HSV mouse serum (1/100)	2 5
Noninfected Chang	Nonimmune peritoneal exudate cells + anti-HSV mouse serum (1/100)	7 0

Mouse anti-HSV serum was added to 5 × 10^4 target cells in plastic test tubes (Falcon No 2054) Effector cells were then added at a ratio of 40 1 in a final volume of 1 0 ml Samples were prepared in triplicate Percentage lysis was computed as
(Mean ^{51}Cr release in test group—mean spontaneous ^{51}Cr release)/(Mean ^{51}Cr release after freeze-thawing—mean spontaneous ^{51}Cr release) × 100

Repeated attempts to demonstrate the presence of cytolytic lymphocytes in immune spleens were unsuccessful, even in the presence of anti-HSV antibodies (Table 1) In contrast, peritoneal exudate cells (PEC) from immune donors 6 d after infection were markedly cytotoxic for HSV-infected Chang cells When peritoneal exudate cells from normal mice were admixed with immune spleen cells (at a ratio of 1 20), a significant degree of cytotoxicity was observed, suggesting that the cytotoxicity might be mediated by nonimmune effector cells This was confirmed by the demonstration that nonimmune peritoneal exudate cells in the presence of heat-inactivated anti-HSV rabbit or murine serum had an even greater degree of cytotoxicity than immune peritoneal cells Immune sera from mouse, rabbit or man were all effective, as demonstrated in Table 2 and both mouse exudate or human peripheral monnuclear cells could serve as effector cells

The efficiency of cytolysis of HSV-infected cells by antibody-dependent cell-mediated lysis and complement-mediated lysis is compared in Fig 1 At high concentrations of rabbit anti-HSV antibody, high degrees of lysis of HSV infected cells were observed in both systems The efficiency of complement-mediated cytolysis however, diminished markedly upon dilution of antibody, whereas the cytotoxicity mediated by

Table 2 Cytolysis of HSV-infected Chang cells by both mouse peritoneal exudate (PEC) or human peripheral blood mononuclear cells (PBL) in the presence of either rabbit or human immune sera

Effector cells	Serum	% Specific ^{51}Cr release
PBL	Nonimmune rabbit 1/100	25
PBL	Rabbit anti-HSV 1/100	83
PBL	Nonimmune human 1/100	31
PBL	Human anti-HSV 1/100	81
PEC	Nonimmune rabbit 1/100	10
PEC	Rabbit anti-HSV 1/100	89
PEC	Nonimmune human 1/100	15
PEC	Human anti-HSV 1/100	81

Nonimmune human serum and peripheral blood were taken from donors with no known previous HSV infection Immune human serum was taken from a patient with recurrent HSV infections Human peripheral blood mononuclear cells were prepared by Ficoll-Hypaque gradient centrifugation[16] In all cases the lymphocyte target cell ratio was 40 1 nonimmune peritoneal exudate cells remained high even in the presence of a 1/10,000 antibody dilution A similarly pronounced effect was observed in the case of murine anti-HSV antibodies obtained early (6 d) after immunisation, in which 52% chromium release was obtained in the presence of normal peritoneal exudate cells with but 3 5% in the presence of guinea pig complement

These observations confirm the prediction of Allison[1] that antibody-dependent cell-mediated cytotoxicity would be operative in viral immunity, and extend the fundamental studies of Perlmann[8], MacLennon[9] and Evans and Alexander[10] to the case of virus-infected cells Although the precise nature of the effector cell(s) in these systems has not yet been fully elucidated, it clearly does not share characteristics with thymus-derived lymphocytes[1,9] Whether it belongs to a subpopulation of B lymphocytes macrophages or is a novel cell type remains unclear, but the effector cells in the mouse have been found to be surface-adherent, poorly phagocytic and dependent on an Fc receptor Here we confirm that removal of adherent cells from the peritoneal exudate population by culture for 2 h in 60 mm plastic Petri dishes results in a 90% diminution in cytotoxic activity of the cells

In their studies on the part played by antibodies and cell-mediated reactions on spread of HSV infection *in vitro*, Lodmell *et al*[11] noted that spread of infection had occurred as early as 2 h before the detection of surface HSV antigen by complement-mediated cytotoxicity, and suggested that consequently antibodies were not likely to be useful in limiting the spread of infection Our studies indicate that antibody-dependent cell-mediated cytolysis of HSV infected cells provides a mechanism orders of magnitude more efficient than complement-mediated cytolysis in terms of antibody required While extrapolation of the *in vitro* results to the *in vivo* situation would be premature, the data suggest that a collaboration of antibody and the appropriate effector cells could provide a significant degree of restriction of infection In addition, other cell-mediated mechanisms, such as T-cell dependent cytotoxicity[12,13] and possibly generation of mediators as a consequence of the inflammatory response[14,15] may be involved

Note added in proof Similar results have recently been obtained independently by Shore, S L, Nahmias, A J, Starr, S E, Wood, T A, and McFarlin, D E, *Nature* (in the press)

Pronounced antiviral activity of human interferon on bovine and porcine cells

INTERFERONS prepared from cells of one species may exhibit some activity on cells of others although the titre on heterologous cells is usually considerably lower than that for homologous cells[1] The one exception to date has been the finding that human fibroblast interferon was far more active on heterologous rabbit cells than on human cells[2,3] We report here that human leukocyte and fibroblast interferon preparations exert a pronounced antiviral activity on bovine and porcine cells, and the activity of the human leukocyte interferon is far greater on heterologous bovine cells than on homologous human or monkey cells

The origins of the interferon preparations and the cells used in their assay are presented in Table 1 Several interferon preparations were prepared in our laboratory and standard techniques were used to eliminate residual inducing virus All cells were cultivated in Eagle's medium with 10% calf or foetal calf serum Dilutions of interferon preparations were incubated with cell cultures for 18 h before the test virus was added Two methods of assay were used First, inhibition of the cytopathic effect (CPE) of 100 $TCID_{50}$ of vesicular stomatitis virus (VSV) or encephalomyocarditis (EMC) virus in monolayer cultures of cells in plastic Microtest II Trays (Falcon)[7] Titres are expressed as the highest two-fold dilution giving approximately 50–75% protection of the cell sheet at a time when virus-infected control cultures showed complete cell sheet destruction Second, inhibition of virus yield determined 12 or 18 h after addition of VSV or EMC virus at a multiplicity of infection of 1 Titres are expressed as obtained in our laboratory (One of our units is approximately the equivalent of 1 5–2 human leukocyte MRC reference interferon 69/19 units)

The antiviral activity of human interferon preparations

Table 1 Interferon preparations

Tissue origin	Interferon inducer	Supplied by
Human leukocyte suspensions	Sendai virus	Dr K Cantell Dr H Strander[4,5]
Human leukocyte suspensions	Newcastle disease virus (NDV)	Dr T Kishida[6]

—, Not tested

on human, monkey, bovine and porcine cells using VSV as the challenge virus is presented in Table 2 and the salient points may be summarised as follows

Three different human interferon preparations derived from leukocyte suspensions (including the MRC standard reference interferon 69/19, a partially purified interferon (Kishida) and a potent preparation (Cantell) used in the treatment of patients[5]) all protect bovine cells to a far greater extent than they protect either human fibroblasts or BSC cells For example, the Cantell preparation had a titre of 1 64×10^4 on human fibroblasts or monkey kidney cells and a titre of 1 25×10^6 on bovine embryonic cells

Human leukocyte interferon preparations protect porcine kidney cells to the same degree as human fibroblasts or BSC cells

Interferon prepared from a continuous Burkitt cell line behaves as an interferon derived from normal leukocyte suspensions and protects bovine cells to a greater extent than BSC cells

Human embryonic fibroblast interferon (induced either by poly(I), poly(C) or NDV—Table 1) crosses on bovine and porcine cells In contrast to leukocyte interferon, however, the antiviral titre of fibroblast interferon was slightly less on bovine cells and considerably less on porcine cells than on human or monkey cells

Although human interferon preparations exhibited antiviral activity on bovine and porcine cells, these cells are not protected by mouse or rabbit cell culture interferon preparations

Bovine embryonic skin interferon exhibited only slight antiviral activity, and porcine kidney interferon exhibited no detectable activity on human fibroblasts

The pronounced antiviral activity of human leukocyte interferon on bovine and porcine cells and the less pronounced activity of human fibroblast interferon on these cells were also observed when EMC virus was used as a challenge virus instead of VSV Likewise, the pronounced antiviral activity of the human leukocyte reference interferon on bovine cells was observed when assayed by inhibition of VSV or EMC virus yield rather than by inhibition of CPE

A number of tests were undertaken using the MRC reference interferon 69/19 to determine the characteristics of the factor responsible for protection of bovine and porcine cells As can be seen in Table 3, this factor fulfilled the usual criteria for acceptance of a viral inhibitor as an interferon[1] Furthermore, a rabbit antihuman leukocyte interferon serum neutralised (to a titre of 1 800) 4 units of the human leukocyte reference interferon 69/19 as determined in simultaneous assays on monkey, bovine and porcine cells

Table 3 Characteristics of human leukocyte reference interferon 69/19 as tested on monkey (BSC) bovine embryo (BE) and porcine kidney (PK) cells

Test	Activity on cells BSC	BE	PK_{106}
Washing (× 2) of cell sheet before the addition of challenge virus	++	++	++
Requires several hours incubation on cells for establishment of antiviral activity	++	++	++
Pretreatment of cells for 1 h with 5 μg actinomycin D	±	0	0
*p*H 2 for 24 h	++	++	++
Dialysis for 24 h	++	++	++
Supernate after centrifugation 100,000*g* 1 h	++	++	++
Heating at 60° C for 1 h	+	+	+
Trypsin 500 μg for 1 h 37° C	0	0	0
DNAase or RNAase 100 μg 1 h 37° C	++	++	++

VSV used as a challenge virus in these tests ++, Activity undiminished by treatment, +, approximately 50% loss of activity, ±, approximately 50–90% loss of activity, 0 = > 95% loss of activity

The finding that human leukocyte interferon exhibited a far greater activity on bovine and porcine cells than human fibroblast interferon of comparable titre is in accord with previous work suggesting that these two interferons differ in their biological[2,3] as well as in their physicochemical properties (V Edy, A Billiau, M Joniau, and P De Somer, unpublished and W E Stewart II, P De Somer and E De Clercq, unpublished)

The finding that human leukocyte interferon has such a high titre on bovine cells (that is, Cantell's human leukocyte interferon had a titre of 1 25×10^6 on bovine cells) may be of value in veterinary medicine Thus, it may prove simpler to prepare human leukocyte interferon (perhaps from a leukocyte cell line) than to prepare bovine interferon preparations of comparable titre Furthermore, since bovine cells are highly sensitive to human leukocyte interferon, they may prove useful for the detection of small amounts of this interferon

It has been suggested[8] that cells contain specific interferon receptors that may be responsible for the usual species specificity of interferon If such receptors exist, our results pose the question whether bovine and porcine cells have receptors for both homologous and human interferon or whether these cells share a common interferon receptor

At least three hypotheses may be suggested to explain why human leukocyte interferon exerts a greater activity on bovine cells than on homologous cells First, fewer molecules of human leukocyte interferon may be needed to induce antiviral activity in bovine cells than in human cells Second, there are more interferon receptors on bovine cells than on human cells Therefore, at limiting dilutions of interferon there is a greater chance of inducing antiviral activity in bovine cells than in human cells Third, an inhibitor of human leukocyte interferon activity is present in human cells but not in bovine cells

The explanation of such high activity of interferon on unrelated heterologous cells should prove relevant to the understanding of the nature of the interaction of interferon with cells and the mechanism of the usually observed limited activity of interferon on heterologous cells

We thank Dr Cantell for supplying rabbit anti-human leukocyte interferon serum, Drs Cantell, Strander, Kishida and Came for human leukocyte and fibroblast interferons, and Dr S G Anderson who made available to us the MRC reference interferon We also thank Drs Parodi and Scherrer for giving us the porcine kidney cell line and Dr Strander for the Burkitt cell line 'Namalwa'

Note added in proof Since submission of this article, we have shown that the human leukocyte reference interferon 69/19 and the Cantell human leukocyte interferon also exhibit a far greater antiviral activity on two other bovine cells, embryonic lung (passage six) and embryonic kidney (passage three to five) than on homologous human fibroblasts or monkey kidney cells

Reactivation of immunocompetence in spleen cells of aged mice

REACTIVITY in both humoral and cellular immune reactions has been shown to decline with age[1–4], but the reasons have not yet been critically established It could be attributed, at least in part, to thymus involution, since the most prominent reduction in reactivity is shown in thymus-dependent responses[5] The question is, therefore, whether decreasing immune reactivity results from a decrease in the stem cell pool, or whether it is due to a failure in one of the processes of cell maturation which are affected by the thymus

This study was designed to distinguish between these two possibilities We used the graft-*versus*-host (GvH) response as the experimental model, since a decrease in the potential to elicit this response during ageing has been reported[6] Thus, spleen cells originating in old mice, when injected into allogeneic newborn recipients, produced splenomegaly reactions at a lower level than cells of young mice To ascertain that the failure to cause splenomegaly does not result from different homing patterns of the cells introduced to the newborn test animal, we used the *in vitro* technique for the GvH response[7] We first attempted to establish at which age the reduction in activity is most apparent in the mice used in this study Thus, (C3H/eb×C57Bl)F_1 mice were tested at four different ages 2–3, 12–15, 23–26 and 32–33 months 5×10^5 spleen cells of each of these groups were added to explants of newborn BALB/c spleens The relative enlargement of these newborn spleen fragments as compared with fragments cultured with syngeneic spleen cells was recorded after 4 d, as previously described[7] As shown in Fig 1, a decrease in the ability of spleen cells to elicit a splenomegaly reaction *in vitro* is manifested with advancing age The 2–3 month old mice (Group *a*) elicited the highest incidence of response High incidence of response was also

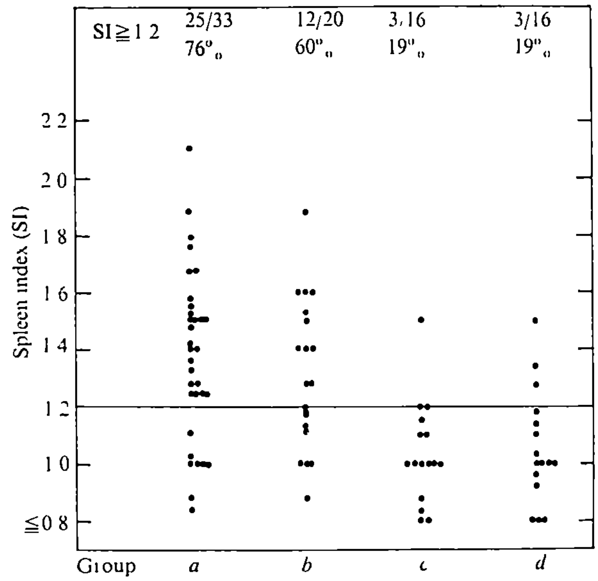

Fig 1 *In vitro* GvH response by spleen cells of aged mice Index of newborn BALB/c spleens following incubation with 5×10^5 spleen cells of (C3H/eb×C57Bl)F_1 mice at different ages Each point represents the results of one individual culture Group *a*, 3 month old mice, *b*, 12–15 month old mice, *c*, 23–26 month old mice, *d*, 32–33 month old mice

obtained in the group of 12–14 month old mice (Group *b*). Cells of the 23–26 (Group *c*) however, and those of the 32–33 month group (Group *d*) manifested a limited reactivity. These *in vitro* results eliminate the possibility that different homing mechanisms account for the failure to produce a response, since the cells were applied directly to the target organ, the newborn spleen. So a reduction in the immune potential of the cells from the aged mice is suggested.

This was further substantiated by increasing the cell doses used to elicit the response. The activity of 10^6 spleen cells from 32–33 month-old mice was tested in comparison with 5×10^6 cells. As seen in Fig 2, group *a*, the larger dose of cells did lead to a higher incidence of response, 75% as compared to 43%, similar to a higher reactivity obtained upon increase of dose of cells from young mice (Group *b*) (94% as compared to 68%, respectively). Yet, even at that higher dose of cells, the response obtained was relatively low compared to that of the young. These results could be attributed to a decrease in number of progenitor cells, or to a failure of maturation of progenitors to immune reactive cells as a result of thymus involution. To test this, we planned to apply thymus extract (THF)[8], since it has been shown to cause cells to become reactive in a GvH response[9]. The *in vitro* GvH experiment was thus repeated, employing spleen cells of 23–26 months, at a dose of 5×10^5 cells, and THF was added to the culture medium, at a concentration of 2% for the entire period of culture[10]. Cultures without THF were set up in parallel. Similarly, cells of 2–3 months old mice were tested with and without THF. As shown in Fig 3, THF enhanced the response elicited by cells from aged donors (Group *a*), whereas it did not lead to any change in reactivity of the cells from young animals (Group *b*).

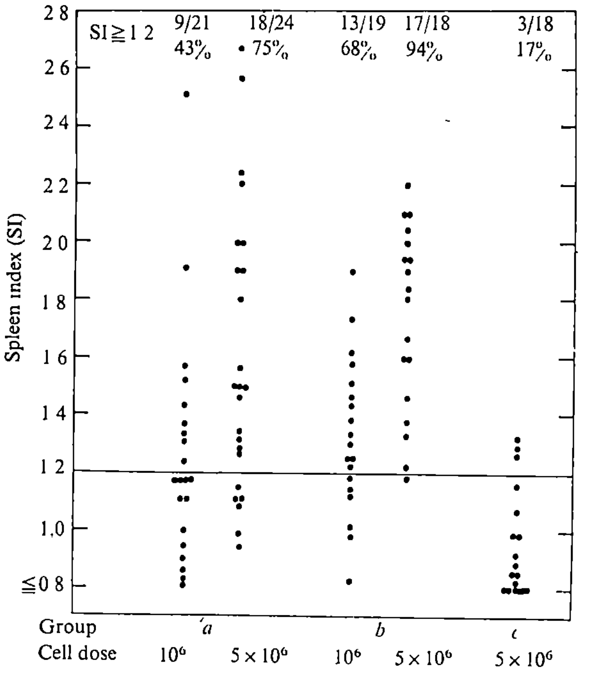

Fig. 2 *In vitro* GvH response by spleen cells of aged mice. Index of newborn BALB/c spleens following incubation with 10^6 or 5×10^6 spleen cells from mice at different ages. Each point represents the results of one individual culture. Group *a*, 32–33 month old (C3H/eb×C57Bl)F$_1$ mice, *b*, 3 month old (C3H/eb×C57Bl)F$_1$ mice, *c*, 3 month old BALB/c mice.

These results cannot be explained by a deficit in progenitor cells, since no cells were supplied to the system from any external source. We suggest that the decline in the ability to produce a GvH response during ageing stems from inadequate activity of thymus hormone, resulting in a failure of maturation.

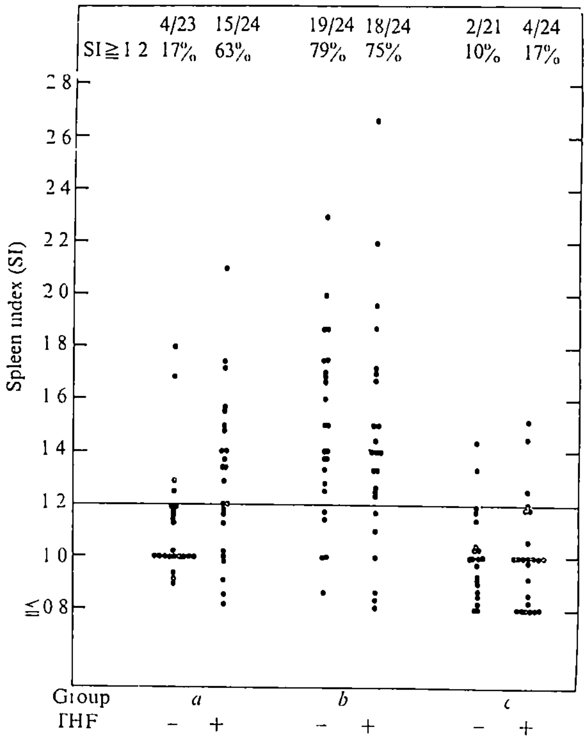

Fig 3 *In vitro* effect of THF on the ability of spleen cells of aged mice to elecit a GvH response. Index of newborn BALB/c spleens following incubation with 5×10^5 spleen cells from mice at different ages. Each point represents the results of one individual culture. Group *a*, 23–26 month old (C3H/eb×C57Bl)F$_1$ mice, *b*, 3 month old (C3H/eb×C57Bl)F$_1$ mice, *c*, 3 month old BALB/c mice.

In earlier studies[11,12] grafting of young thymus tissue into aged mice had no effect on the response. This may be due to the hormonal activity of the grafts being depressed by central control mechanisms[13] of the aged recipients.

We thank Professor Nathan Trainin for supplying the thymus humoral factor employed in this study. This work was supported by a grant from the Thyssen Foundation, Köln, Germany.

Immunological surveillance against altered self components by sensitised T lymphocytes in lymphocytic choriomeningitis

THE cytotoxic activity[1,2] of immune thymus-derived lymphocytes (T cells) for ^{51}Cr-labelled fibroblasts, or macrophages infected with lymphocytic choriomeningitis (LCM) virus is restricted by the H-2 gene complex[3 4] Specific lysis of LCM-infected monolayer cultures occurs only when targets and overlaying, sensitised T cells share at least one set of H-2 antigenic specificities

Operationally, this restriction may reflect one of two quite distinct mechanisms[1,2] First, H-2 compatibility is essential for sufficiently close association[3] between lymphocyte and target cell for lysis to occur This intimacy model implies either that the H-2 gene complex specifies a product, or products, involved in self-recognition, or that there is some mutual interaction between H-2 antigens Such a process would be additional to recognition of viral antigen by the T cell receptor The alternative possibility is that infection with LCM virus modifies self components in a way recognised only within a H-2 compatible system Altered self may be thought of as changes in H-2 antigens (or in structures coded for in the H-2 region) induced by the process of virus synthesis, or as some complex of viral and H-2 antigens

Lymphocytes from F_1 immune mice lyse virus-infected targets of parent H-2 type as effectively as do syngeneic T cells[1] If the intimacy model is correct, therefore, F_1 mice need possess only one clone of sensitised T cells, recognising viral antigen by a specific receptor and like H-2 antigen, of either parent type, in some non-immunological way (Fig 1) The altered self hypothesis, however, requires the presence of at least two clones of T cells, each reactive to modified H-2 of one parent type

These possibilities have been examined using the following experimental system When LCM-immune T cells are injected into immunosuppressed[5], virus-infected recipients they home equally well to lymphoid tissue of syngeneic or allogeneic hosts, but continue to multiply only in the syngeneic system[6] Further replication is apparently not triggered by free virus, but is dependent on thymus-derived lymphocytes being exposed to histocompatible, virus-infected target cells

Table 1 Cytotoxic activity of donor T cells in LCM-infected irradiated recipients*

Donor cells*	Recipient strain	H-2 type	% ^{51}Cr release† from L cells (H-2^{k}) Infected	Normal
Experiment 1				
Immune	CBA/H × BALB/c	k/d	51 2 ± 0 5	12 5 ± 1 9
	C57Bl × BALB/c	b/d	17 3 ± 0 1	13 9 ± 1 3
	BALB/c	d	16 1 ± 1 8	13 0 ± 1 3
Normal	BALB/c	d	14 4 ± 1 9	11 7 ± 1 1
Experiment 2				
Immune	CBA/H	k	83 7 ± 5 4	19 0 ± 1 4
	C57Bl	b	23 3 ± 1 3	19 1 ± 1 0
Normal	C57Bl	b	20 3 ± 1 2	18 5 ± 1 7

*Donor CBA/H × C57Bl F_1 were injected intracerebrally with 300 LD50 of WE3 LCM virus and killed when clinically affected 7 d later Recipients were irradiated (850 r) 24 h before i v injection of 10^6 LD50 of WE3 LCM virus, and inoculated i v with 5 0 × 10^7 spleen and lymph node cells 6 h later

†% ^{51}Cr release above normal values is a measure of activity of H-2 compatible sensitised T cells[1-4] Spleen cells from LCM-immune mice caused % ^{51}Cr release of 46 6± 0 9% from infected L cells and 15 2± 1 3% from normal L cells (experiment 1)

Table 2 Evidence that sensitised T cells are of donor origin

Donor	Recipient	Treatment	% ^{51}Cr release from L cells Infected	Normal
CBA/H × C57Bl F_1	AKR	Anti-θ+C	22 3 ± 1 2	21 4 ± 2 5
H-2$^{k/b}$, θC3H	H-2^{k}, θAKR	N ascitic+C	89 1 ± 1 8	23 3 ± 1 2

The protocol is the same as in Table 1, except that a proportion of lymphoid cells were treated[3] with AKR anti-θ (C3H) ascitic fluid and rabbit complement or normal AKR ascitic fluid and complement

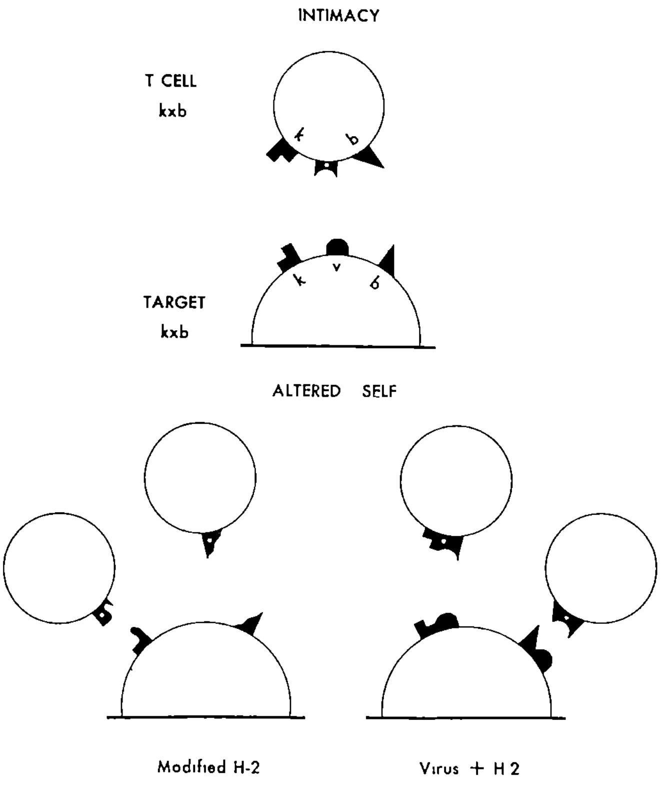

Fig 1 Capacity of sensitised F_1 (H-2$^{k/b}$) T cells to interact only with histocompatible virus-infected target cells may be considered to reflect any one of the models shown The intimacy concept proposes a single immunologicslly specific T cell receptor for viral (v) antigen, additional to a requirement for physiological interaction coded for by the H-2 gene complex (mutuality between either H-2^{k} or H-2^{b}) The two models proposed for altered self postulate that, in each case, there are at least two T cell populations with receptors of different immunological specificities recognising modified H-2, or virus +H-2 of either parent type

Continued proliferation of F_1 (H-2$^{k/b}$) immune spleen cells with capacity to lyse H-2^{k} LCM-infected monolayers occurs only in recipients with H-2^{k} antigenic specificities, and not in those possessing H-2^{d} (Table 1) These sensitised T cells are of donor origin, as lymphocytes recovered from H-2 compatible AKR recipients adoptively immunised with CBA/H × C57Bl spleen cells were shown to bear θ C3H (Table 2) The intimacy hypothesis, therefore, is probably not correct, as the postulated single clone of F_1 lymphocytes (Fig 1) should continue to proliferate equally well in recipients of either parent strain The results cannot, however, exclude this model totally, the reservation being that there may be alleleic exclusion in the F_1 of this hypothetical self-recognition product The simplest explanation of our results is, however, that there are sensitised T cells of at least two specificities in LCM-infected $H\text{-}2^{k/b}$ mice, each recognising a complex of virus + H-2 (or modified H-2) of one parent type Recirculating T cells may function essentially to survey the integtity of transplantation antigens, or structures coded for by the H-2 gene complex Recognition of cell surface changes due to virus infection, chemical modification[7] or genetic difference (alloantigens) may then be accommodated within the same model

We thank Professor G L Ada, Dr A J Cunningham, Dr R V Blanden and Andrew Hapel for discussion and particularly Dr L Pilarski for emphasising the possibility of a complex of virus-induced and H-2 antigen The anti-θ serum was a gift of Dr A J Cunningham

Immunodeficiency and runting syndrome in rats from congenital pyridoxine deficiency

CONGENITAL pyridoxine deficiency is teratogenic in the rat, producing digital defects, cleft palate, omphalocoele, micrognathia, exencephaly and hypoplasia of the spleen and thymus[1] Surviving offspring may develop convulsions[2-4], presumably because of a delay in the development of the γ-aminobutyrate shunt in the brain[5] Congenital pyridoxine deficiency also causes cleft palate in the mouse[6] I have now found that congenital pyridoxine deficiency has an adverse effect on the immunological function of surviving pups

I used six dietary groups one with congenital pyridoxine deficiency (group *a*) and five control groups (*b*–*f*) Virgin female Sprague–Dawley rats were placed with males in the evening The morning after mating, when copulatory plugs or sperm could be found, was counted as day 0 To obtain group *a*, we gave pregnant rats pyridoxine-deficient diet (Nutritional Biochemicals) with 0 1 mg ml^{-1} 4-deoxypyridoxine (4-D), an antagonist of pyridoxine in their drinking water from day 4, 5 or 6 to day 21 of gestation, when they were returned to a regular diet and tap water All these rats developed dermatitis and other clinical signs of pyridoxine deficiency which disappeared within a few days after resumption of the regular diet Convulsions were not observed among the newborn offspring, possibly because the dams were given the regular diet before delivery To obtain group *b*, I gave pregnant rats pyridoxine-deficient diet with antagonist in the water and supplemental pyridoxine (1 0 mg ml^{-1}) in the drinking water from day 5 to day 21 of gestation Group *c* received the regular diet and tap water throughout gestation Group *d* was given 8 g of the regular diet each day, which constituted a dietary restriction severe enough to limit maternal and foetal growth without causing anomalies in Sprague–Dawley rats[7] Group *e* was given 8 g per day of pyridoxine-deficient diet with antagonist and excess pyridoxine in the drinking water because of the possibility that a restricted intake of the deficient diet might lead to some deficiency other than pyridoxine Group *f* was given equal molar concentrations of antagonist and pyridoxine in the drinking water

Mean weights for the litters for the first 4 weeks of life are in Table 1 Rats in *d* and *e* were small at birth while those in all control groups grew rapidly for the first 4 weeks No control pup developed runting Rats in litter 1 of group *a* grew slowly A male rat in litter 1 and a male rat and three females in litter 2 developed a runting syndrome

Rats were weaned at 28 d of age, individually identified with ear tags and separated in cages according to sex Rats in group *a* which did not develop a runting syndrome grew vigorously and all rats in the five control groups grew vigorously Weights are shown in Table 2 for the second month of life for male rats in group *a* and group *c* Two females in litter 2 with the runting syndrome died between 32 and 39 d of age A third female runt in that litter was killed at 60 d of age when its weight was 43 g

As shown in the Tables, there was considerable variation from litter to litter with respect to the frequency of runting and the rate of growth In some litters all rats grew normally and there was no runting

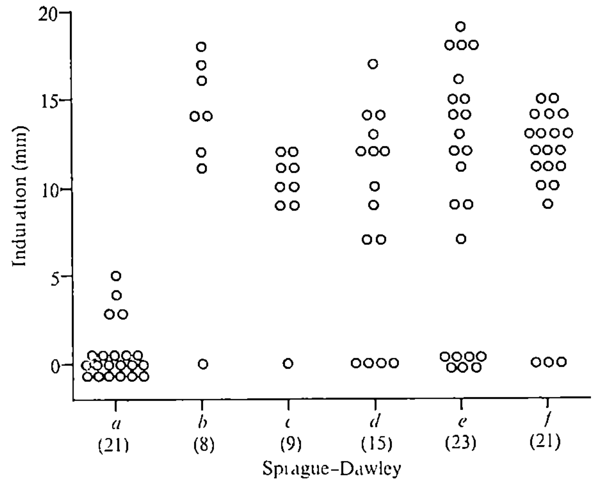

Fig 1 Results of tuberculin test at 8 weeks of age

I next bred 12 female Sprague–Dawley rats and gave them the diet for group *b* from day 5 to day 21 of gestation Two rats were not pregnant (17%) The average maternal weight gain was 155 g The 10 pregnant rats gave birth to 114 live and one dead offspring The average birth weight was 7 0 g No anomalies were recognised among the offspring, and none of them developed a runting syndrome All survived to 6 weeks of age when immunisations were begun

Thirty-eight rats were bred and given dietary treatment *a* from day 5 to day 21 of gestation Five rats were not pregnant (13%) Two pregnant rats died in late gestation, and two died on the day of delivery The average maternal weight gain was 20 g Of the 429 pups born, 207 died or were eaten on the first day Average birth weight was 4 8 g Ninety-four other pups died before 6 weeks of age, leaving 128 alive (30%) Eight of the survivors had developed a runting syndrome by 6 weeks of age Several rats with a runting syndrome were killed and examined histologically

There were severe atrophic changes in the thymus, spleen and lymph nodes

To examine the capacity for delayed hypersensitivity, healthy rats with no signs of runting syndrome in dietary groups *a–e* were immunised at 6 weeks of age with 0 05 ml of killed BCG bacilli 3 mg ml^{-1} in complete Freund's adjuvant Group *f* was immunised with 8 mg ml^{-1} *Mycobacterium tuberculosis* in heavy mineral oil Two weeks later animals were tested intradermally in a shaved flank with 250 tuberculin units of purified protein derivative (Connaught Laboratories) Diameter of induration was recorded 24 h later Results are shown in Fig 1 By median tests, the tuberculin reactions of the control groups did not differ significantly from each other and the skin test reactions of group *a* were significantly smaller than for the five control groups

I next investigated the effect of congenital pyridoxine deficiency on 25 Lewis rats in group *a* and 10 Lewis rats in group *c* Healthy non-runted rats of both sexes were immunised at 6 weeks of age with 0 05 ml killed *M tuberculosis* (8 mg ml^{-1} in heavy mineral oil) in one hind footpad and 0 05 ml complete Freund's adjuvant in the other hind footpad Tuberculin tests were done 2 weeks later The average diameter of induration for the 10 rats in group *c* was 7 3 mm and only one rat had no induration Fifteen of 25 rats in group *a* had no tuberculin reaction and the average diameter of the reaction was 2 2 mm The differences were statistically significant Work with Lewis rats was abandoned because of their low fertility

To study antibody responses, healthy male non-runted Sprague–Dawley rats in all six dietary groups were immunised intravenously with 10^8 sheep red blood cells at 6 weeks of age These animals had not been used in the tests for delayed hypersensitivity mentioned above Haemagglutination titres were determined at weekly intervals for 4 weeks on four rats in group *a* and 24 rats among the five control groups Four weeks after primary immunisation, all rats were given a second intravenous immunisation with

*A male runt weighed 37 g on day 32, 36 g on day 39, 33 g on day 46 and died on day 67
†A male runt weighed 36 g on day 44, the day of death

sheep red blood cells and haemagglutination titres were then determined at weekly intervals for 4 weeks Antibody responses in group *a* fell within the range of those of the control groups after both immunisations A similar result was obtained after primary and secondary intravenous immunisation with *Escherichia coli* of 4 male Sprague–Dawley rats of group *a* and 26 male rats of the five control groups Although the groups were small, the results were sufficient to show that congenital pyridoxine deficiency did not cause an obvious deficiency in primary or secondary antibody responses to these two antigens

At 8 weeks of age, when the congenitally pyridoxine-deficient rats exhibited a defect in delayed hypersensitivity, routine histological examination showed that the thymus, spleen and lymph nodes were in normal condition

These results demonstrate that congenital pyridoxine deficiency produces a defect in the capacity for expression of delayed hypersensitivity in 8-week-old rats The normal expression of delayed hypersensitivity in the five control groups excludes deficiency of other dietary factors or maternal protein-calorie malnutrition as causative factors How long the immunodeficiency persists remains to be determined

B-cell suppression of delayed hypersensitivity reactions

DURING certain normal immunisation schedules, suppressor cells are generated and act in suppressing the expression of delayed hypersensitivity reactions[1,2] The suppression is immunologically specific and is dependent on living cells We have suggested that the suppressor cells were B cells because they are depleted when 300 mg kg^{-1} cyclophosphamide (CY) is given 3 d before sensitisation[3–5]

The most direct method of determining, with greater certainty, which lymphocyte subpopulation is responsible for the suppression of the expression of delayed hypersensitivity reactions is by using cell separation techniques Antibody coated immunoabsorbent (plastic bead) columns were therefore used to separate T and B lymphocytes

We used the same *in vivo* models as previously described for the assay of suppressor cells[1] Briefly, Hartley strain guinea pigs, treated with 300 mg kg^{-1} CY intraperitoneally (LD$_{10-20}$) 3 d before immunisation with 1 μg ovalbumin (OA) in Freund's incomplete adjuvant (FIA) given subcutaneously in the footpads, served as cell recipients 8 d later They were then potentially susceptible to the effect of suppressor cells which they were lacking In other experiments normal recipients were used Thrice washed pooled spleen cells (3×10^8 viable as determined by 0 2% trypan blue exclusion) were obtained from animals sensitised with 1 μg OA in FIA subcutaneously 8 d previously These cells were injected intravenously into the CY treated recipients which were skin tested, 1 h later, by an intradermal injection of 100 μg OA into the shaved flank Skin test reactivity was assessed as described previously[6] Spleen cells from the same pool were passed down plastic bead (Degalan V26) columns which had been coated with specifically purified rabbit anti-guinea pig γ globulin (R/GPγ) The R/GPγ was prepared in rabbits, which were sensitised to purified ($(NH_4)_2SO_4$ precipitation followed by three passages through DEAE cellulose columns) guinea pig γ globulin (GPγ) in Freund's complete adjuvant It was purified by binding to and elution from GPγ coated cyanogen bromide-activated sepharose beads (Pharmacia) The method of Campbell and Grey was used to coat the plastic beads[7] A flow rate of 2–2 5 ml min^{-1} was used and approximately 2×10^9 spleen cells (viability 50–60%) were applied to each of the 30×1 5 cm columns There was a 12–20% recovery of cells from each column A direct immunofluorescent (IF) technique using either FITC labelled goat or R/GPγ (Nordic) was used to identify B cells The effluent cells were pooled and found to be depleted of 90–95% of the 27–36% of IF positive cells which were present in the original cell suspensions applied on to the columns Effluent cells did not stain with FITC-labelled goat anti-rabbit γ globulin which indicated that the cells were not coated with R/GPγ when they were passed through the columns Plastic bead columns coated with normal rabbit serum (NRS) were used in control experiments Since one-third of the 3×10^8 viable donor cells were IF-positive in the original suspensions, we transferred 2×10^8 viable effluent (B-cell depleted) cells into the CY treated recipient animals and assayed their ability to suppress the delayed hypersensitivity reactions

††$P < 0 001$ when compared to control animals and separated cell recipients using Student's *t* test

Table 1 shows that cells that were not passed through the columns suppressed reactions of the recipient CY-treated animals to a similar extent as previously described[1] When cells depleted of 90–95% of B cells (after passage through R/GPγ coated columns) were transferred into identically treated recipients, however, there was no suppression of the delayed-in-onset skin reactions (Table 1) The cells passed through NRS coated columns contained 26% B cells (compared to 28% in the original cell suspension) and suppressed delayed reactions of the CY-treated recipients to a similar degree as the unseparated cells (Table 1)

We had previously demonstrated that the passive transfer of spleen or PEC from animals sensitised to 1 μg OA in FIA 8 d earlier caused more intense and more indurated reactions in normal recipients when donors had been pretreated with CY 3 d before sensitisation, as compared to those reactions transferred from sensitised animals which had not received CY (ref 1) We therefore passively transferred spleen cells, which had been depleted of B cells (as above), into normal guinea pigs to determine whether they would also transfer the more intense and more indurated reactions Table 2 shows that 2×10^8 viable column-separated, B cell-depleted, spleen cells from animals sensitised with OA in FIA 8 d earlier caused more indurated reactions than the 3×10^8 viable unseparated spleen cells from the same cell pool We favour the interpretation that B cells are suppressing the expression of delayed hypersensitivity reactions because after removing B cells, the same number of transferred non-B cells were causing more indurated reactions in normal recipients but no longer suppressed the skin reactions in the CY-treated sensitised recipients

§2×10^8 viable, containing < 3% IF-positive cells

‖$P<0\ 001$ when compared to control animals and separated cell recipients using Student's *t* test

These experiments demonstrate that, after immunisation with OA in FIA, B cells or their product(s) suppress the expression of the delayed hypersensitivity reactions These reactions are undoubtedly T-cell functions because, in the absence of B cells, they are more indurated and more intense Other recent studies have also demonstrated B-cell suppression of T-cell functions[8–10] It should be mentioned that numerous published studies have demonstrated that T cells may amplify, as well as suppress, other T cell functions[11–14] It seems therefore that B cells, as well as T cells, are important in the homeostasis of T-cell functions

The mechanism of the suppression of T-cell functions by B suppressor cells remains unknown We, as well as others cited above, have been unable to implicate the antibody product of B cells in the mechanism of the suppression It could be that the suppressor cells in delayed hypersensitivity form a separate subpopulation of easily identifiable Ig-coated cells that is distinct from those which become antibody producers Effective methods for recovering pure B cell populations should help elucidate the mechanism(s) involved in this suppression

New method for extending the diffraction pattern from protein crystals and preventing their radiation damage

A CONSIDERABLE problem hampering the analysis of protein crystal structures has been the damage caused to the crystals by the X-ray beam Another limiting factor has been the resolution in the diffraction pattern To increase the useful life of a protein crystal in the X-ray beam[1], single crystal monochromators and low temperatures have been used We now report that styrene and other vinyl monomers can decrease the radiation damage of the crystal in the X-ray beam by a factor of as much as 10, and extend the diffraction pattern so that higher angle reflections can be measured

We used crystals of an intact IgG immunoglobulin molecule (DOB) whose crystal structure has been determined to a resolution of 6 Å (ref 2) These crystals are extremely sensitive to radiation, and intensities of even very low order reflections with d spacings greater than 8 Å decrease to 80% of the starting value in about 15 h of exposure The diffraction pattern does not show any meas-

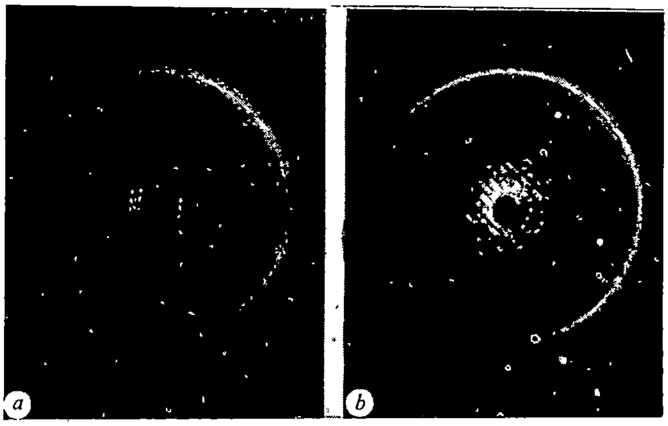

Fig 1 Diffraction pattern from (*a*) an untreated and (*b*) styrene-treated immunoglobulin crystal The precession angle is 15°, exposure time 45 h Both crystals were of comparable size The X-ray beam was parallel to the *b* axis

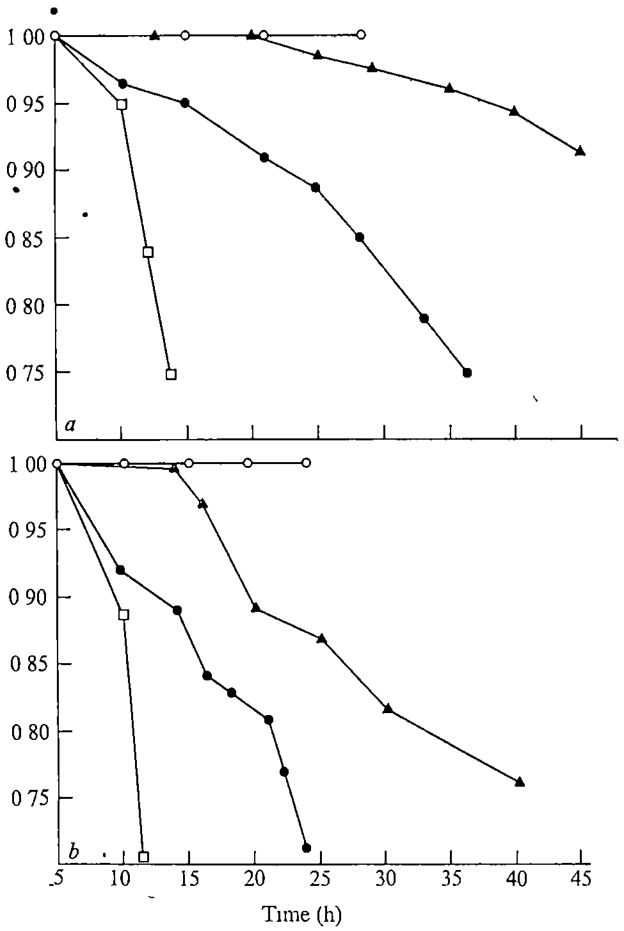

Fig 2 Variation of I_t/I_0 with exposure time for two reflections (0 8 0) (*a*) and (−12 0 6) (*b*) with the following styrene concentrations ●, control, ○, 2 0 mM, ▲, 1 2 mM, □, 30 mM These are styrene concentrations in the protein solution at the start of crystallisation The actual concentration of styrene inside the crystal lattice is unknown I_0 corresponds to the background corrected intensity at time=5 h A single crystal monochromator was used on the diffractometer and all measurements were carried out at room temperature

urable reflections beyond a resolution of about 5 5 Å (ref 3) (Fig 1*a*)

These crystals are usually grown at 4° C in 0 1M sodium borate buffer at *p*H 8 8 We have grown the same crystals in the presence of various amounts of concentrated styrene monomers added to the protein drop before it is set for crystallisation When irradiated, the treatment crystals continued to diffract even after 150 h in the X-ray beam showing sharp reflections that extend to a resolution of 4 Å (Fig 1*b*) Due to increased error involved in adding less than 0 5 μl of styrene directly to the protein drop, we also crystallised the immunoglobulin by adding different amounts of the buffer saturated with styrene

Figure 2 shows the variation in intensity with time of exposure of two arbitrarily chosen reflections from an untreated crystal and crystals treated with styrene Data were collected using a Nonius CAD4 automatic diffractometer Table 1 shows the intensities of a typical row of reflections with decreasing interplanar spacings from two control crystals of different dimensions and one treated crystal The intensities from the treated crystal were greater than those from the control cyrstal even when the latter had a volume 50% greater than the former This effect was particularly noticeable with the higher order reflections

We have diffused styrene monomers into pregrown immunoglobulin crystals by placing a drop of the concentrated styrene adjacent to the protein drop in a sealed well

Table 1 Intensity values for a typical row of reflections with decreasing of spacing

h k l	d(Å)	2 mM styrene treated (I_s)	No styrene control 1 (I_1)	No styrene control 2 (I_2)	I_s/I_1	I_s/I_2
9 1 0	20 3	9,287	2,931	6,299	3 1	1 5
11 1 0	16 8	11,054	3,335	7,183	3 3	1 5
13 1 0	14 3	3,819	1,355	2,226	2 8	1 7
15 1 0	12 4	6,497	1,935	3,406	3 3	1 9
17 1 0	10 9	190	0	0	∝	∝
19 1 0	9 8	291	18	141	16 0	2 0
23 1 0	8 1	280	82	142	3 4	2 0
25 1 0	7 5	375	0	223	∝	1 7
29 1 0	6 5	1,390	410	703	3 4	2 0
31 1 0	6 0	613	177	288	3 5	2 1
33 1 0	5 7	199	45	70	4 4	2 8
35 1 0	5 4	233	53	78	4 4	3 0
37 1 0	5 1	504	0	156	∝	3 2

The treated crystal had dimensions 0 8 × 0 5 × 0 15 mm The control crystal 1 had dimensions 0 7 × 0 5 × 0 15 mm, comparable with the size of the treated crystal The control crystal 2 was larger than the treated crystal and has dimensions 1 0 × 0 6 × 0 15 mm The increase in the ratio for the high order reflections suggests a lowering of the temperature factor for the treated crystal The zero intensities represent those reflections for which the peak to background ratio was less than one A single crystal monochromator was used on the diffractometer and all measurements were carried out at room temperature

Results similar to those described above were obtained, but the concentration of the styrene in the protein drop was not so well determined as in the cocrystallisation experiments We have also used monomers such as chlorostyrene, and methyl methacrylate with similar results We have not used any styrene-treated crystals for preparing isomorphous heavy atom derivatives

We propose to calculate a difference electron density map between the treated and the untreated crystal to locate regions of styrene binding in order to understand the actual mechanism of the protection provided by styrene We speculate that styrene monomers are trapped in the intermolecular volume of the crystal lattice and are polymerised by the X radiation The aromatic nucleus in styrene is a well known energy trap[4] and presumably scavenges the free radicals formed in the crystal, thereby reducing its radiation damage We also suggest that at low styrene concentrations, a polystyrene cage surrounds regions of the protein molecule limiting its movement, thus extending the diffraction pattern But with very large concentrations of styrene, the rapid polymerisation combined with the increased concentration of polymer presumably gives rise to large disordered regions in the protein molecule thus worsening the observed diffraction pattern

We thank Dr W D Terry of the National Cancer Institute for immunoglobulins This work was supported by grants from the American Cancer Society and the National Institute of Allergy and Infectious Diseases

Do immunologically privileged sites require a functioning spleen?

WHEN solid tissue allografts are transplanted orthotopically to alien hosts they are rejected with a characteristic tempo and vigour that depends primarily on the immunogenetic disparity between donor and host There are, however, several anatomical sites in which prolonged graft survivals have been documented These so-called immunologically privileged sites include the brain[1,2], anterior chamber (AC) of the eye[3–5], cheek pouch of the Syrian hamster[6] and artificially created skin pedicle flaps in guinea pigs and rats[7,8] There is considerable experimental evidence that these sites share at least one common feature—absence of a demonstrable lymphatic drainage[7–9] As a consequence, it has been assumed that the putative immunological privilege of these diverse sites results from the anatomical aberration which interrupts the afferent limb of the immunological reflex arc (which is composed of an afferent limb, a central mechanism and an efferent limb) We have now found that allogeneic cells placed within the AC of the eye are not isolated from the immunological apparatus of the host, but instead induce a primary immune response within the spleen which alters the systemic immunological response of the intact animal

To determine the status of a lymphatic drainage route from the AC, we used a local graft-*versus*-host lymph node assay Lymph node cells from Fischer rats specifically sensitised to tissue antigens of DA strain rats were inoculated into either the AC or the subconjunctival space (SCS) of (F×DA)F_1 recipients Eight days later (Table 1) hypertrophied cervical lymph nodes developed in response to SCS injections, whereas local lymphadenopathy did not follow AC injections of donor cells This provided strong circumstantial evidence that the AC lacks lymphatic drainage

Subconjunctival space	10	237 2	84 2	<0 005
Anterior chamber	22	88 0	89 4	>0 20

*Lymph nodes to be weighed were removed from (F × DA)F_1 hybrid hosts 8 d after the inoculation of 10 × 10^6 F anti-DA lymph node cells into the anterior chamber or subconjunctival space

†The weights of the superficial cervical lymph nodes, that is the submandibular and facial nodes are reported

Slit lamp microscopy showed that after being placed in the AC the inoculated cells disappeared within a few days by an unknown route These cells reached the systemic circulation and made a significant impact on the host's immunological apparatus, as our next series of experiments showed In the first, genetically tolerant (F×DA)F_1 lymphoid cells were inoculated into the AC of normal Fischer rats whose sera were regularly tested for haemagglutinating activity directed at DA alloantigens Surprisingly, anti-DA antibodies were indentified as soon as 4 d after inoculation and persisted for at least 10 d thereafter (Fig 1) In the second series of experiments, panels of Fischer animals were inoculated similarly with (F×DA)F_1 lymphocytes into the AC and challenged orthotopically with (F×DA)F_1 skin allografts 4, 7, 10 and 14 d later During the second week after inoculation the animals exhibited significantly prolonged survival of (F×DA)F_1 hybrid skin grafts (Fig 2) The median survival time (MST) of F_1 skin grafted 10 d after inoculation was 12 0 d, with some grafts surviving 14 d Since first set (F×DA)F_1 skin grafts were rejected by normal hosts with a MST of 9 1 d, the prolonged MST in the experimental group during the second week is highly significant It is interesting that F_1 skin grafts applied during the first week after inoculation had a MST similar to that of first set grafts The similarity of MSTs for first and second set skin allograft rejection in rats with an AgB histoincompatibility makes it very difficult to distinguish between the two Consequently, it is possible that during the first week after inoculation of F_1 lymphoid cells into the AC, some recipients were sensitised specifically without its being revealed by the gross test of graft rejection

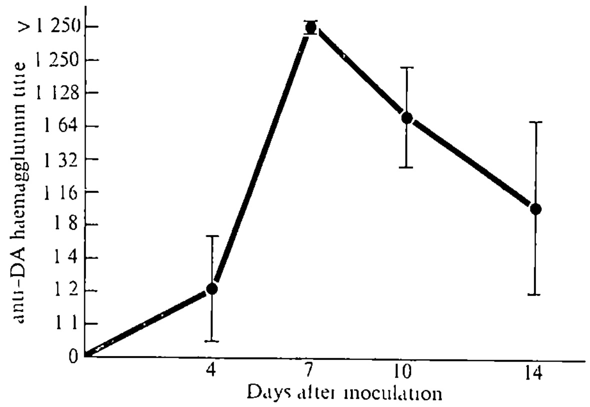

Fig 1 Anti-DA haemagglutinin antibody titres after the inoculation of 10 × 10^6 (F × DA)F_1 lymphoid cells into the AC of Fischer hosts ($n=6$) Bars represent one standard deviation

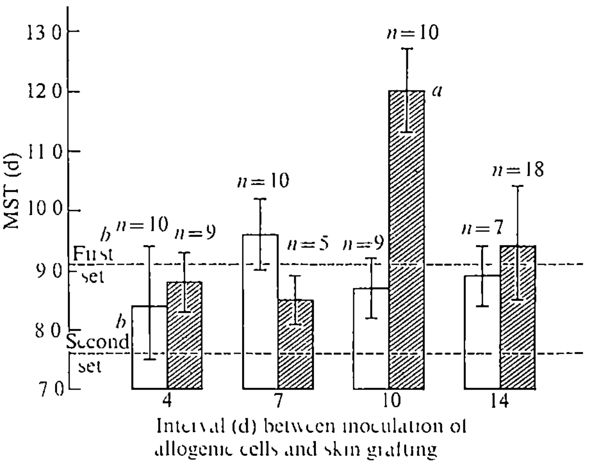

Fig 2 The comparative MSTs of (F × DA)F_1 hybrid skin grafted within the first 2 weeks after inoculation of 10 × 10^6 (F × DA)F_1 LNC into the AC (hatched columns) or subconjunctival space (open columns) of Fischer hosts The 95% confidence limits are represented *a*, The MST of F_1 skin allografts 10 d after inoculation of allogeneic lymphoid cells into the AC is statistically significant from a first set reaction, using Student's *t* test, with $P < 0.001$ *b*, MSTs of first and second set (F × DA)F_1 grafts in normal Fischer hosts are presented for comparison

By contrast, grafts of F_1 origin placed on Fischer hosts that had been inoculated subconjunctivally with (F×DA)F_1 lymphoid cells were rejected abruptly irrespective of the time between inoculation and graft application (Fig 2)

Only intravenous antigen presentation gave results similar to those obtained with injection into the AC (Fig 3)

Since the AC lacks lymphatic drainage, and since our data suggest that alloantigens on lymphocytes placed in the AC made an impact on the host's immunological apparatus, we suggest that donor lymphoid cells escaped from the AC directly into the blood vasculature of the host By virtue of its size and blood flow, the spleen receives the majority of antigen presented to an animal intravenously[10–12] Moreover, the spleen has been identified as a major source of enhancing antibodies[13] Consequently, it seemed reasonable to determine whether the facilitation of skin graft survival displayed by Fischer hosts during the second week after inoculation of (F×DA)F$_1$ cells, by the AC or intravenous routes, depended on an intact, functioning spleen Accordingly, Fischer hosts were splenectomised and after 28 d were inoculated, into the AC or intravenously, with (F×DA)F$_1$ lymphocytes Challenge with skin grafts of (F×DA)F$_1$ origin (Fig 3), revealed no evidence of enhancement or facilitation, in fact, the MST of these grafts (8 3 and 7 8 d respectively) approached the accelerated rejection usually found in specifically sensitised hosts (7 8 d) These data suggest that the spleen is an essential component of the immunological mechanism that temporarily subverts cell-mediated responses

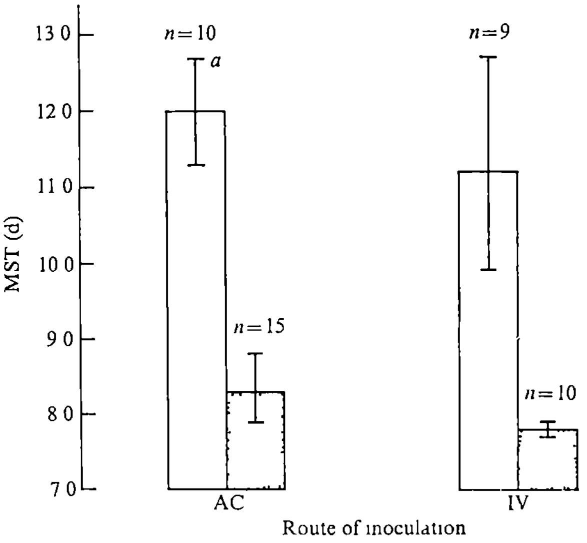

Fig 3 A comparison of the MSTs of (F×DA)F$_1$ hybrid skin grafts in normal (open columns) and splenectomised (dotted columns) Fischer hosts after the inoculation of 10×10^6 (F×DA)F$_1$ lymphoid cells into the AC, 10 d before grafting, or intravenously, 7 d before grafting The shortened survival time of allografts on splenectomised hosts, after both AC or intravenous injection of antigen, is highly significant compared with normal hosts ($P < 0 0005$) *a*, The 95% confidence limits are represented

Skin grafts placed within the AC exhibit survival patterns significantly different from orthotopically placed grafts, which cannot be attributed solely to a delay in host sensitisation[4,20] We propose that although all immunologically privileged sites appear to lack demonstrable lymphatic drainage routes[7–9 14], the critical feature for at least some of them is the ability to allow antigen direct access to the blood vasculature without first encountering a peripheral lymph node As a consequence, the host's initial antigen exposure occurs predominantly within the spleen and our results indicate that the microenvironment of this initial encounter significantly influences the nature of the subsequent immunological response Our data do not reveal which components of the spleen give it the special properties we have observed But, together with other results[15–19], they suggest that one immunological function of the spleen is to divert what would otherwise be essentially a cell-mediated and tissue destructive response into an antibody-mediated response which is often protective of the same target tissue It seems reasonable to speculate that the spleen achieves this conversion by deflecting potential effector T lymphocytes (killers) into cooperative interactions (helpers) with appropriate B cells An effective cell-mediated response is thus thwarted by (1) a temporary reduction in the number of circulating killer cells and (2) an enforced competition between the remaining killer cells and enhancing antibodies directed at the same target tissue

It is conceivable that this immunoregulatory role of the spleen in the induction of the immune response represents the evolutionary advantage of vertebrates in coping swiftly and successfully with certain kinds of hazardous microbial infections[21–24] By the same token, however, it may place the host at considerable disadvantage with regard to the capacity to control aberrant and neoplastic growth for which cell-mediated immune processes are crucial

We thank R E Billingham for helpful discussions and critical review, R Zeppa for support, and R G Holt for technical assistance This work was supported by a National Institutes of Health research grant and research training fellowship

reviews

Some corner of a foreign field

by R. V. Jones

H G J Moseley The Life and Letters of an English Physicist, 1887–1915 By J L Heilbron Pp viii+312 (University of California Berkeley, Los Angeles and London, June 1974) £7 50

"I BEG to apply for the Poynting Professorship of Physics I have been nominated for and hope to obtain a temporary commission in the regular army preferably in the Royal Engineers My services are not therefore likely to be available while the war lasts " So wrote H G J Moseley, then 26 years old, to the University of Birmingham on October 8, 1914 On August 10, 1915, he was killed in a desperate action against the Turks in Gallipoli

With a father and grandfather both Fellows of the Royal Society, with an Eton and Oxford education and a private income, Moseley was, as his American biographer shows, a very English physicist In his short life he had already accomplished one of the most brilliant pieces of experimental physics of this century, and he was a hero to the schoolboys of my generation who learnt, as E J Holmyard put it in his texbook of Chemistry (quoting Soddy), that Moseley had "called the roll" of the chemical elements and put them all in their place

Moseley's example was a comfort, too, to the undergraduates of my day, for he had taken only Second Class Honours in Physics Finals at Oxford At an Oxford Physical Society dinner in 1931 I was sitting next to our Professor, J S E Townsend, and asked him whether this was so, Townsend told me how indignant he had been that Moseley had been given a Second, and said that if he had known that Moseley was ill (from hay fever) he would have remonstrated with the examiners before the results were published

That was in 1910, after finals Moseley went to Manchester, where he had been attracted by the brilliance of Rutherford The latter put him on to determining the number of electrons emitted in the decay of radium, a task which he completed in April 1912 In that same month, Friedrich and Knipping, prompted by von Laue, discovered the diffraction of X rays, and the work was taken up in Leeds by the Braggs Barkla had already discovered that elements under election bombardment emitted two characteristic rays, one harder than the other, which he designated K and L, and Whiddington had found in 1911 that the velocity which cathode rays must have to excite K radiation in an element of atomic weight A is about $A\times10^8$ cm s^{-1} With the debate going on between the Braggs, von Laue and Barkla concerning the nature of X rays, Moseley became interested, and together with C G Darwin he started to experiment with them (But could he have used a mercury vapour pump in 1912? (page 73)—Gaede did not describe such a pump till 1915)

Moseley's skill with apparatus quickly resulted in his recognition of X-ray wavelengths as characteristics of atomic structure and, as he wrote to his mother in May 1913, "there is here a whole new branch of spectroscopy, which is sure to tell one much about the nature of an atom " He was soon recording the X-ray spectra of various elements, and by the following November he had found that the frequency of the K_α line is given by

$$\nu_{K\alpha}/\nu_0=(3/4)(Z-1)^2$$

where ν_0 is the Rydberg frequency already known from optical spectroscopy, and Z the atomic number, and he equated the atomic number with nuclear charge which he recognised as chemically more significant than atomic weight At that point he returned to the Electrical Laboratory in Oxford, where he completed the work on some 30 elements and was able to put all these elements in order, including some hotly disputed rare earths, simply by determining the atomic numbers from the K_α frequencies Moreover, he could show exactly where any gaps remained to be filled in the Periodic Table, and he could make sense of those few elements which, judged by their atomic weights, had seemed to be out of place

By 1914 Moseley was interested in the prospectively vacant chairs in Oxford and Birmingham, but war broke out just as he was about to land in Australia for the British Association meeting He made a rapid return to England with Henry Tizard after the meeting, both to volunteer for active service They left ship at San Francisco to cross America by rail, and ran to catch the Lusitania in New York, arriving in England on September 28 After a period of military training with the Royal Engineers (he had been in the OTC at Oxford) Moseley volunteered for the Royal Flying Corps, but his transfer was vetoed, and he was sent to Gallipoli

On the way out he made a will bequeathing all his interests to the Royal Society "to be applied to the furtherance of experimental research in Pathology, Physics, Physiology, Chemistry, or other branches of science but not in pure mathematics, astronomy, or any branch of science which aims merely at describing cataloguing or systematizing" This bequest formed the basis of the Moseley Studentship, whose second holder was P M S Blackett

Moseley had been one of the 15 or so King's Scholars elected to Eton in 1901 six of them "including all who were natural leaders in work or play" were killed in the war Moseley's death, recognised even in Germany for the loss it was to science, was more than any other event instrumental in our wiser use of scientific talent in the Second World War

The story of Moseley's life is admirably told by Professor Heilbron, who has been to great pains to gather Moseley's letters and to investigate many private papers of his contemporaries The letters are both piquant and poignant they give impish sidelights on figures such as Hugh Dalton, Harold Hartley, Julian Huxley, Lindemann, Rutherford, Tizard and Townsend, and show both the attractions and defects of Edwardian Oxford with its overpowering classical complacency As Professor Heilbron speculates in his epilogue, the development of physics at Oxford would probably have been different if Moseley had survived, for he would probably have been preferred over Lindemann, and he would have been more active in the laboratory and a Nobel prize winner

Though physics is no medium for nationalism, the sub-title of this volume is significant for more than the fact that in connection with Moseley it must recall the lines of *The Soldier* by his contemporary Rupert Brooke, who was also to die in the Gallipoli campaign For Moseley himself wrote to Rutherford "the French point of view [of physics] is essentially different from the English Where we try to find models or analogies, they are content with laws" But irrespective of whatever truth there may have been in this comment, physicists of all nationalities who are interested in the development of their subject owe Professor Heilbron a debt for his excellent biography And if this review seems to have been coloured by Moseley's own opinion that "reviews in *Nature* are usually such pure honey", in this case both the subject and his biographer deserve it

Evolution of populations

Genetical Structure of Populations By Kenneth Mather Pp viii + 197 (Chapman and Hall London, 1973) £4 00

Professor Mather's latest book is a survey of topics in population genetics, intended for advanced undergraduate and postgraduate students seeking a general orientation The subject is the way in which proportions of genetic types change from generation to generation in response to various factors, and the effect of these changes on the status of the population in relation to its environment The approach is quantitative but not mathematical, being directed to readers with biological education and interests The mathematical level varies considerably from chapter to chapter with more extensive algebraic treatment of traditional topics such as the Hardy-Weinberg law and its generalisations

After a short introduction the style of the work is established in the second chapter which reviews the causes of viariability in biology Professor Mather assumes that readers understand the basic facts of inheritance, and devotes himself to a detailed exposition of the way in which these affect population changes Although the results of algebraic analysis are stated, most proofs are omitted Later in the book, chapter 6 on "Life Cycles and Genetic Systems" is a mine of interesting information but contains no mathematical analysis at all Chapter 7 on "Genic Balance and Genetic Architecture" involves quantitative statements about the population effects of the manner in which the genetic system acts on numerical characteristics, but again contains no proofs

Chapters 3 and 4 ("Equilibria" and "Theory of Variability") reveal the strength and weakness of the attempt to discuss a quantitative subject while eschewing advanced mathematics In mathematical books on population genetics (among which Moran's *Statistical Processes of Evolutionary Theory*, published in 1962 remains unsurpassed despite many subsequent competitors) the problem of selection, random tendency to fixation, mutation, non-random mating and so on, are treated as separate topics In nature they are all acting simultaneously, one reinforcing or counteracting the effect of another Professor Mather makes this clear by detailed examples in a full and well balanced discussion This chapter leaves the reader with a profound respect for the author's deep knowledge of what is really going on in a natural population and a realisation of how much can be lost through oversimplification

Two points of substance are worthy of note It is clear towards the end that Mather believes that competition is always frequency dependent, and it must follow that much recent work in mathematical genetics is of little value since it assumes fixed selection coefficients He devotes several pages to a discussion of the concept of 'genetic load' which has been so hotly debated in recent years Mathematicians with an interest in genetics, who have been worried by their inability to see the point of all this, will be pleased that such a distinguished geneticist concludes "it is far from clear that the concept, as it has been defined and used, has much significance at all for the understanding of populations and their structure"

In discussing the theory of variability, Professor Mather applies a statistical analysis of variance to the variation in a numerical trait in a population He supposes, however, that it contains equal proportions of the alleles at one locus or at each of two loci, and obtains components of free, potential and utilised variability which can be transformed into one another as a result of various effects and which are "acted on" by the factors of selection These ideas clearly give insight into the heart of Mendelism, the fact that variability provides the basis for evolution They would explain it completely if, when the gene proportions are not equal, the transformation of components behaves qualitatively in the same way Now in the case of constant selection depending on two or more loci this is not true There may be several stable equilibria, each with its domain of attraction, and it is unlikely that the same analysis of the responses of components of variability to selective factors will hold in the neighbourhood of them all The analysis is therefore too restricted in its validity to be convincing The weaknes of this chapter and the previous one is the readiness with which it is assumed that the qualitative results of algebra applied to simple systems can be extended to complex systems for which results have not been obtained

This has led to wrong conclusions in the past, and the student should be warned against the practice rather than led into it It may well be that when it becomes possible to analyse fully realistic models, the results will prove to be on the lines described by Professor Mather on the basis of his wide knowledge, since factors neglected in (say) the multilocus constant selection model may then appear and eliminate superfluous stable equilibria It is also probable that a satisfactory mathematical analysis of these problems cannot be achieved through classical algebra and will require the application to genetics of topological considerations such as those introduced by Thom in biology

This is an admirable textbook for students, containing a masterly exposition of what is really important in our current knowledge of population genetics In order to go beyond it a student will need to study the mathematical side of the subject at a much higher level, and should be encouraged to regard at least some of the assertions as tentative until they have been proved

Philip Holgate

Reproduction of marine invertebrates

by R. P. Dales

Reproduction of Marine Invertebrates Vol 1 Acoelomate and Pseudocoelomate Metazons Edited by Arthur C Giese and John S Pearse Pp xi+546 (Academic New York and London, 1974) $38, £13 45

This useful and scholary work is the first of seven volumes The first six will give a systematic treatment with a chapter devoted to each class or phylum, the final volume will be devoted to general aspects of reproductive physiology This first volume is especially useful for its coverage of so many minor but interesting phyla such as Kinorhynchs and Gnathostomulids But all of the chapters are useful I found the amount of descriptive detail to have been well judged and the accounts of reproduction and embryonic development to be concise and informative The appearance of the series is timely for there has been much recent work on reproduction in invertebrate phyla

References are given in full at the end of each chapter and the volume as a whole is provided with separate indices to authors, subjects and taxonomic names The volume, containing many line figures and half-tones, is well produced No zoological library can afford to be without this series

Dangers of lead

by B. E. Clayton

Sub-Clinical Lead Poisoning By H A Waldron and D Stoffen Pp x+224 (Academic London and New York, May 1974) £5 50, \$14 25

THE authors define sub-clinical lead poisoning as the production of morbidity or mortality without the appearance of the classical signs or symptoms of lead poisoning This is a highly emotive subject and the authors are to be congratulated for dealing with it in a balanced and scientific manner They have provided an excellent review of the literature including that from eastern Europe, and over 1,000 references are given together with an author's index

The book is divided into six main sections lead in the environment, lead metabolism, pathological effects of lead, sub-clinical effects, diagnosis and lastly prophylaxis and treatment With such a controversial subject it is not surprising that I do not agree with all the statements made but the authors' main conclusion would be accepted by most workers They consider that more studies are required before it is possible to assess whether or not excessive exposure below that causing clinical lead poisoning is producing harmless physiological or psychological effects, especially in children

The book is well produced The list of references would have been even more valuable if titles of papers had been given An appendix listing quantities of lead in food and drink is included It is written clearly and workers from various disciplines would find it valuable I recommend it to all those concerned with this difficult environmental problem

Natural death

Biological Control By C B Huffaker Pp xix+511 (Plenum New York and London, 1974) \$11 75

IN recent years, increasing concern at the possible pollution of the environment by chemical pesticides has directed attention back to studies of non-chemical methods of pest control Before DDT and other efficient synthetic insecticides were brought into general use in the 1940s, control of pests by biological means, particularly by parasitic or predatory insects, had resulted in many successes Some of these, like the classical case of the Australian ladybird *Rodalia cardinalis*, which, in 1877, controlled the cottony cushion scale *Icerya purchasi*, have never been bettered, but there have been many other successes, some partial control, and some complete failures Nevertheless, as F J Simmonds has shown, the investment in research was so paltry, and the results in increased crops were so great, that the whole exercise, on a world scale, was extremely cost-effective The trouble was often that the individual who gained could not easily be implicated in the costs of the control Commercially produced chemical pesticides, on the other hand, could bring their financial rewards to industrial concerns

This paperback reprint of the proceedings of a conference, aims at making up to date information about biological and other methods of pest control available to a wider audience, and particularly to university students of entomology, agriculture and allied subjects If read critically, it should form a useful text

Nobody doubts that, particularly when improperly used, some agricultural chemicals can endanger wildlife the environment and even man himself We would all like to reduce the use of dangerous chemicals, and to use non-polluting methods of pest control But, unfortunately, some of the authors whose articles are reprinted here tend to overstate their case Thus the editor, C B Huffaker, says in his preface "employment of synthesised chemicals for insect pest control has posed an enormous and as yet unfathomed contribution to the degradation of our environment" This, and other similar statements, conceal the fact that over ninety per cent of pesticide usage throughout the world is effective, in that it achieves its object and no measurable damage can be demonstrated Yet we are clearly right to worry about potential dangers, and to try to find more effective controls

This book differs from previous texts on biological control in that although it describes once more all the well known successes, it includes a section on the ecological background to the subject and also devotes considerable space to 'integrated control' or what is now often called 'pest management' G C Varley and G R Gradwell deal with the fundamental basis in population ecology in their paper "The Use of Models and Life Tables in Assessing the Role of Natural Enemies" An understanding of these matters is obviously essential if biological control is to cease to be a hit and miss affair Unfortunately, these authors are still unable to demonstrate a single case where theoretical or mathematical studies have given any practical help to those engaged in practical control measures The inspired hunch has, on the other hand, often paid off It is to be hoped that this will not discourage others from these fundamental studies, which are necessary long-term—and which, it must be accepted, may never produce the desired results

The main lesson the book teaches is that put forward many years ago by the late W E Ripper that is that an "insecticide should be used like a rapier, not like a bludgeon" This is the essence of integrated control—natural enemies of pests should be encouraged but when they fail the correct chemical may be carefully used Also we are now learning that total pest eradiction is neither essential nor desirable Pests can often be 'managed' to prevent patent crop damage, and, at the same time, so as to ensure the survival of their natural enemies All these techniques will undoubtedly increase in importance, particularly if premature bans on allegedly dangerous chemicals continue to be introduced in some countries But the farmer, and even more the medical entomologist, will rely mainly on chemicals for many years to come It is right, however, that the disadvantages as well as the gains from chemical control should be recorded, though few writers can yet take a really objective view of the situation KENNETH MELLANBY

obituary

B. L. Astaurov

ACADEMICIAN BORIS L'VOVICH ASTAUROV, the eminent Soviet geneticist, died on June 21, 1974

Astaurov was born in 1904, and was educated at the University of Moscow, where he studied under S S Chetverikov, the founder of the Soviet school of experimental genetics Shortly after graduation, he began working on the heredity and genetics of silkworms, completing his first major work in 1937 A convinced anti-Lysenkoist, whose career suffered considerably during the years of Lysenkoism, Astaurov became a focus for the anti-Lysenkoist reaction His 60th birthday party became a celebration of the fall of Lysenkoism and Astaurov played a significant part in the rebirth of Soviet genetics He was elected President of the 'Vavilov' All-Union Society of Geneticists and Breeders in 1966

M. Reinhard

PROFESSOR MAX REINHARD, a leading authority on Feldspars, died on August 17, 1974 He was 92

After acting as an assistant to Professor Duparc at the University of Geneva, he was appointed to the Chair of Mineralogy and Petrology at the University of Basel in 1923 He became Rektor of the University in 1943 and retired in 1952 with the title Professor Emeritus

October 14–18, **Air Quality Management Systems,** Milan (Richard Tudway, International Institute for the Management of Technology, 59–63 Corso Magenta, Milan, Italy)

October 24, **Natural Products in Aquatic Environments,** London (Dr John F Gibson, The Chemical Society, Burlington House, London W1V 0BN)

Corrigendum

In the article "Exchange of neurotransmitter amino acid at nerve endings can stimulate high affinity uptake" by G Levi and M Raiteri (*Nature,* **250,** 735, 1974) the sentence at lines 21–22, p 737 should read Net uptake, which may or may not have a high affinity component

Errata

In the article "Interaction of coherent electromagnetic waves with relativistic electrons in a medium" by S Schneider and R Spitzer (*Nature,* **250,** 643, 1974) the following corrections should be made In equation (2) the factor $(\tau)\Theta(\gamma u\tau-\theta)$ should be replaced by $\theta(\tau)\theta(\gamma u\tau-\rho)$ The relationship $\varepsilon=n^2$, three lines above equation (2), should read $\varepsilon\neq n^2$

In the article "Nitrosoguanidine mutagenesis during nuclear and mitochondrial gene replication" by I W Dawes and B L A Carter (*Nature,* **250,** 709, 1974) Figs 1 and 4 were transposed The legends were given correctly

Investigating the paranormal

We publish this week a paper by Drs R. Targ and H. Puthoff (page 602) which is bound to create something of a stir in the scientific community. The claim is made that information can be transferred by some channel whose characteristics appear to fall "outside the range of known perceptual modalities". Or, more bluntly, some people can read thoughts or see things remotely.

Such a claim is, of course, bound to be greeted with a preconditioned reaction amongst many scientists. To some it simply confirms what they have always known or believed. To others it is beyond the laws of science and therefore necessarily unacceptable. But to a few—though perhaps to more than is realised—the questions are still unanswered, and any evidence of high quality is worth a critical examination.

The issue, then, is whether the evidence is of sufficient quality to be taken seriously. In trying to answer this, we have been fortunate in having the help of three independent referees who have done their utmost to see the paper as a potentially important scientific communication and not as a challenge to or confirmation of prejudices. We thank them for the considerable effort they have put in to helping us, and we also thank Dr Christopher Evans of the National Physical Laboratory whose continued advice on the subject is reflected in the content of this leading article.

A general indication of the referees' comments may be helpful to readers in reaching their own assessment of the paper. Of the three, one believed we should not publish, one did not feel strongly either way and the third was guardedly in favour of publication. We first summarise the arguments against the paper.

(1) There was agreement that the paper was weak in design and presentation, to the extent that details given as to the precise way in which the experiment was carried out were disconcertingly vague. The referees felt that insufficient account had been taken of the established methodology of experimental psychology and that in the form originally submitted the paper would be unlikely to be accepted for publication in a psychological journal on these grounds alone. Two referees also felt that the authors had not taken into account the lessons learnt in the past by parapsychologists researching this tricky and complicated area.

(2) The three referees were particularly critical of the method of target selection used, pointing out that the choice of a target by "opening a dictionary at random" is a naive, vague and unnecessarily controversial approach to randomisation. Parapsychologists have long rejected such methods of target selection and, as one referee put it, weaknesses of this kind reveal "a lack of skill in their experiments, which might have caused them to make some other mistake which is less evident from their writing".

(3) All the referees felt that the details given of various safeguards and precautions introduced against the possibility of conscious or unconscious fraud on the part of one or other of the subjects were "uncomfortably vague" (to use one phrase). This in itself might be sufficient to raise doubt that the experiments have demonstrated the existence of a new channel of communication which does not involve the use of the senses.

(4) Two of the referees felt that it was a pity that the paper, instead of concentrating in detail and with meticulous care on one particular approach to extra-sensory phenomena, produced a mixture of different experiments, using different subjects in unconnected circumstances and with only a tenuous overall theme. At the best these were more "a series of pilot studies … than a report of a completed experiment".

On their own these highly critical comments could be grounds for rejection of the paper, but it was felt that other points needed to be taken into account before a final decision could be made.

(1) Despite its shortcomings, the paper is presented as a scientific document by two qualified scientists, writing from a major research establishment apparently with the unqualified backing of the research institute itself.

(2) The authors have clearly attempted to investigate under laboratory conditions phenomena which, while highly implausible to many scientists, would nevertheless seem to be worthy of investigation even if, in the final analysis, negative findings are revealed. If scientists dispute and debate the reality of extra-sensory perception, then the subject is clearly a matter for scientific study and reportage.

(3) Very considerable advance publicity—it is fair to say not generated by the authors or their institute—has preceded the presentation of this report. As a result many scientists and very large numbers of non-scientists believe, as the result of anecdote and hearsay, that the Stanford Research Institute (SRI) was engaged in a major research programme into parapsychological matters and had even been the scene of a remarkable breakthrough in this field. The publication of this paper, with its muted claims, suggestions of a limited research programme and modest data, is, we believe, likely to put the whole matter in more reasonable perspective.

(4) The claims that have been made by, or on behalf of, one of the subjects, Mr Uri Geller, have been hailed publicly as indicating total acceptance by the SRI of allegedly sensational powers and may also perhaps now be seen in true perspective. It must be a matter of interest to scientists to note that, contrary to very widespread rumour, the paper does not present any evidence whatsoever for Geller's alleged abilities to bend metal rods by stroking them, influence magnets at a distance, make watches stop or start by some psychokinetic force and so on. The publication of the paper would be justified on the grounds of allowing scientists the opportunity to discriminate between the cautious, limited and still highly debatable experimental data, and extravagant rumour, fed in recent days by inaccurate attempts in some newspapers at precognition of the contents of the paper.

(5) Two of the referees also felt that the paper should be published because it would allow parapsychologists, and all other scientists interested in researching this arguable field, to gauge the quality of the Stanford research and assess how much it is contributing to parapsychology.

(6) *Nature,* although seen by some as one of the world's most respected journals cannot afford to live on respectability We believe that our readers expect us to be a home for the occasional 'high-risk' type of paper This is hardly to assert that we regularly fly in the face of referees' recommendations (we always consider the possibility of publishing, as in this case, a summary of their objections) It is to say that the unusual must now and then be allowed a toe-hold in the literature, sometimes to flourish, more often to be forgotten within a year or two

The critical comments above were sent to the authors who have modified their manuscript in response to them We have also corresponded informally with the authors on one or two issues such as whether the targets could have been forced by standard magical tricks, and are convinced that this is not the case As a result of these exchanges and the above considerations we have decided to publish in the belief that, however flawed the experimental procedure and however difficult the process of distilling the essence of a complex series of events into a scientific manuscript, it was on balance preferable to publish and maybe stimulate and advance the controversy rather than keep it out of circulation for a further period

Publishing in a scientific journal is not a process of receiving a seal of approval from the establishment, rather it is the serving of notice on the community that there is something worthy of their attention and scrutiny And this scrutiny is bound to take the form of a desire amongst some to repeat the experiments with even more caution To this end the *New Scientist* does a service by publishing this week the results of Dr Joe Hanlon's own investigations into a wide range of phenomena surrounding Mr Geller If the subject is to be investigated further—and no scientist is likely to accept more than that the SRI experiments provide a *prima facie* case for more investigations—the experimental technique will have to take account of Dr Hanlon's strictures, those of our own referees and those, doubtless, of others who will be looking for alternative explanations

Perhaps the most important issue raised by the circumstances surrounding the publication of this paper is whether science has yet developed the competence to confront claims of the paranormal Supposedly paranormal events frequently cannot be investigated in the calm, controlled and meticulous way that scientists are expected to work, and so there is always a danger that the investigator, swept up in the confusion that surrounds many experiments, abandons his initial intentions in order to go along with his subject's desires It may be that all experiments of this sort should be exactly prescribed beforehand by one group, done by another unassociated group and evaluated in terms of performance by the first group Only by increasing austerity of approach by scientists will there be any major progress in this field

For those in peril on the factory floor

In this article Peter J Smith argues that a greater commitment (in deed as well as word) to community science by the Scientific Establishment might help the world of science regain some of the public respect it has lost

THE question of who speaks, or should speak, on behalf of the scientific community has been debated on many occasions, most often without result On the face of it, such lack of resolution is hardly unexpected, for scientists and scientific institutions are not noted for their ready ability to achieve consensus Yet there is no doubt that they can put up a pretty collective front when they feel so moved The one famous occasion on which a near consensus was reached was when the scientific community saw itself put at risk financially by the Rothschild proposals Then individuals and institutions miraculously found a common cause of self-preservation

But when it comes to the defence of less privileged groups it is quite a different story, the voice of the British scientific community is seldom to be heard, whether taking a moral stance, exerting humanitarian pressure, supplying expertise or even simply providing information A good case in point is provided by a new *Socialist Worker* pamphlet entitled *Asbestos The Dust that Kills in the Name of Profit* As the title hints, the object of *Socialist Worker* is nothing less than the complete overthrow of the capitalist system, and one of the ways of achieving this aim, it seems, is to give strident publicity to defects in the capitalist-industrial system Fortunately, one can easily avoid a sharp turn to the left and still admit that what some British workers have been subjected to in the name of asbestos production is beyond the limit of acceptability in a humanitarian society

For what clearly emerges from the rhetoric of the pamphlet in question is a picture of men and women reacting in some bewilderment to the long-term ill effects of a technological activity The chief consequence is, of course, asbestosis—a killing disease acquired by breathing in asbestos fibres The bulk of the pamphlet is devoted to case histories of men to whom asbestosis has come as a shock after a decade or so in the industry But more instructively, there is also a short account of the fight for safety put up by a small group of the 7/162 Glasgow insulation workers' branch of the Transport and General Workers Union against the obstruction of the asbestos companies, the indifference of politicians, the weakness of the Factory Inspectorate, the silence of much of the press, the impotence of health authorities, the equivocal official stance of unions in general, and, last but not least, apathy among many of the asbestos workers themselves

And there is certainly something to fight about According to Patrick Kinnersly (*The Hazards of Work How to Fight Them,* Pluto Press, 1973), asbestosis is taking an increasing toll 64 are known to have died in 1965, 107 in 1970 and 113 in 1971 The number of new cases diagnosed rose from 82 in 1965 to 153 in 1970 Moreover, asbestosis is only one of the asbestos-induced diseases Lung cancer appears to require a smaller exposure to asbestos There is also another form of cancer known as mesothelioma which involves growths in the linings of the lungs and stomach Almost all mesotheliomas are caused by asbestos, but no one knows how many workers in Britain are killed by them, partly because they take so long to develop and partly because they are not always identified The TUC Centenary Institute of Occupational Health has suggested that, 30 years after first exposure, about one in 200 will be found to have died of mesothelioma, but Dr Irving J Selikoff of Mount Sinai Hospital in New York is apparently more pessimistic He has recently been quoted as saying that, for every 100,000 workers entering the asbestos industry under the safety standards obtaining in the United States as recently as 1971, he would expect 20,000 to die of lung cancer, 7,000 of mesothelioma and 7,000 of other cancers and asbestosis

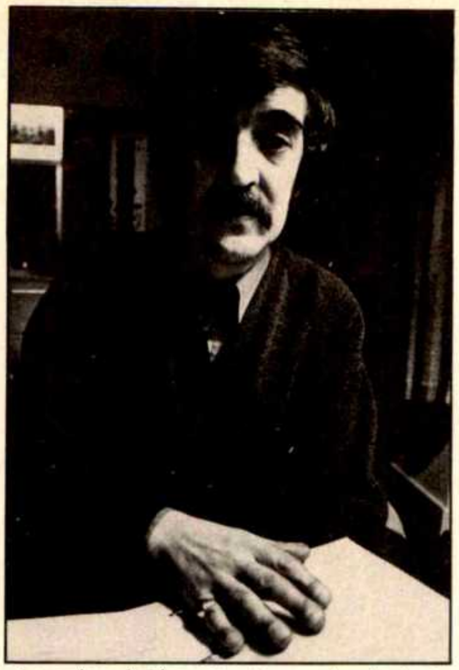
The point of drawing attention to the asbestos problem is not to elevate it into some sort of special case; any one of a hundred examples could just as easily be used for illustration. Nor is it to argue that the whole asbestos industry should be closed down forthwith. Such a course of action would be inconceivable in the face of the fact that asbestos currently finds some 3,000 uses in almost every sphere of material living (a testimony to its unique combination of fibrosity and imperviousness to heat). Asbestos products (and thousands of other equally or more dangerous substances) are here to stay.

But under what conditions are they to stay? And who is to influence those conditions? The most striking thing to emerge from the story of the asbestos workers of Glasgow and elsewhere is that no organisation remotely connected with the world of established science has played any part in it. The British Association has been silent. The Science and Natural Environment Research Councils have been silent. The Royal Institution has been silent. The University Grants Committee has been silent. The Association of University Teachers has been silent. In this and many other comparable cases a few individual scientists and science journalists have spoken and acted; but what has been completely lacking is the evidence of any sense of collective responsibility on behalf of the whole, or even a significant part, of the British scientific community.

It is true of course, that the Medical Research Council and the recipients of their grants are responsible for a great deal of basic biological and medical research into this and other industrial diseases; and my remarks should not be construed as criticism of that organisation, the individuals associated with it or the valuable work they do. The point I make is much more general—that even when the adverse side-effects of science and technology directly involve health (and they do not always do so), their mitigation requires much more than fundamental research into the nature of the disease itself.

Here, with particular reference to the asbestos case but with general applicability to many other situations, are some specific things which the scientific community could (and should) have done and could still do.

- Admit moral responsibility for taking a clear lead in seeing that the ill effects of science and technology are eliminated or at least mitigated. As Dr. Bernard Dixon (*What is Science for?*, Collins, 1973) has said: "When an unexpected, unforeseen calamity does happen, the scientist is more, not less or equally, responsible compared with others in doing all he can to fight against it". In practical terms, taking a moral lead would probably first mean overseeing the organisation of a suitable team to map out the full extent of the problem and identify gaps in existing knowledge. Between them, the organisations mentioned above encompass the elite (albeit often self-elected), if not most participants, of British science, and form a body with an almost infinite variety of expertise and an immense potential for influencing public and government opinion. That these powers are so often allowed to lie dormant is, to say the least, astonishing.



A worker displays symptoms of asbestosis

- Ensure that the outstanding questions and problems identified by the investigating team are followed through. In almost all cases it is probable that more research is needed, in which case the distinguished bodies of science should regard it as their duty to create the necessary political, financial and organisational climate in which such research can be carried out. Is monitoring equipment highly enough developed? Are safety levels adequate and are they formulated in the right way? To what extent is the general public, as well as factory workers, at risk? These and many other questions covering a variety of disciplines can be investigated but they require effort. Again, the principal scientific organisations have it in their power to encourage the mobilisation of scientists for this purpose. Will they use this influence?
- Exert pressure to ensure that the high principles so proudly proclaimed by the scientific community are actually put into effect. For example, it is quite plain that one of the greatest difficulties encountered by industrial workers and others exposed to risk is that of securing the scientific data (for example, from monitoring) from which a proper assessment risk may be made. Up to July of this year, Factory Inspectors divulging such information to employees or others without the employer's permission were actually subject to imprisonment. The Health and Safety at Work Act 1974 has mitigated these harsh conditions, although as the Trade Union Research Unit at Oxford has pointed out (*Health and Safety at Work Legislation: A Critical Study*, 1974), disclosure of information is still left largely to the Factory Inspector's discretion. It is difficult to understand how a community which puts such a high value on the freedom of scientific information can reasonably continue to allow the principle to be treated with contempt. Is there any respectable reason why human health should be less privileged in this respect than the activity of pure science? Of course, employers frequently attempt to justify their refusal to disclose vital information on the grounds of commercial secrecy—a ploy which is sometimes legitimate, sometimes not. The scientific community has a unique role to play here, for a group of independent scientific experts of integrity is the only body able to make a proper assessment of what is truly confidential and what is unreasonably claimed as such.

Why has the scientific community as a whole failed in this respect? The reason seems to be that, in the past, scientists have found it adequate to justify widespread public support of science on the grounds of the supposed cultural value of the activity and of its supposed role as the progenitor of technology. But what they have failed to grasp is that the first of these grounds was never very convincing to the wider world (at least as justification for a high level of public support) and that the second is rapidly losing its credibility.

In fact, science has a third role, which is neither "science for its own sake" nor science conceived as a means to a materialistic end. This is science for human welfare—call it "community science" if you like. It is practised in a few university departments; it is practised with great effect by, for example, the staff of the Greater London Council's Scientific Adviser. It is regarded as second rate by most university scientists, as a threat by industry, and with indifference by our major scientific institutions. But it is just possible that a greater commitment to it by the scientific community might go some way towards regaining for science the public respect (not to mention the public money) it has so patently lost in recent years. ☐

international news

Frameworks for energy in the US...

by Colin Norman, Washington

On the eve of its recess for the November elections, the US Congress approved what could turn out to be the most significant piece of energy-related legislation to reach the lawbooks since the oil crisis began to bite.

Minutes before President Ford appeared before a joint session of Congress to deliver his economic pep talk, a House-Senate Conference committee reached agreement on a bill which will abolish the Atomic Energy Commission and replace it with a Nuclear Regulatory Commission (NRC) and an independent Energy Research and Development Administration (ERDA). Two days later, the bill was sitting on Ford's desk awaiting his signature. Until last week, the bill had been making glacial passage through the Congressional mill, and there were fears that no agreement would be reached on the measure before the end of the session.

The importance of the legislation is that it consolidates energy research and development programmes which are now spread out over a host of federal departments and agencies into a single agency. Furthermore, it removes a long standing complaint that the Atomic Energy Commission suffers from a conflict of interest by both promoting and regulating nuclear energy, because it splits those functions into separate agencies. Furthermore, the bill considerably elevates the status of research programmes concerned with nuclear safety and the safeguarding of nuclear materials.

The bill, which was originally proposed by former President Nixon's Administration, sets up the NRC to take over virtually all of the regulatory functions that are now performed by the Atomic Energy Commission, but it also completely alters the present bureaucratic structure. The NRC will consist of three co-equal offices, each of which will report to a 5-member commission. The Office of Nuclear Reactor Regulation will be concerned with licensing nuclear reactors. The Office of Material Safety and Safeguards will license reprocessing facilities and facilities associated with transporting nuclear materials, and it will also make sure that nuclear materials are adequately safeguarded.

The third, the Office of Nuclear Regulatory Research, will perform backup research for evaluating licence applications to ensure that safety and safeguards criteria are met.

As for ERDA, it will take over virtually all the energy research and development activities performed by the federal government, using the laboratories of the Atomic Energy Commission as the base of its operations. It will be split into six divisions, each of which will be headed by an Assistant Administrator, concerned with fossil fuels; nuclear energy; environmental safety; conservation, solar, geothermal, and advanced energy systems; and nuclear security.

ERDA will carry out all the energy programmes related to Project Independence—the much vaunted drive to make the United States self-sufficient in energy supplies—and it will be armed with a huge budget, amounting at present to about $2,000 million a year. Nuclear energy will soak up nearly half of the ERDA funds, with the breeder reactor getting the biggest single slice. But it will also take over such programmes as the solar energy research effort which was recently launched by Congress (see *Nature*, 251, 368, 1974), as well as Congressionally inspired research and development programs concerned with geothermal energy and other longer-term energy options. □

... and in Holland

from Arie de Kool, Amsterdam

The Netherlands are going nuclear, but slowly, and with a maximum of government control. In fact, the government will increase its influence in the whole of the energy field considerably—if possible, together with other European countries, if not, alone.

Its proposals are set out in a long-awaited White Book on Energy. Several of these are concerned with getting the government a measure of control in the privately owned energy supply sector. As far as nuclear power is concerned, the government proposes to establish a monopoly for the exploitation of nuclear power stations and promises to undertake studies on overall nuclear safety within two years. It plans to build three 1,000 MW nuclear power stations, to be on stream by 1985 or when the establishment of the government nuclear monopoly and the safety studies permit.

The government also wants to negotiate a say in the managerial conditions of energy supply corporations, and by bringing the planning of all types of power stations under government responsibility, ensure that electrical power supply is discussed in parliament. To stimulate the use of coal for electricity generation the government will stipulate that all new power plants shall be fitted for oil and coal firing. The Dutch will also continue to participate in the German-Belgian-Dutch prototype sodium-cooled fast breeder reactor at Kalkar in Germany, although the government is strongly considering pulling out of the next phase, the construction of a 1,000 MW demonstration reactor.

Looking outwards, the government plans to take a 40% share in all natural gas and oil exploitations on the Dutch part of the continental shelf, with the condition that the government share in the profit may rise as high as 80% if conditions allow "without impeding the attractiveness to the oil companies". The Dutch government also plans to build up a "strategic reserve" of natural gas by stimulating exploration and exploitation of smaller fields in order to have the major source at Slochteren available in case of another oil crisis.

It is no secret, that the cabinet has been highly divided, especially over the use of nuclear energy. A couple of days before the White Book was officially released, it leaked out that the government proposed a considerable delay in the construction of nuclear power plants. This was the interpretation the 'progressive' members of the cabinet were giving (and were supposed to give) to the delay that is bound to result from the establishment of the government monopoly and the requirements of an overall safety report.

However, Dr Lubbers, Minister of Economic Affairs, maintained at a press conference, that the three plants should be ready by 1985. The safety reports might lead to a change in reactor type, a change of site, even to a postponement of the start of the first reactor, but not to the goal of 3,500 MW of nuclear energy in 1985.

Naturally, the opponents of nuclear energy are not very happy with the White Book. Some 10,000 people biked and bussed to Kalkar in protest, three days after the White Book was published. □

The chemistry of profits

from Nechemia Meyers, Rehovot

DETAILED plans are now being made for an investment of some £240 million in Israel's chemical industry. Roughly half this sum will be used to promote the exploitation of inorganic Negev chemicals, with the other half being used to expand the Haifa Bay complex of petrochemical firms.

The investment, enormous in Israeli terms, is a natural outcome of the chemical industry's growing success, both in supplying vital products to the home market and in the export sphere. Overseas sales of Israeli chemicals already account for 20% of her industrial exports (excluding diamonds), and there is no apparent limit to potential customers.

The 393-square-mile Dead Sea, most saline of the world's lakes, has long been the major focus of Israel's chemical industry in the 20th century. Plans for exploiting its potash and other mineral resources were drawn up in 1911 by Moshe Novomeysky (an immigrant from Siberia) and the first plant, run by Novomeysky, began operation in 1931. For many years, however, the Dead Sea Works were usually in the red, causing cynics to suggest that "the only thing that can sink in the Dead Sea is money".

It sinks no longer. On the contrary, Dead Sea potash, bromine and magnesium oxide—extracted from a 50-square-mile area of evaporation pans at the southern end of the saline lake whose waters initially contain only 1% (by weight) of potassium chloride—are today sold at a handsome profit to customers in Europe, Africa and the Far East.

Other Negev enterprises are also profitable, in large measure because of rising prices. Israel's phosphate mines—part of the Mediterranean phosphate belt that stretches from Morocco in the west to Jordan in the east and Turkey in the north—are a striking case in point.

In 1971 Government experts, dismayed by 20 years of losses, suggested that they be closed down. Fortunately they were not, and as a result profits are now rolling in to the State Treasury. Ironically, they largely reflect Arab Morocoo's successful exploitation of the world-wide fertiliser shortage to push up phosphate prices from $11 to $60 a ton in just one year.

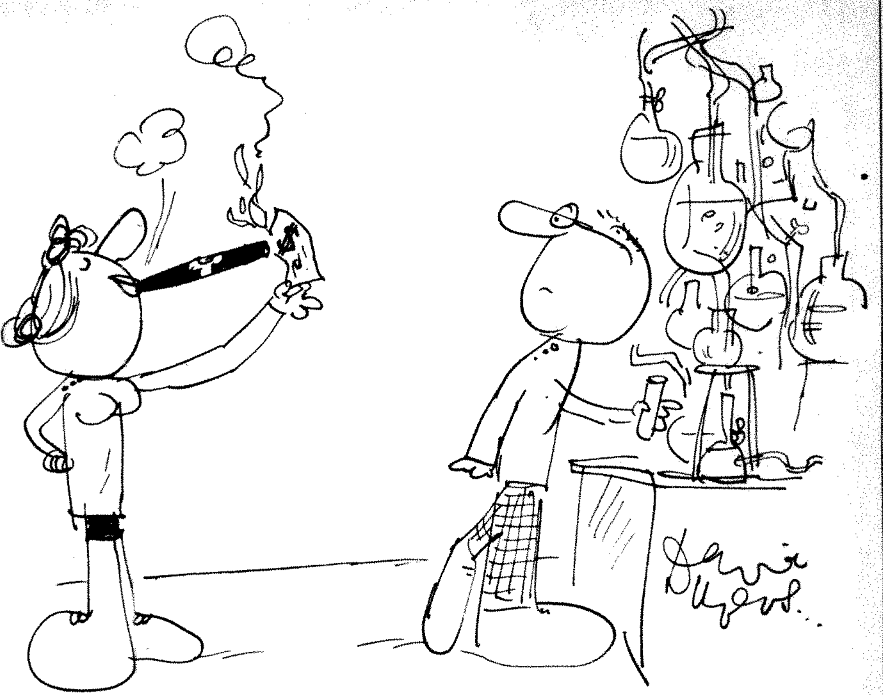
Copper prices are now lower than they were at their peak, but they are still high enough to ensure the profitability of the modern copper mines at Timna (which are very near the Chalcolithic ones). However, the copper-bearing strata that were worked in ancient times are not the same as those mined today. Formerly copper nodules associated with fossilised trees within the Middle White Sandstone were exploited. This layer appears near Timna about 330 feet above the copper-bearing Cambrian rocks that are now worked (by both underground and open-cast mining).

The only major failure in this sphere has been with a controversial plant, near the Judean Desert town of Arad, for the manufacture of phosphoric acid by means of hydrochloric acid produced from residual Dead Sea brines. An American firm whose fluidised refining process was used in the plant, the Madera Company, is being sued in an attempt to recover at least part of the £25 million loss, and alternative operating methods are now being studied.

When the current expansion plan is completed, potash production will rise from one million to 1.5 million tons a year, phosphate production from one million to 2.8 million tons a year and bromine production from 20,000 to 50,000 tons annually. Profits from the mining and processing of Negev chemicals, this year expected to total £15 million, will presumably also rise in at least the same measure.

The scheduled £240 million investment in the petrochemical industry will meet local needs for petrochemicals (including raw materials for plastics) and also give a boost to exports. Items whose production is to rise include polyethylene, styrene, polystyrene, phenolics and PVC. In addition, much larger quantities of potassium nitrate — a highly regarded, Israeli-developed chemical fertilizer—will be produced in the Haifa area.

While the cost of the oil used as a base for these petrochemical products has obviously risen steeply, Israel is no worse off in this respect than her competitors, and looks ahead to profits from petrochemicals in addition to those she is already earning from inorganic chemicals. □



WOMEN who graduated from American universities this year with a degree in chemistry or chemical engineering commanded higher salaries than their male counterparts, according to a study carried out by the American Chemical Society. It is the first time since the society began keeping track of such matters that women graduates have earned more than men.

The ACS survey showed that, on average, the starting salary for women chemists this year was 5% higher than that for men, whereas in 1964, newly graduated women chemists could expect to earn only 68% of the starting salary for men. While this seems to indicate that employers are attempting to recruit more women, the survey also turned up evidence that the battle for equal employment opportunities still has some way to go. For one thing, women and minority groups had a higher unemployment rate than the average for all ACS members. The overall rate of 1.4% was exceeded by American Indians (6.3%), Orientals (3.1%), Spanish surnamed and black chemists (1.5%), and women (3.5%). But at least that's an improvement on previous years, when the unemployment rate among women chemists was typically running at about three times that for men.

ICI puts money on genetic engineering

by Miranda Robertson

THE news that Britain's Imperial Chemical Industries Ltd (ICI) is to invest £40,000 over the next three years in research on genetic engineering initiated by University of Edinburgh biologists seems to bring the more optimistic speculations on the potential benefits of these controversial techniques a step closer to reality. One of the most widely cited possibilities has been the production of insulin from a mammalian gene inserted into a bacterial phage or plasmid. Yet projects aimed at this kind of application, including the Edinburgh-ICI collaboration, are still very much at the research, and short of the development, stage.

The outstanding problem takes the form of a fundamental question in molecular biology: will the synthetic machinery of a bacterium lend itself to the production of a protein specified by a mammalian (or any other eukaryotic) gene? Morrow and his colleagues in the United States have succeeded in demonstrating that bacteria can transcribe eukaryotic DNA into RNA (*Proc. natn. Acad. Sci.*, **71**, 1743; 1974); but whether they can achieve the next step—the translation of the RNA into protein—is still not known. Furthermore, this is much the trickier step of the two, for while the genetic code is universal, the software for translating it into protein is not. Optimists believe that the first eukaryotic protein will be emerging from bacterial cells within the next year or two. Equally distinguished sceptics foresee that the highly specific molecular recognition and control systems governing protein synthesis will present serious problems.

Dr Kenneth Murray, whose work with his wife Noreen on phage lambda (*Nature*, **251**, 476; 1974) led to the ICI project, suspects that bacteria can be made to translate mRNA specified by eukaryotic genes, though perhaps rather inefficiently. One way in which he can conceive of overcoming specificity problems is by reducing the inserted DNA to the bare structural gene, as free as possible from regulatory sequences that would be unrecognisable to a bacterial synthetic system.

That raises the further technical problem of accurate excision of single genes from the donor DNA. The current burst of genetic tailoring took off from the isolation in 1972 of the bacterial restriction enzyme *Eco*RI, whose peculiar properties make it particularly suitable for the cleavage and reconstitution of heterologous DNA. But the very property of specific cleavage that makes the enzyme so useful also makes it inflexible: it will only cut a molecule where it wants to, and not necessarily where you want it to. Consequently one of the first requirements will be a range of enzymes with different specific cleavage sites. Researchers at Edinburgh and elsewhere are already at work on the accumulation of such a versatile set of molecular scalpels, but no-one is yet ready even to think in concrete terms about operating on such exotica as insulin genes.

With the recent emphasis on the possible hazards of genetic engineering research, safety has become a prominent issue. In fact, the experiments on phage lambda fall outside the forbidden categories I and II of the US National Academy of Sciences' cautionary statement, into the more amorphous category of experiments which "should not be undertaken lightly". One of the principal points which Murray has stressed in connection with the phage lambda system is its relative intrinsic safety. It does not carry drug resistance factors and is therefore susceptible to control, and has only been used so far with strains of *E. coli* to be found in the human gut. If the system comes into use on a commercial scale, Dr Murray is willing to envisage the development of bacterial protein factories custom-built to be incapable of infecting a human host.

THE bacterial engineering argument so far has been given most prominence in the United States and Britain, and it is likely that these two countries will be the first to formulate a set of guidelines, either as legal constraints or as informal codes of practice.

But the problem is worldwide, and the International Association of Microbiological Societies has recently set up an *ad hoc* committee to advise it on the hazards inherent in recently developed techniques of genetic engineering.

This committee will not attempt to duplicate the activities of either Professor Paul Berg and his committee in the United States or Lord Ashby's Working Party in the United Kingdom, according to the chairman, Professor S. W. Glover of the University of Newcastle-upon-Tyne. Rather it hopes to evaluate any recommendations made by these committees or at the international meeting planned to take place in California next February, and if necessary, to arrive at a set of constraints or guidelines which it can recommend to the IAMS for worldwide communication through the network of national societies affiliated to the IAMS.

Apart from Professor Glover, the committee consists of Dr E. Wollman (France), Dr A. Demain (US) and Professor G. Terui (Japan).

In the meantime, precautions at Edinburgh include scrupulous sterilisation procedures. So far, the Murrays themselves have been the only people to have handled doctored phage particles. Not that they really believe that phage presents a serious threat to health; with the courage of their conviction, each Murray swallowed an experimental dose of 10^9 labelled phage—without either immediate ill effects, or traces of surviving organisms in the gut flora thereafter.

The injection of ICI funds will now, of course, make it possible to adapt a laboratory designed to contain pathogens, while at the same time the expansion of the project will mean the involvement of more personnel. Proper training of laboratory personnel will be emphasised since structural safeguards such as air-locks and protective hoods—both on the agenda—offer no protection from human carelessness.

The obvious advantage of an academic-industrial collaboration such as that between Edinburgh University and ICI is the pooling of intellectual resources not normally available to industry and practical resources not normally available to universities. There is one university department, however, which is uniquely placed from both points of view. The Department of Biochemistry at Imperial College London possesses a pilot plant for growing up to 60 kg of bacteria, as well as facilities for purifying large quantities of enzymes, and is now under the chairmanship of Professor Brian Hartley. Hartley and his collaborators have been working for the past few years on enzyme adaptations in bacteria (see for example *Nature*, **251**, 200; 1974). The most recent development in this work has been the use of genetic engineering techniques to transfer the genes specifying the enzymes between bacterial species. Hartley's plans for the biochemistry department include the recruitment of young molecular geneticists with a view to developing and exploiting these sophisticated techniques in the production of commercial quantities of enzymes tailor-made to the purposes of medicine and industry.

His approach differs from that of the Edinburgh team in a number of ways. For one thing, their project is based principally on the use of phage lambda as the vehicle for the transplanted genes, whereas Hartley's will involve both phage (where that seems advantageous) and bacterial plasmids. (This will bring the Imperial College project into NAS category I, so that out of respect for the moratorium it will have to be deferred, though probably not for long.) But there are also

Business report

by Roger Woodham

FACED with two proposals for dealing with their company's liquidity crisis, employees of George Kent Ltd have voted in favour of an arrangement with the Swiss company Brown Boveri which would give Kent more cash to the tune of £6 million but leave effective control of the company in the United Kingdom The name Kent on scientific instruments is well known in its own right in research laboratories, as is that of a company which it owns—Cambridge Scientific Instruments

The result of this exercise in industrial democracy flew in the face of Mr Anthony Benn, Secretary of State for Industry, who preferred an arrangement whereby George Kent would be taken over by GEC, Sir Arnold Weinstock's company But Mr Benn was also keen that Kent's employees should have a chance to make their views known and he now has to decide, in the light of the ballot, how to use the 24% of the Kent shares which the government owns when it comes to a vote among shareholders If he decides to go along with the Brown Boveri plan it seems almost certain to be the one that will win the day

Brown Boveri originally proposed that it should buy 53% of the Kent shares but it has now decided to be content with less than 50%, thus assuaging fears that control of George Kent would be lost to a foreign company It also envisages Kent's scientific and medical instruments business being set up as a separate company owned by the mooted Brown Boveri Kent Ltd, and this is where some Kent employees part company with the Brown Boveri plans The 600 employees of Cambridge Scientific Instruments voted in favour of the GEC plan to a man because they regard an independent instrument company as a doubtful starter because of its small size Over George Kent as a whole, however, 75% of the 7,300 employees said yes to Brown Boveri

This desire to run into the arms of of a Swiss-based multinational is almost certainly based on fears that 'rationalisation' after a takeover by GEC would threaten job security By contrast there is little overlap between the activities of Kent and Brown Boveri, and the latter sees Kent as a useful marketing base in the United Kingdom Indeed the prospect of access to France, Germany and Switzerland, where Brown Boveri sells some £780 million worth of equipment and where neither Kent nor GEC is particularly strong, is an added attraction from Kent's point of view

major differences in both methods and aims With his background in enzyme evolution and bacterial adaptation, Hartley expects to rely very much more heavily than the Murrays on the adaptive potential of the bacteria themselves This might be used, for example, to produce enzymes stable enough to survive long periods of storage at room temperature The first step would be to introduce the gene into *Bacillus stearothermophilus,* which thrives at high temperatures If an environment could then be devised in which the bacterium's survival would be greatly enhanced by the production of large quantities of the new enzyme, the bacterium would be under considerable selective pressure not only to make the enzyme, but to evolve a structure for it that would be stable at high temperatures

In a collaborative effort with the Microbial Research Establishment at Porton, Hartley has already achieved the purification to homogeneity of 20 enzymes from thermophilic bacteria, in quantities of 50 kg The facilities are to be moved to Imperial College in January 1975, and the intention is eventually to produce enzymes for sale to industry There is also the possibility of selling enzymes for research to other laboratories Imperial College has at its disposal a potential wealth of restriction enzymes in the vast range of organisms grown there for antibiotic research Isolation and purification of these enzymes will be an important part of the research programme

The problem of maximising bacterial production of a particular enzyme for either commercial or research purposes may be another case in which the answer lies in the versatility of the bacteria themselves In the case of phage lambda, there is a well known promotor system which it may be possible to commandeer This enzyme system, together with the product of another phage gene, can override the controls which normally serve to prevent or limit the transcription of a given gene Up to half the cell's synthetic capacity may in consequence be recruited to the production of a single type of protein molecule In bacteria, however, it may actually be possible to increase the number of genes from which transcription of a given mRNA taken place Hartley and his colleagues have recently demonstrated (*Nature,* **251,** 200, 1974) that bacteria often respond to metabolic demands for large quantities of a particular enzyme by duplication of the genes which code for it Again, of course, this technique would involve manipulation of the environment and not the bacterium

Hartley draws a categorical distinction between the prospect of getting bacteria to mass-produce enzymes to human specifications (science), and that of inducing them to make mammalian hormones such as insulin (science fiction) This is partly because of his own emphasis on bacterial evolutionary potential in the implementation of human designs While it may not be too difficult to devise environmental exigencies that would force a bacterium into an unnatural need for an *outré* enzyme, it is extremely difficult to imagine how one might provide it with an incentive to produce insulin—although with elaborate genetic manipulation it may be possible Hartley is not, however, among those who think translation will be a major problem, though he concedes it is the rate-limiting step But in view of the extensive use already made in industry of microbial enzymes, not to mention long-term plans for solving the global food problem with microbial proteins, bacterial enzyme production may prove quite enough to be getting on with □

Little Red greenery book

from our Soviet Correspondent

THE all-Union Botanical Society of the USSR has completed compilation of its "Red Book" of flora, listing some 20,000 forms in need of governmental protection, some 600 of which are in immediate danger of extinction

In commenting on the report, *Pravda* predictably pays prime attention to those species which provide "irreplaceable" raw material, such as the Siberian and Korean cedars, and the Caucasian ironwood, and notes that such valuable species as the waterfall poplar, Vavilov's almond, and the Kolyma currant are apparently, already, irretrievably lost

Nevertheless, the red book also includes plants which have so far found no economic use, including certain weeds "against which mankind has waged an agelong struggle" This would appear, at first glance, contrary to Soviet utilitarian theories, but, the commentator explains, the "dialectics of 'harm' and 'use' is in this case complicated and contradictory", and quotes the classic case of penicillin in order to justify the presence of the weeds □

Musical chairs on Capitol Hill

by Colin Norman, Washington

FOR six days early in October the US House of Representatives put on a display of squabbling and infighting which would almost have done justice to Gladstone's Parliament during the stormy days of Irish 'reform' One venerable Representative announced at one point that she would "fight to the death" to get her way, while another remarked that the House had lost its collective sanity In the end, however, there were no open fisticuffs on the floor, as there were in Gladstone's day, and the whole affair got scant attention from the general press But for science and technology, the titanic struggle on Capitol Hill holds some important implications

The basis of the squabbling was a bold attempt to reform the House's antiquated committee structure—not exactly a heart-stopping issue, which is probably why it did not grab too many headlines—and the outcome can best be described as a standoff between the reformers and those who were hoping to preserve the *status quo* But it will, at least, change the way in which the House handles a good deal of legislation involving research and development

In short, the committee on Science and Astronautics, which has never exactly been a giant on the Congressional landscape and whose influence has been shrinking recently along with the decline in the space programme, is set to pick up some important new responsibility

In addition to its present authority, which is essentially limited to the programmes of NASA, the National Science Foundation, the National Bureau of Standards and general science policy deliberations, the committee will pick up jurisdiction over all non-nuclear energy research and development, environmental research and development, civil aviation research and development and the Weather Service In line with its new roles, the committee also gets a new title—the Committee on Science and Technology

Certainly, it can be argued that the committee still cannot be called the focal point for scientific matters in the House since the really big spenders remain outside its jurisdictional patch Defence research and development stays under the jurisdiction of the Armed Services Committee, for example, the Commerce Committee retains control over biomedical research, and the Joint Committee on Atomic Energy has lost none of its authority over nuclear matters But the changes could turn out to be significant, particularly in regard to energy research and development

First, by way of background, some remarks are in order on the functions of Congressional committees and the need for reform

Committees in the House resemble a collection of mediaeval fiefdoms presided over by extremely powerful—and usually elderly—chairmen who have risen slowly through the ranks during their years of residence on Capitol Hill The so-called seniority system requires that committee chairmanships (and the chairmanships of subcommittees) go to the longest-serving—and not necessarily the most able—committee members who belong to the political party which holds the majority of House seats

Each committee has its own area of responsibility—thus, for example, the Armed Services Committee deals with legislation concerning programmes of the Department of Defense and the Agriculture Committee deals with agricultural legislation When a bill is introduced into the House, it is referred to the appropriate committee, which usually assigns it to one of its subcommittees Hearings are held on the bill, it usually gets amended or completely rewritten by the subcommittee before being passed on to the main committee, which can further amend it before it moves on to the full House for further amendment and final passage

The committee therefore represent the centres of power since they shape the legislation which reaches the floor Moreover, committee chairmen (and to some extent subcommittee chairmen) wield a tremendous amount of power over the system since they control the appointment of committee staff, who deal with the nuts and bolts of the committee work and frequently write the legislation themselves And, equally important, the chairmen can kill off legislation with which they disagree simply by keeping it bottled up in their committees, never allowing it to be brought to a vote on the floor of the House

One problem with the system is that it has been more than a quarter of a century since any serious attempt was made to alter committee jurisdictions, and areas of authority have consequently become considerably blurred Take energy research and development, for example The Committee on Science and Astronautics is deep into that subject since it has jurisdiction over the programmes of the National Science Foundation, but so is the Interior Committee, the Public Works Committee, the Commerce Committee and the Joint Committee on Atomic Energy The net result is that there has been considerable jurisdictional turf fighting between committee members for control of energy research legislation

Another effect of confused jurisdictions is that when a member of the Committee on Science and Astronautics, for example, writes a bill aimed at setting up a programme of, say, solar energy research, he shapes the legislation to give the programme to the National Science Foundation or NASA so that his committee gets jurisdiction over it The result is that programmes don't always get assigned to the most suitable agencies

Then there is the problem that Members of Congress often serve on several committees, which considerably dilutes their effectiveness

So, all-in-all, the House of Representatives is not a terribly efficient place, and that's why two years ago a special bipartisan committee, headed by Richard Bolling, a skilled legislator from Missouri, was appointed to recommend some reforms

Almost a year ago, the Bolling Committee came up with a batch of recommendations which immediately threw most of the committee chairmen into fits of apoplexy It suggested a fundamental realignment of committee jurisdictions, that members could only serve on one major committee, and that the powers of the Speaker should be elevated

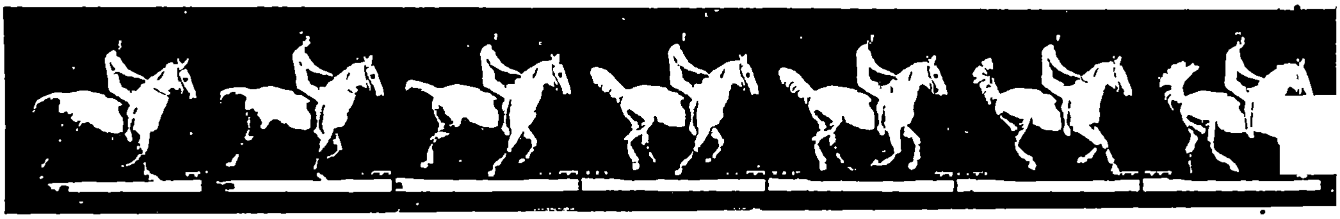
But by far the most controversial provisions it contained were the committee realignments

For a start, the Bolling proposals would have stripped one of the most powerful committees—the Ways and Means Committee—of many of its functions, it would have split the Education and Labour Committee in two, and it would have abolished the Post Office Committee, the Internal Security Committee, and—to all intents and purposes — the Merchant Marine Committee

Not surprisingly, a good number of committee chairmen who had reached the pinnacle of their political careers were not altogether happy about having their power suddenly stripped from them, and they persuaded the Democratic Caucus to appoint another committee to come up with some counter proposals

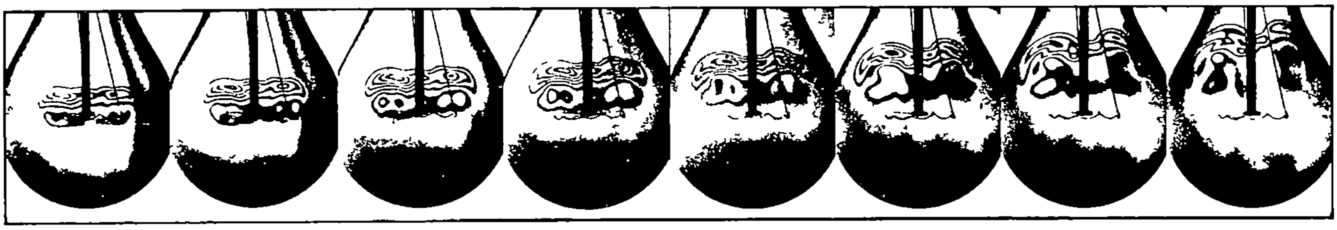
It was those recommendations which were adopted last week, with a few minor modifications, after six days of bitter debate which at times left the House leadership entirely confused

As far as science and technology are concerned, the Bolling Committee had recommended that the Committee on Science and Astronautics should be given authority over all energy research and development, including



Fast workers

EADWEARD MUYBRIDGE (he thought the Anglo Saxon version more striking than plain Edward Muggeridge) was a Victorian photographer who left Kingston-on-Thames in 1852 to sail for America There he was run over by a stage coach and tried for the murder of his wife's lover He was declared insane and acquitted after a former employee had testified "He was most eccentric in his work, he would not take a picture unless the view suited him " On the credit side, he made a stereoscopic record of the Modoc Indian war and toured Central America (as Edwardo Santiago Muybridge), later selling collections of 120 prints at 100 dollars the set, which was a close call to skinning the market at 1876 exchange rates More importantly, Muybridge made photographic studies of movement which laid the foundations of a completely new high speed photographic industry (not to mention a completely new movement in European art) In 1880 he became the first person to photograph movement (using "the famous zoopraxiscope camera") and resynthesise the movement on a screen A strip from this original sequence (above) was featured in an exhibition accompanying the eleventh international congress on high speed photography at Imperial College, London The same congress was marked by an exhibition of applied photography at the Royal Photographic Society, where the very latest achievements of the high speed photographic industry included the series reproduced below It shows the development of a convective flow in the gas filling of an electric bulb as the current through the filament is switched on The photographs are from eight three-dimensional holographic images reconstructed from a sequence of double exposure holograms recorded on a single plate with a pulsed ruby laser The pulse length was about 1 ms and the interval between pulses was 20 ms The pictures were produced by the National Physical Laboratory, with whose permission they are reproduced The Muybridge series appears by courtesy of the John Judkyn Memorial



nuclear energy But the powerful Joint Committee on Atomic Energy objected at such an intrusion on its patch, and the Science and Astronautics Committee eventually wound up with only non-nuclear energy research and development But that is a distinct improvement over the present arrangement in which authority is split over a number of committees, and it also means that the new Science and Technology Committee will get jurisdiction over the non-nuclear programmes of the umbrella Energy Research and Development Administration

The Bolling Committee had also recommended that the science committee be given "special oversight" over military R & D, which would have given it authority to make studies and recommendations on the Pentagon's programmes, but it wouldn't have had the power to write laws in that area But Edward Hebert, the 74-year-old chairman of the Armed Services Committee would have none of that, and his monopoly over the Defense Department programmes remains unbroken

Finally, the Bolling proposals would have given the Science and Astronautics Committee jurisdiction over virtually all the programmes of the National Oceanic and Atmospheric Administration

But Mrs Lenore Sullivan, Chairman of the Committee on Merchant Marine and Fisheries didn't relish the idea of her committee disappearing from under her, and the upshot is a grotesque split with some atmospheric programmes going to the new Science and Technology Committee, while oceanography stays with the Committee on Merchant Marine But at least it was agreed during the floor debate last week that the two committees will work together on oceanic and atmospheric matters

As for environmental research and development, both the Bolling Committee and the Democratic Caucus committee recommended that the new Science and Technology Committee would gain responsibility for that entire area, and so it will

The upshot, then, is that many science and technology matters in the House will now be consolidated into one committee, which should make for smoother operations in some areas But it should be pointed out that the seniority system has survived completely untouched, and nobody had the temerity to alter the workings of perhaps the most powerful committee of all—the House Appropriations Committee, which deliberates on the budgets of the executive departments and agencies

Bolling, at least, remains philosophical about the outcome of his attempts at reform "It is a good start", he said last week, and indicated that he will try again next session

Meanwhile, the Senate has for some time been making noises about taking a look at its own hopelessly confused committee structure, but so far has shown no signs of doing anything about it It is far from clear at this stage, for example, which committees will get jurisdiction over the Energy Research and Development Administration, and science affairs are strung out over a whole range of Senate committees

Since all bills must be approved by both the House and the Senate before they become law, the House reforms are clearly only half-way measures, no matter how good they are ☐

news and views

Fluctuations in climate

THROUGH most of the first part of this century it was widely taken for granted that climate is essentially constant, apart from short-term fluctuations, some of which might involve shadowy cyclic changes In fact, the global climate was at that time changing—a rather general warming and increasing moisture in continental interiors (apart from the Americas)—in ways that made life easier for most people in most places Hence, there was little investigation of the phenomenon Now, however, the decades of neglect have given place to widespread concern over climatic change This is partly because there is some evidence of a global cooling, and a change in the rainfall trends also, setting in from the 1950s onwards There is also a more pressing alarm over the many signs in recent years of an increased range of variability of climate from one year (or short group of years) to another The world population is already so large that there is no margin for even occasional bad years—bad, that is, in the sense of lowered harvest yields in several of the world's principal grain-producing areas Indeed, the world's grain reserves have been reduced each year since 1970 both 1972 and 1974 will rank as bad years in the sense just mentioned, but even in a good year, such as 1971, the reserves fell, and are now under a quarter of what they were before this decade

It was with facts such as these in mind that US Secretary of State Henry Kissinger told the United Nations General Assembly in April 1974

> "The poorest nations, already beset by man-made disasters, have been threatened by a natural one the possibility of climatic changes in the monsoon belt and perhaps throughout the world The implications for global food and population policies are ominous The United States proposes that the International Council of Scientific Unions and the World Meteorological Organisation urgently investigate this problem "

And, in similar vein, Lord Rothschild wrote recently

> " there are several subjects in which I regret that the Think Tank has not so far taken an interest one of these is the effect of the possible changes in our climate on the life of the inhabitants of this island It would, I believe, repay study "

Also, the Climatic Research Unit at the University of East Anglia in Norwich, of which I am director, whose financial plight over the first $2\frac{1}{2}$ years of its existence has several times been mentioned in *Nature*, now has the funds needed to start its work—thanks to the generosity of the Wolfson and Nuffield Foundations in this country and the Rockefeller Foundation in the United States

This issue of *Nature* carries three more in the series of contributions to knowledge on the variations and variability of climate which it has been publishing in recent years Drs Wood and Lovett report on page 594 on the rainfall variations measured in Ethiopia over the last 70 years, and the records of major drought years since AD 1540, analysed in relation to the 11-year sunspot cycles Their result highlights the great range of variation of the annual rainfall in that country within each 10 or 11-year period as likely to have more impact than the longer-term trends, though possibly made more serious by these On page 592 Brown reports a new link between variations in the Earth's magnetic field at the time of sunspot minimum and the strength of the subsequent sunspot maximum, together with the climatic evidence such as that presented by Wood and Lovett this raises the possibility of the use of the Earth's magnetic field to forecast changing weather patterns five or six years ahead

The third contribution, on page 582, is concerned with what can be learnt of the longer record of climatic behaviour from tree rings, in this case the year-rings in spruce (*Picea*) growing in southern Germany Dr Schiegl uses deuterium measurements on the tree rings to show how an indication of a long history of annual mean temperature might be derived This technique is one example of a rapidly increasing number of types and uses of 'proxy' data to extend and corroborate the climatic record for periods before the invention of most meteorological instruments

H H LAMB

Mass extinctions in the fossil record

THE problem of what caused the extinction of particular groups of fossils continues to intrigue both palaeontologist and layman Every schoolboy learns about the dramatic and relatively sudden extinction of the dinosaurs at the end of the Mesozoic Era, and many are the more or less ingenious hypotheses put forward to account for it My own favourite relates the extinction to the relative decline of the gymnosperms or naked seed plants in favour of the flowering plants during the Cretaceous period The surviving conifer and cycad representatives include many producing oils with renowned purgative properties, from which one is drawn ineluctably to the conclusion that the poor dinosaurs died of constipation[1] The trouble with all such hypotheses is their *ad hoc* character, devoted specifically to the dinosaurs Viewed in a broader context, the dinosaurs are seen as but one of a whole series of animal groups, both terrestrial and marine, which died out at the end of the Cretaceous about 65 million years ago An even more spectacular phase of mass extinction, affecting a majority of invertebrate and vertebrate classes both on land and in the sea, took place towards or at the end of the Permian some 160 million years earlier It is no coincidence that the three faunally defined eras of Phanerozoic time, the Palaeozoic, Mesozoic and Cainozoic, are divided by these two so-called crises in the history of life

Attempts to account for these, and lesser, phases of mass extinction can be grouped into two broad categories, involving phenomena either extrinsic or intrinsic to our planet The extraterrestrial explanations have usually centred around the deleterious effect of high levels of cosmic radiation, leading to widespread destruction of organisms, either directly or by damaging genes and thereby preventing successful reproduction Some have argued for episodic pulses of increased radiation compared with that operating at present, for which there is no independent evidence, others have postulated that at times when the geomagnetic field was reversing the 'magnetic protection' of the Earth diminished for period of perhaps as much as a few thousand years, allowing more radiation to penetrate to the surface of the continents and oceans Explanations such as these have fallen out of favour in the last few years for a variety of reasons For example, they have not been able to explain why marine organisms have been affected at the era boundaries more than terrestrial ones, especially plants Furthermore, in the ocean the intensity of radiation diminishes to a small fraction of its atmospheric value only a few metres below the surface

Attention has now turned to intrinsic factors Following the pioneer work of Valentine and Moores (*J Geol*, **80,** 167, 1972) who were the first to seek an explanation for the Permian extinctions by bringing together concepts derived from plate tectonics and modern ecological theory, attempts adopting a similar approach have been made recently to account for the 'crises' at the close of the Mesozoic and Palaeozoic

Hays and Pitman (*Nature,* **246,** 18, 1973) have speculated along the following lines In the late Cretaceous there was a huge marine transgression over as much as a third of the continents, when sea level was raised hundreds of metres as a result of uplift of the mid-oceanic ridges This was a consequence of an acceleration in the rate of seafloor spreading for which there is apparently good independent evidence The transgression was instrumental in inducing a more stable, equable world climate, which led to significant diversification of many animal groups including the dinosaurs and, in the marine realm, reef corals, rudistid bivalves and planktonic foraminifera Highly diverse, stenotopic organisms in stable environments are vulnerable, however, to even slight environmental change The pronounced marine regression at the end of the Cretaceous, related by Hays and Pitman to deceleration of seafloor spreading rates, induced an episode of increased thermal gradients, seasonal temperature contrasts and storminess, together with a significant change in oceanic circulation patterns This sudden decrease in environmental stability was sufficient to cause widespread extinction, affecting the groups cited above and many others The dinosaurs' unsatisfied need was not so much for laxatives as for winter woollies[1]

A significant relationship between the late Permian extinctions and fall of sea level is also inferred by Schopf (*J Geol*, **82,** 129, 1974) His survey disclosed that the number or marine invertebrate families halved from the beginning to the end of the period while at the same time the area of shallow epicontinental seas diminished by rather more than half The lowering of sea level was probably a consequence of the creation of the supercontinent Pangaea as separate continents collided When this happened the seafloor spreading rate diminished as a 'brake' was inevitably applied to plate movement There is no satisfactory explanation of why sea level began to rise again in the early Triassic, although Pangaea did not begin to disintegrate, with the creation of a new spreading axis between Africa and North America, until the early Jurassic In the earlier hypothesis of Valentine and Moores, the extensive late Permian extinctions were attributed partly to increased interfaunal competition as formerly isolated continental shelves were joined together, and partly to a reduction in environmental stability consequent upon the creation of one large continent from several smaller ones (thus, seasonal climatic contrasts would have increased) Schopf draws attention to another factor

Ecologists recognise an exponential relationship between species number and area of the habitat occupied Modern theory has it that animal populations in a given region are in a condition of dynamic equilibrium, with rate of immigration being balanced by rate of extinction The theory has been applied with great success to oceanic islands, which form an excellent laboratory for ecologists Small islands cannot be held to possess 'impoverished' faunas, as formerly thought, they can only support small populations and consequently extinction rates are higher It is a big jump from species abundance in tiny islands to familial abundance in seas bordering whole continents, with rate of immigration being replaced by rate of origination through evolution, but Schopf is prepared to take this bold step He can at least claim the support of a leading researcher in the new ecology (D Simberloff, *J Geol*, **82,** 267, 1974), who has erected a model for the Permian diversity reductions and extinctions based on reasonable biological assumptions, which shows a good accord with Schopf's data Thus merely reducing the area of the Permian shelf seas might be sufficient in itself to explain the increased rate of extinction, reaching a maximum at the end of the period

An attractive feature of the two hypotheses outlined above is that they account for changes in organisms inhabiting a wide variety of habitats in a way which is consistent with modern ecological theory, and provide a satisfying correlation with independently deduced geological events of great significance In both cases the fundamental control on the extinctions is likely to have been variation in heat flow from the mantle, affecting the density, volume and spreading rates of oceanic ridge systems Though many important questions remain unanswered, an explanation along these lines is much less of a *Deus ex machina* than that involving variations in cosmic radiation

A HALLAM

Neural hypothesis of muscular dystrophy is flourishing

MANY workers in the field of neuromuscular diseases will feel that there is more evidence in favour of the neural hypothesis of muscular dystrophy than Professor Bradley's article[1] would imply Although it is true that Harris and Marshall[2] did not find evidence of functional denervation in dystrophic mouse muscle, the earlier and contrary observations of McComas and Mrozek[3] have now been confirmed by Law and Atwood[4] Fibrillation potentials, usually regarded as a sign of denervation, are also a feature of murine dystrophy[5] Possible ultrastructural correlates of synaptic dysfunction have been found in the axon terminals of dystrophic mice in studies from two laboratories[6,7] Even if Harris and Marshall were correct, these authors demonstrated nonetheless that the neuromuscular junctions of dystrophic mice were unusually susceptible to adverse conditions within the experimental milieu

Dr Salafsky[8] was one of the first to transplant minced muscle between normal and dystrophic mice and, by controlled experiments encouraging reinnervation of the transplants, was able to study their contractile properties The explanation offered by Dr Bradley is insufficient to account for all his findings Of those muscle transplantation studies in which care was taken to permit reinnervation, two[9,10] have largely confirmed Salafsky's work and one[11] has not

In the cases of human Duchenne dystrophy the evidence is mixed Fibrillation potentials certainly occur[12] and the work of Desmedt and Borenstein[13] is cited as indicative that denervated muscle fibres become reinnervated In contrast, a careful electron-microscopical study by Dr Andrew Engel and his associates[14] has not yielded any evidence of structural abnormality in the motor axon terminals This result, and the finding of normal numbers of motoneurones at autopsy[15], does not contradict the neural hypothesis as originally proposed[16] Indeed, recent studies with A Upton and P Jorgensen, as yet unpublished, strongly suggest that it is possible for motoneurones to have 'silent' synapses In patients with unequivocally neuropathic disorders it now seems that neuromuscular junctions may become inexcitable but still capable of transmitting a neurotrophic influence to the muscle fibres If this interpretation is correct, it is not difficult to conceive of more severe dysfunction in which the synapses, although present, can no longer subserve a trophic action

So far as the motor unit counting results are concerned, the necessary electrophysiological technique was first applied by McComas, Sica and Currie[17] to the extensor digitorum brevis (EDB) muscle The choice of muscle was subsequently criticised on the grounds that the motor nerve was vulnerable to trauma, particularly in disabled patients such as those with dystrophy[18,19] This criticism would seem unfounded if the recent reports[20,21] of normal numbers of motor units in Duchenne dystrophy are correct Our own solution to the problem of trauma was to study patients with very early stages of the disease and to extend the technique to muscles other than EDB These last results[22] are in keeping with the earlier ones Since the full papers by Panayiotopoulos *et al*[23] and by Ballantyne and Hansen[24] have yet to appear, it is difficult to be certain that these workers have achieved the refinements of the counting technique reported by Bradley Scarpalezos and Panayiotopoulos[20] in their brief description claim to be able to detect very small muscle responses "overlapping at noise level" on single, rather than superimposed, oscilloscope sweeps Not only is this feat a logical impossibility, but the value of the superimposition technique (employed by ourselves) in detecting very small evoked biological signals has been accepted ever since the pioneering experiments of Dawson[25] As practised by our own group, the motor unit counting technique has proved itself as a sensitive and reliable means of detecting neuropathic disorders and it is gratifying that Ballantyne and Hansen[24] have obtained almost identical values for healthy subjects It is important to add that the technique has recently been employed in a 'blind' study of 17 possible cases of malignant hyperthermia (unpublished work with B A Britt and W Kalow) and has so far been completely accurate in predicting the status of the subjects

I feel that the most direct evidence against a neural aetiology of dystophy is the parabiotic cross-innervation experiment of Douglas and Cosmos[26] in mice The strongest evidence against a myopathic aetiology (though not necessarily for a neural one) is the exceedingly elegant chimaera study of Peterson[27] At first sight contradictory, these observations may be reconciled by taking into account the stage of development of the animal at which the foreign nerve was introduced to the muscle Thus, it is possible that the very first contact between a genotypically dystrophic motoneurone and a genotypically normal muscle fibre in the embryo will commit the latter to a dystrophic growth thereafter, if so, any later experimental manipulations with innervation would be ineffective

Regardless of the true state of play, the neural hypothesis has successfully drawn attention to the possibility of deranged trophic mechanisms being present in neuromuscular disease Whether or not the hypothesis is eventually shown to be correct, it will have served a useful function if it advances our understanding of dystrophy or brings a cure one step closer

Drilling in the Antarctic

from Peter J Smith

So much attention is given to the large-scale geological programmes, such as the Deep Sea Drilling Project, that there is a tendency to overlook the more modest investigations which face technical and logistic problems scarcely less formidable A good case in point is the three-nation programme of drilling in the McMurdo Sound region of Antarctica By the late 1960s it was clear that if significant progress were to be made in investigating the geology, geochemistry, glaciology, lake-bottom stratigraphy and thermal characteristics of the dry valleys west of McMurdo Sound, it would be necessary to supplement surface studies with borehole data Accordingly, several drilling proposals were submitted to the National Science Foundation which coordinated all acceptable proposals into a single programme with participating scientists from the United States, Japan and New Zealand Thus was born the Dry Valley Drilling Project (DVDP), since expanded to include Ross Island and McMurdo Sound itself

The original aims of the DVDP as described by McGinnis *et al* (*Antarctic J* , **7,** 53, 1972) included studies of palaeontological and volcanic evolution during the poleward migration of Antarctica palaeomagnetic reversals, the geochemistry of polar desert soils and permafrost, heat flow, the hydrogeology of ice cap margins and the global tectonic significance of the McMurdo volcanics although it is already clear that the first of these objectives will not be met An initial exploratory season was envisaged, followed by three drilling seasons involving a minimum of 10 holes During the exploration in the 1971-1972 summer season electrical depth soundings were taken to determine permafrost thickness and the nature of the material beneath the permafrost, seismic refraction profiles were run in lake basins to establish the relief and structure of bedrock and overburden thicknesses, and a regional aeromagnetic survey was made to provide structural control. In addition, environmental monitoring (physical and microbiological) was begun and will be continued throughout the project.

Drilling began during the 1972-1973 season with two holes through the volcanic rocks of Ross Island; and preliminary geological and geochemical results from these sites (boreholes 1 and 2) were described about a year ago (*Antarctic J.*, **8,** 157; 1973). During the 1973-1974 summer, seven more holes were drilled in the Ross Island volcanics (borehole 3 adjacent to hole 2) and in the dry valleys at Lake Vanda (boreholes 4 to 9); and a series of reports on this work has just been published (*Antarctic J.*, **9,** 125; 1974).

According to Kyle and Treves the cores from holes 1, 2 and 3 reveal that the geological history of Hut Point Peninsula (Ross Island) is much more complex than the surface geology suggests, which is itself sufficient vindication of drilling. The oldest unit penetrated by holes 2 and 3 is a 200+ m thick pile of hyaloclastite representing early eruptive events that took place below ice or water; in other words, an early stage of marine volcanism involved the construction of a hyaloclastite pedestal which may have impinged on a thick ice shelf covering the Ross Sea more than 1.2 million years ago. The higher lavas, on the other hand, are apparently subaerial flows and pyroclastic units which represent a single differentiation series starting with olivine–augite basalts, working through augite–kaersutite basalts and ending with kaersutite hawaiites, although the phonolites on an adjacent hill may well be more extreme differentiates of the same magma chamber.

The cores from the dry valleys not unexpectedly comprise glacial and marine sediments, although two of the holes also penetrated the crystalline basement. Both sedimentary and igneous cores are still under laboratory investigation so few geochemical and mineralogical results are available. But Tarii reports that stable isotope studies have already revealed the sources of core ice; in Lake Vanda, for example, most of the present water apparently originates as fresh water whereas deeper sedimentary layers are still under the influence of sea water. Also Gumbley *et al.* have begun to use the upper few metres of sediment from Lake Vanda to trace the lake's Late Quarternary history.

The DVDP can already be credited with the resolution of at least one long-standing disagreement. Over a decade ago, Armitage and House (*Limnol. Oceanog.*, **7,** 36; 1962) discovered that although Lake Vanda lies in a region where the mean air temperature is −18° C, it has a bottom water temperature of +25° C. This led Armitage and House, and later Angino *et al.* (*Sci. Bull.*, **45,** 1097; 1964), to suggest that below the lake there are either high geothermal gradients or hot springs.

Wilson and Wellman (*Nature*, **196,** 1171; 1962) ruled out hot springs on the grounds that the measured isotherms in the lake are nearly horizontal. Not only are hot springs unlikely in Antarctica because the great thickness of frozen ground precludes abundant groundwater; they argued that the entrance of springwater into the lake in conjunction with any possible hot spring would produce a much more complicated thermal pattern. Instead, they developed a theory of solar heating in which solar energy penetrates the lake's ice cover (found to be extremely transparent) and is absorbed in the water below. In support of this view, Wilson and Wellman pointed to the extreme clarity of the water and to the decrease in temperature gradient with depth (which implies a heat 'source' in the water itself). Heat flow measurements in the upper 30 cm of lake sediment also seemed to show that heat is flowing from the water to the sediment. But Ragotzkie and Likens (*Limnol. Oceanog.*, **9,** 412, 1964) produced precisely the opposite result from similar measurements and therefore attributed the high bottom temperature to a combination of solar heating and high geothermal gradient.

Wilson *et al.* have now resolved this question by making thermal measurements in DVDP hole 4 which penetrated the crystalline basement below Lake Vanda. The temperature in the basement 15.5 m below the lake bottom is consistently 0.48° C lower than that in the sediment 0.5 m below the lake bottom. The corresponding temperature gradient (average 0.032° C m^{-1}), combined with estimates of thermal conductivity, shows that Lake Vanda is losing heat downwards at a rate of 0.5–1.0 cal cm^{-2}s^{-1}, thus convincingly supporting the view that geothermal heat is not the reason for the lake's high temperature.

Eltanin bailed out

To oceanographers the name Eltanin probably stands second only to Glomar Challenger. From 1962 to 1972 this vessel carried out geological, geophysical, geochemical, biological and meteorological researches which covered some 80 per cent of the southern ocean between 35° S and Antarctica. Then a $1.5 million budget cut in the US Antarctic Research Program ended its active work.

But now the Eltanin is about to begin a new five-year programme on Antarctic research as a result of an agreement between the United States and Argentina. The ship, renamed Islas Orcadas and operated from Buenos Aires by the Argentine navy, will carry out joint scientific expeditions with support from the National Science Foundation and the Argentine National Antarctic Directorate.

Corvine cannibalism

from our Animal Ecology Correspondent

ARGUMENTS have been raised for years about the functions and consequences of territories to animals. Since the ultimate restraint to population increase is availability of food, one might expect the relationship of territory size to food to be both positive and linear. For some species, mostly herbivores, this may be true or nearly so. But often for both carnivores and herbivores territory size is unrelated to food supply (Watson and Moss, in *Animal Populations in Relation to their Food Resources*, 167, Blackwell, Oxford, 1970). Hinde points out that territories have complex functions with consequences both harmful and advantageous to an individual's chance of breeding success (*Ibis*, **98,** 340; 1956). Simple answers cannot be expected to complex questions.

In a well designed series of field experiments on carrion crows in north-east Scotland, Yom-Tov added extra food to the environment to ascertain if there was a direct relationship between territory size, food supply and breeding success (*J. Anim.Ecol.*, **43,** 479; 1974). There was circumstantial evidence that there was no absolute food shortage during the breeding season. Food in the form of hens' eggs and dead hens' chicks was placed near to artificial trees both within and without established crow territories. This treatment failed to increase the breeding density of adults. But one egg and five chicks offered daily to a group of fourteen breeding pairs in the close proximity of their nests resulted in a significantly higher survival rate of nestlings although there was no difference in clutch size. At fledging an average of 2.3 young had survived in the experimental nests compared with 1.1 in the controls.

The other effect of food added daily from the start of the year was to significantly shift the date of the start of laying, bringing it forward by 5 days. Earlier layed clutches were almost twice the size of late clutches, but the number of fledglings produced per nest was about half. So increased winter food affected date of laying but not, *per se,* the number of fledglings produced per nest.

How does extra food increase the survival rates of nestling crows? Predation of the eggs and desertion by the adults were the main factors responsible. Krebs has pointed out that artifically increased winter food has no effect on the number of territorial breeding pairs of great tits during the following spring (*Ecology,* **52,** 2; 1971). Those nests that were closer together than 45 m suffered 12% more predation (mostly by weasels) than did those nests spaced over 45 m apart. Carrion crows are their own chief predators—they prey to a significant extent upon the eggs and nestlings of their own kind. With cannibalism as the regulatory mechanism, the ultimate limiting factor for the number of nestlings reared is the dispersion of food within the territory. An abundance of food close to the nest means that the clutch is left unattended for shorter intervals than if the food is widely scattered. To remain near the nest breeding crows limit their territory size. The lower limit to territory size depends upon the amount of food available and the upper limit depends upon its dispersion and the ability of the pair to defend its nest.

Cyclic AMP and pattern formation

from Paul Epstein

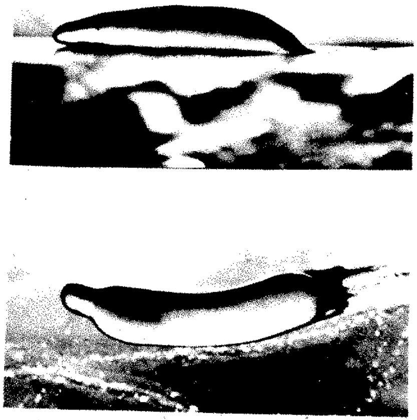
By staining with fluorescent antibody specific for cyclic AMP, Pan *et al.* (*Proc. natn. Acad. Sci. U.S.A.,* **71,** 1623; 1974) have been able to observe the distribution of cyclic AMP in both the unicellular amoebae and the multicellular pseudoplasmodium of *Dictyostelium discoideum* and several related species of cellular slime mould. Cyclic AMP was first shown to be important in the life cycle of *D. discoideum* when it was isolated as the naturally occurring acrasin, or chemotactic agent by which the vegetative amoebae signal each other to aggregate (Barkley, *Science,* **165,** 1133; 1969). Now the studies by Pan *et al.* suggest that cyclic AMP is important not only for aggregation, but for determination, or pattern formation, as well.

In the cellular slime moulds, once the aggregation process is completed, the amoebae form a pseudoplasmodium, or grex, which, depending on environmental conditions, may migrate for an indefinite period before beginning to differentiate into two morphologically and functionally distinct cell types—spore cells and stalk cells. By staining with vital dyes, Bonner (*The Cellular Slime Molds, second ed.,* Princeton University Press, Princeton, New Jersey, 1967) showed that the cells in the anterior third of the grex become stalk cells, whereas the cells in the remaining posterior portion become spore cells.

The cells in the grex are not predetermined, however, since a grex which is sliced transversely can form two normal fruiting bodies, containing the normal proportions of spore and stalk cells (Raper, *J. Elisha Mitchell scient. Soc.,* **56,** 241; 1940). This observation indicates that the cells can recognise their position within the grex, and somehow alter their developmental fate accordingly.

How do the cells know their position in a field? One theory is that they respond to gradient(s) of concentration of small molecule(s) (Wolpert, *J. theoret. Biol.,* **25,** 1; 1969). More recently, McMahon developed a theory of pattern formation using *D. discoideum* as a model, which holds that a sharp concentration boundary of a small molecule can develop through its regulation by contact-sensing molecules on the plasma membranes of cells in the field (McMahon, *Proc. natn. Acad. Sci. U.S.A.,* **70,** 2396; 1973). These regulatory molecules would be the macromolecules which synthesise and degrade the small molecule. In this case, the polarity of the morphogenetic field is determined by the boundary of the small molecule, which in turn is determined by the distribution of contact-sensing molecules.

Although one theory invokes a gradient and the other a boundary, both models require non-uniform distribution of a small molecule to determine the pattern of development. The results of Pan *et al.* suggest that cyclic AMP might be one such small molecule which determines pattern formation in *D. discoideum.* Pan *et al.* showed that as the pseudoplasmodium was allowed to migrate, a distribution of cyclic AMP arose such that the higher concentration was found in the anterior, pre-stalk region. In some cases, they observed an abrupt boundary of cyclic AMP concentration between the anterior and posterior portions of the grex, as theorised by McMahon.



Migrating grex of *Dictyostelium discoideum* seen from the side and from above. From *Developmental Biology* by Nelson Spratt.

It is interesting to consider two earlier observations which bear on pattern formation and differentiation in *D. discoideum,* and to see how they fit with the idea that pattern formation in the grex is determined by the distribution of cyclic AMP. Bonner (*Proc. natn. Acad. Sci. U.S.A.,* **65,** 110; 1970) subjected isolated amoebae to high concentrations of cyclic AMP and found that they developed into stalk cells. From this observation, he concluded that cyclic AMP functions as an inducer of stalk cell differentiation. The observation of Pan *et al.* is consistent with this conclusion.

The other observation was made by Raper (*J. Elisha Mitchell scient. Soc.,* **241,** 1940), who sliced a pseudoplasmodium transversely into four sections. Section one, the anterior tip, could be made to migrate for various times. If induced to begin fruiting body formation immediately, without any resumption of migration, this section developed into an extremely abnormal fruiting body, bearing very few or no spores, and an excessively heavy stalk. If 3–6 h of migration were allowed before fruiting formation began, the resulting structure was less abnormal but still bore fewer spores and more stalk. If 24 h of migration were allowed, the tip gave rise to a completely normal fruiting body, with the correct proportion of spore and stalk cells. Hence, Raper demonstrated that the cells at the anterior tip of a pseudoplasmodium are determined to become stalk cells, and that this determined state is altered progressively as the tip migrates.

In accord with this observation, Pan *et al.* found that the distribution of cyclic AMP in the grex becomes more apparent as it migrates. Likewise, McMahon, in his theoretical treatment, showed the boundary of cyclic AMP concentration arising near one end of the field, and moving along the field with time. McMahon calculated that by about 3–5 h the boundary becomes stabilised at a position one-third of the way down the field; that is, at the position which would give rise to the normal proportion of spore and stalk cells.

Although substantial proof is required before one can state that cyclic AMP is responsible for pattern formation in *D. discoideum,* the results of Pan *et al.* at least suggest such a function. If further studies provide proof, this would represent the first identification of a small molecule responsible for pattern formation. ●

Clustered genes and non-transcribed spacers

from Benjamin Lewin

MOST eukaryotic genes are probably present in only one copy for each haploid genome Two notable exceptions to this rule are provided by the genes coding for histone proteins and those which specify ribosomal RNAs here many genes, apparently identical for ribosomal RNA genes and with little variation in the histone genes, are organised in a cluster in which each transcribed sequence seems to be separated from the next by a non-transcribed spacer region The structure and function of the spacer are presumably relevant to the control of gene activity, and perhaps to the problem of the suppression of variation in the multiple copies of each transcribed sequence

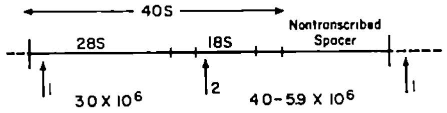
During oogenesis in *Xenopus laevis* the nucleoli which contain ribosomal DNA are amplified to become a major cell component The ribosomal DNA can thus be isolated in bulk and has been the subject of much work on sequence organisation This DNA was recently used as a substrate for the *Eco*RI endonuclease of *Escherichia coli* by Morrow *et al* (*Proc natn Acad Sci U S A* **71**, 1743–1747, 1974) who found that each repeating unit (transcribed plus non-transcribed) suffers two cuts When *X laevis* rDNA molecules of about 50×10^6 daltons were treated with excess *Eco*RI enzyme the principal fragments had weights of $3 0\times10^6$ and $4 2\times10^6$ daltons, prominent among the minor fragments were two of $3 9\times10^6$ and $4 8\times10^6$ daltons These products were annealed with DNA of the plasmid pSC101 (which is cleaved at a single site, generating a linear molecule from its circular genome) to give plasmid–rDNA recombinant molecules that were then replicated by growth in *E coli*

When the recombinant plasmid DNAs were isolated from several bacterial cell lines and analysed by cleavage with the *Eco*RI restriction enzyme, each recombinant plasmid gave fragments with sizes typical of the linear molecule of pSC101 and of the cleavage products of *Xenopus* rDNA

By hybridisation with 18S and 28S *Xenopus* rRNA, Morrow *et al* showed that the hybrid plasmid CD4, which contains both the $3 0\times10^6$ and $4 2\times10^6$ cleavage fragments, anneals equally well with both rRNAs, the CD18 plasmid containing only the $3 0\times10^6$ dalton fragment anneals principally with 28S rRNA while the DNAs of plasmids CD30 and CD42, which contain the $3 9\times10^6$ and $4 2\times10^6$ dalton fragments respectively, react mostly with 18S rRNA These results suggest that the tandem repeats in the rDNA are heterogeneous, each consisting of the $3 0\times10^6$ dalton sequence (which contains the 28S rRNA sequence) and the $3 9\times10^6$ or the $4 2\times10^6$ dalton sequence (containing the 18S rRNA sequence and presumably differing by the presence or absence of an extra sequence, other variations in this region are suggested by the existence of other size fragments)

Since the transcribed region of *Xenopus* rDNA takes only one form, heterogeneity in sequence must be ascribed to the non-transcribed spacer region, a conclusion supported by the report of Wellauer *et al* in the *Proceedings of the US National Academy of Sciences* (**71**, 2823–2827, 1974) By cleaving *Xenopus* rDNA with the *Eco*RI enzyme, they were able to isolate two classes of fragment on agarose gel electrophoresis Every preparation contains a prominent band of $3 0\times10^6$ daltons and several bands are present in lesser amounts which vary from 4 0 to $5 8\times10^6$ daltons To decide whether the heterogeneity of the larger bands exists within single genomes or reflects differences between animals, they examined the rDNA from a single nucleolus organiser, this contained at least three of the larger size classes as well as the $3 0\times10^6$ dalton band The repeat length of transcribed plus non-transcribed *Xenopus* rDNA is about 8×10^6 daltons, clearly implying that the repeats must be heterogenous in length (since otherwise the total length of fragments would equal rather than exceed the repeat length) When the duplex lengths of the fragments were measured by electron microscopy, the smallest proved to have a homogenous size of $3 0\times10^6$ daltons and the number of these small fragments equalled the sum of the number of the larger fragments Each repeat therefore seems to comprise one 3×10^6 dalton region and one of the larger regions

Secondary structure mapping has previously been used by Wellauer and David (*Proc natn Acad Sci U S A* **70**, 2827–2831, 1973) to order the sequences for ribosomal RNA in the precursor of the mature rRNA (see Lewin, *Nature*, **250**, 619–621, 1974) When RNA is spread for electron microscopy, hairpin loops may form between short complementary sequences and the position of each loop along the linear molecule provides a map of it The 28S rRNA has a characteristic map present at the 5′ end of the precursor and the 18S rRNA is characterised by an absence of loops Wellauer *et al* now extend this technique to DNA which has been denatured to single strands The small $3 0\times10^6$ dalton fragment cleaved from *Xenopus* rDNA by the *Eco*RI enzyme is homogeneous in structure, it seems to result from cuts made by the enzyme about $0 3\times10^6$ daltons into the 28S rRNA sequence and about $0 2\times10^6$ daltons into the 18S rRNA sequence, this fragment thus represents the starting region of the rRNA precursor, lacking the immediate 5′ end The other fragment generated by these two cuts has one end devoid of structure, presumably corresponding to the 18S rRNA sequence, with the other end displaying the structure typical of the very beginning of the 28S rRNA structure



Summary by Wellauer *et al* of structure of an rDNA repeat unit

The central regions of all larger fragments show a related structure, but vary in length It is therefore the non-transcribed spacer region in which the heterogeneity resides and the formation of heteroduplexes suggests that the shorter large fragments represent deletions of sequences present in the longer large fragments How this heterogeneity relates to the functions of the nucleolar rDNA is not yet known, one reservation about the interpretation of these results, however, is that the source of the rDNA is the amplified material of the oocyte and it remains to be proven whether the same situation is found in the somatic cell

Analysis of histone genes is at a less advanced stage than that of ribosomal RNA genes Each of the five histone proteins seems to constitute a unique amino acid sequence in any species, and the hybridisation analysis of Weinberg *et al* (*Nature*, **240**, 225–228, 1972) suggested that their messenger RNAs are coded by genes repeated some 500–1,000 times in the genome of the sea urchin *Psammechinus miliaris* Because of the multiple codons representing each amino acid, identity of protein sequences need not imply identity of the repeated nucleic acid sequences coding for them, but the hybridisation analysis suggests only limited heterogeneity The histone messengers of another sea urchin, *Lytechinus pictus*, have been separated by gel electrophoresis into a small number of groups by Grunstein *et al* (*Cold Spring Harb Symp quant Biol*, **38**, 717–724 1973) and a fingerprint analysis of one of these messengers is consistent with the idea that its sequences are fairly uniform

The histone genes of *Psammechinus miliaris* band on CsCl gradients at a density only slightly greater than that of bulk DNA, but Birnstiel *et al* (*Proc* *natn Acad Sci U S A*, **71**, 2900–2904, 1974) now report that they can be isolated by their ability to bind preferentially to actinomycin C_1 which causes them to form a low density band The band isolated in this way hybridises well with a preparation that contains the messengers for four histones (mRNA activity for histone F_1 has not yet been demonstrated), since each of the four histone messengers shows a virtually identical reaction with the fractions of DNA separated on the CsCl–actinomycin gradient, it is likely that the different histone genes are intermingled rather than clustered in four individual groups

Comparison of G+C content of histone DNA and RNA, and the results of shearing and of melting histone DNA all suggest that the histone gene cluster also contains other sequences that are poorer in G+C content The release of the histone-coding from the other sequences only by shearing suggests that both components are integral parts of the gene cluster The melting curve of renatured DNA from the preparation implies the presence of some heterogeneity in sequence, probably in the sequences which do not code for histones Whether the component poor in G+C represents a non-transcribed spacer region analogous to that of the rDNA gene cluster is not of course revealed by present data but this is one of the functions that can be imagined for it

Two by two

from D H Jennings

It is rare these days to attend a conference covering the whole spectrum of biology But the Society for Experimental Biology mounted such a conference—on symbiosis—at Bristol on September 2–6 By retaining the original de Bary definition, namely that symbiosis is the association of two different organisms, it was possible to have all shades of interest from molecular to whole organism biology represented Thus, ecologists, though not contributing directly, could find much to interest them Indeed, two contributions were particularly seminal for ecological studies Fricke (Max-Planck-Institut, Seeiweesen) indicated how behavioural studies of organisms in the Red Sea can provide an understanding of animal interactions in nature thus adding flesh to the bare bones of numerical population studies Cox (Kings College, London) discussing his work on intraerythrocytic parasites, pointed out that population biologists cannot continue to think about particular species without considering their parasites He showed how susceptibility to various virus diseases can be dramatically modified by the presence of parasites

There was much emphasis on how the invading symbiont avoids attack by its potential host Terry (Brunel University) and Smithers (National Institute for Medical Research, Mill Hill) presented their elegant studies on the evasion of the immune response by *Schistosoma* which can survive by its ability to acquire host molecules Muscatine (University of California, Los Angeles) provided data indicating the recognition by *Hydra* of the appropriate *Chlorella* cells takes place after engulfment at the stage when the algal cells move to the base of the digestive cells Studies on symbiosis in *Paramecium* are now also beginning to yield relevant information with respect to bacteria (Preer, University of Indiana, Bloomington) and *Chlorella* (Karakashian, Max-Planck-Institut, Wilhelmshaven)

In spite of the decision to use the de Bary definition, there was much discussion of what is meant by the term 'symbiosis' Mortimer Starr (University of California, Davis) produced a new classificatory scheme which has the virtue of both clarifying thinking about the phenomenon and indicating where further experimental work is required—to decide, for example, whether a symbiotic association is mutualistic or obligately parasitic In this respect, Smith (University of Bristol) put those interested in lichens further in his debt by his careful analysis of the present data in the field which indicate that there is no detectable benefit to the algal partner Also Coffey (Trinity College, Dublin) presented further information about the rust fungi, once thought to be the classic example of obligate pathogens in plants but which can now be grown in culture

Many problems are emerging for the biochemists, particularly on how a symbiont affects the physiology of the host which it has invaded Biochemists should be impressed by *Aplysia* which does a far better job than they of isolating chloroplasts There is no doubt, as shown by Trench (Yale University), that these chloroplasts are fully functional, though the relationship between these organelles and the animal cytoplasm in which they reside is not the same as that which exists in the intact cell from which the chloroplasts are extracted

But biochemists and molecular biologists have other reasons for being interested in symbiosis Chloroplast symbiosis is, in a number of ways, the living expression of how eukaryotic organelles are believed to have arisen, namely by successful invasion of a primitive glycolytic prokaryote by oxygen utilising (to give mitochondria) and photosynthesising (to give chloroplasts) prokaryotes Though the theory has a respectable age, Lynn Margulis (University of Boston) has done the most recently to bring it up to date In a debate on the theory she propounded her views with infectious enthusiasm But though most of the audience were believers, Raff (University of Indiana, Bloomington) in a careful comparison of bacteria and mitochondria showed that their faith may be blind

Five hundred million years ago in Wales

from I Strachan

About half of those attending the symposium organised by the Palaeontological Association of London on the Ordovician System (September 17-20) had spent the previous week touring Wales looking at the classic geological sites of Arenig, Llandeilo, Caradoc and Bala

Much of the material presented at the meeting in Birmingham was factual and included new information as well as regional summaries, but there was also a considerable questioning of current dogmas F J Fitch (Birkbeck College, London) and others speaking on Ordovician geochronology pointed out the possible sources of error inherent in radio-isotopic dating, particularly in Lower Palaeozoic rocks, and stressed the need for the use of standard reference scales (such as that produced by the Geological Society of London in 1964) so that data from different sources could be accurately compared They concluded that a length of 65 Myr (between 510 and 445 Myr ago) was reasonable for the Ordovician, compared with 70 Myr for the preceding Cambrian and 40 Myr for the succeeding Silurian

Given this broad time span, it was not surprising that the details of the regional pictures presented by later speakers should show some differences The biostratigraphical problems were analysed in various groups of fossils W B N Berry (University of California) related his graptolite faunas to warm and cool water masses using a palaeogeographical reconstruction with the land all on one hemisphere M Lindstrom (University of Marburg) felt that the conodont faunas agreed in provincialism with the graptolites but C R C Paul (University of Liverpool) found distinct North American, Baltic and Mediterranean cystid faunas only up to the lower part of the Caradocian, after which time provincial boundaries became fuzzy This he related to closing up of ocean basins during late Ordovician plate movements.

He also discussed the functional aspects of respiration in cystids to critically low oxygen levels in shallow tropical seas. This linked the palaeogeographic approach to the climatic one which was discussed by N. Spjeldnaes (University of Aarhus, Denmark). The now well known glacial deposits of the Moroccan Anti-Atlas were beautifully illustrated by J. Destombes (Service géologique, Rabat) and other speakers referred to climatic cycles in the Ordovician which influenced the occurrence of various groups of fossils. Changes in faunas could be caused as much by climatic changes as by migration between continental plate margins and the disentangling of plate movements through the whole length of the Ordovician needs much further work.

None of the formal papers included any discussion of the boundaries of the Ordovician, most speakers making it clear whether they regarded the Tremadocian as Cambrian (as in English usage) or Ordovician. But the large gathering of experts from so many countries, including the Soviet Union, provided the opportunity for meetings of the Commission on Stratigraphy of the International Union of Geological Sciences. Several recently formed subcommissions and working groups of the commission will have a great deal to do with correlation of strata between countries and continents. Differences of interpretation were much in evidence during the closing general discussion in Birmingham, particularly between those based on groups of fossils traditionally used, such as brachiopods and trilobites, and those which have come into prominence in the last few years, such as conodonts. Some of the ideas were certainly provocative and augur well for the future liveliness of the subject. As an eminent worker on Palaeozoic gastropods put it to close the meeting—a snail never gets anywhere unless he sticks his neck out.

Expanding wings in moths

from our Insect Physiology Correspondent

EVERY lepidopterist knows that emerging butterflies and moths go through a characteristic sequence of wing-folding movements, with wing expansion and general hardening of the cuticle, before settling down into their normal resting posture, and that the force for wing expansion is the hydrostatic pressure of the blood generated by strong contraction of the abdomen. Truman and Endo (*J. exp. Biol.*, **61**, 47, 1974) have now elucidated the complex of physiological factors engaged in this familiar phenomenon.

It was shown by Fraenkel many years ago that if the newly moulted blowfly is obliged to continue burrowing through the soil, it remains soft with the wings and body unexpanded for many hours. Only when it makes its escape is the cuticle expanded, hardened and darkened. It was generally assumed that this hardening process must be controlled by a hormone, but that was demonstrated by Cottrell only in quite recent years and confirmed by Fraenkel and Hsiao, who named the hormone in question 'bursicon'. It is liberated from the brain and other ganglia of the nervous system.

Truman and Endo found that the emerging adult of the tobacco hawkmoth *Manduca* behaves in the same way. It likewise pupates in the soil, and so long as the emergent moth is confined it shows intense digging behaviour, and the spreading of the wings is suppressed, sometimes for 24 hours. The stimulus which maintains the inhibition comes from the head: decapitated moths spread their wings immediately, regardless of whether they are confined. Moths decapitated at the very moment of eclosion, however, show neither wing inflation nor wing folding. But if decapitation is delayed until five seconds after emergence, the full wing-spreading behaviour occurs.

This effect of the brain is not dependent on the nerve supply, it is the result of the neurosecretory 'eclosion hormone': a brain removed from the pupa and implanted into the abdomen of a decapitated pupa is wholly effective in evoking complete wing spreading. The suboesophageal ganglion is also necessary for wing spreading, but this seems to be a neural effect on movement. The hormone bursicon, set free from the abdominal nerve cord, will cause neither wing inflation nor wing folding; it has two important functions: it serves to plasticise the cuticle (as was shown by Cottrell in the blowfly) and it sets in motion the hardening of the cuticle which, in turn, apparently dictates by feedback to the central nervous system the timing of the wing-folding movements.

In brief the eclosion hormone, discovered by Truman a few years ago, not only initiates emergence, but also wing spreading, which is brought about by a central motor programme involving neural and hormonal stimuli and some degree of sensory feedback.

Plant conifers and lose water

from Peter D. Moore

A KNOWLEDGE of the rate of water loss from a forest is essential both for forest water budget calculations and in the management of water catchments. Many comparative studies have been undertaken to provide such information, on forest stands and on other vegetation types. Differences in water loss from various types of vegetation are explicable in terms of transpiration rates, in the effect of vegetation upon evaporation direct from the soil by providing insulating layers of varying thickness and spatial structure, and in the interception of precipitation and its subsequent evaporation directly from leaf surfaces.

The quantification of these parameters, however, is extremely difficult. One of the most useful approaches has been the development of detailed models which attempt to account for all of the microclimatic and spatial variables, each of which can be determined individually (for example, Monteith, *Symp. Soc. exp. Biol.*, **19**, 205, 1965). Various attempts have been made to compare water losses from deciduous and coniferous stands by observational rather than theoretical methods, but most of these have shown negligible differences during the summer months (for example Zahner, *Forest Sci.*, **1**, 258, 1955), no reliable data are available for longer periods covering the winter season, when evergreens may continue to transpire and also to intercept more rainfall than deciduous trees. Comparative data between forest stands on different sites will always be somewhat suspect because of possible differences in the soil water storage capacities, hence long term studies on a single site where deciduous trees have been replaced by conifers seems to be the most hopeful approach to this problem.

The results of just such a study have now been published by Swank and Douglass (*Science*, **185**, 857, 1974). Their study area is in the Appalachian Mountains of the south-western region of North Carolina, originally bearing oak–hickory forest. Streamflow studies were carried out on selected watersheds within the area over a period of ten years, which provided data sufficient for the prediction of stream flow under any given conditions of precipitation In 1956 a 16 hectare watershed was clear-felled and planted with eastern white pine (*Pinus strobus*) For the next six years the streamflow was greater than that predicted for the forest stand, in the initial period by as much as 15% Subsequently streamflow fell below predicted annual values and for the past 6 yr it has been between 15 and 20 cm (equivalent to 15–20%) below that expected from a hardwood stand on the same site

Monthly streamflow values over the course of a year are particularly interesting because they show that between June and October the monthly streamflow is less than 1 5 cm below the expected value, whereas in November, December, April and May streamflow is over 2 0 cm below expected Thus the additional losses of water from a conifer stand take place mainly in winter and spring, the possibility of this being the case had already been postulated by Penman (in *Forest Hydrology,* edit by W E Sopper and H W Lull, Pergamon Press, Oxford, 373, 1967) on the basis of very little observational evidence

The difference is likely to be caused by both the increased interception and the higher transpiration rates in the conifers in winter and spring The leaf area index of hardwoods in winter is low (<1) in comparison with white pine (9 9), which indicates the much larger surface area with pine available for the interception of precipitation

This provides one more good reason for caution in replacing hardwood forests with conifers, especially in water catchment sites

Field effect seen in glassy semiconductors

from Andrew Holmes-Siedle

AT the start of the solid-state age, Bardeen and colleagues attempted to modulate the conductivity of a slab of germanium by putting a metal plate near to the surface and applying a high electric field Unexpectedly, the conductivity of the slab did not change and, because of this, the idea of the 'field-effect transistor' lay dormant for over ten years while the reasons for failure were explored Meanwhile, in order to meet the urgent pressure for a working solid-state amplifier, the device makers (Sockley and colleagues) went on to develop the less elegant point-contact and diffused bipolar transistor principles

The field-induced 'accumulation' or 'inversion' of current carriers in the germanium did not take place as predicted because immobile charge was generated in surface states The sheet of charge 'screened' the interior of the semiconductor and prevented the required bending of energy bands Nowadays, surface states in crystalline semiconductors are under fair control and the metal-oxide–silicon field-effect transistor is a standard component in computer circuits It might now be said that we are at the start of the 'glassy solid state' age, it is perhaps a good omen that, despite a slow start, the field effect experiment can apparently be performed successfully in some glassy semiconductors This is fortunate because the penetration of a semiconductor by a field provides a probe of band structure which is particularly appropriate for the glassy semiconductors

Table 1 Estimated densities of localised states in chalcogenide glasses deduced from field-effect experiments

	Fritzsche	Egerton	Tick *et al*
Typical composition	$As_{35}Te_{28}S_{22}Ge_{15}$	$Te_{50}Si_{12}Ge_{10}As_{10}$	$Te_2As\ Si$
Form	Evaporated	Evaporated	Melted and drawn
Bulk states ($eV^{-1}\ cm^{-3}$)	6×10^{19}	10^{19}–10^{20}	3×10^{17}– 2×10^{19}
Surface states ($eV^{-1}\ cm^{-2}$)	not estimated	2×10^{13}	2×10^{12}– 3×10^{16}

Spear and le Comber (*J non-cryst Solids,* **8–10**, 727, 1972) gained some information on localised states within the band gap of amorphous silicon, but H Fritzsche failed to find any effect in the 'switching' materials, of chalcogenide composition, despite painstaking attempts (*Ann Rev Mater Sci*, **2**, 697, 1972) R F Egerton (*Appl Phys Lett*, **19**, 203, 1971) reported definite field effects which were, however, too small to be useful in determining the nature of the localised states Now, by special methods of preparation, Tick and Watson of Corning Research and Development labs and Hindley of the University of Birmingham (*J non-cryst Solids,* **13**, 229–242, 1974) have prepared samples which have lower apparent densities of localised states and which thus give a higher response to the field effect There is, therefore, some hope of using the field effect to determine the distribution with energy of the localised energy states in this very important group of materials

The fabrication technique used was unusual It is a fair assumption that the evaporated glass layers used by many investigators are more disordered than glasses cast and cooled from the melt But a field-effect experiment on a sizeable cast block of glass would be hopelessly swamped by the conduction currents in the bulk of the sample In order to make the bulk volume of the sample commensurate with the thin field-modulated region on the surface, Tick and co-workers used a thin filament of chalcogenide with an unusual form of surface passivation The filament was produced by melting and drawing down a sample of chalcogenide powder enclosed in a special silica glass jacket The result was a thin silica glass rod of diameter 7 mm with a very thin central filament of chalcogenide, of diameter only 0 01 mm When this was sliced, one could gain contact to the ends of the filament with probes while the glass disk contributed support for an annular metal field plate as well as providing surface passivation and mechanical strength For normal semiconductors and high fields, the surface space-charge regions are of the order of micrometres, so with these dimensions there is a chance that the field will influence a fair fraction of the filament volume

In fact, negative fields of the order of 10^6 V cm^{-1} modulated the bulk conduction by about 5%, though greater fields produced little further effect, this could be termed a saturating dependence on field Positive fields (metal positive) gave a much smaller effect The simple analysis which best fits the saturating characteristic is that of a density distribution of localised states which is uniform with energy all across the band gap The field dependence of current predicted for a sharply peaked distribution of localised states, such as that called for in the Davis–Mott model for chalcogenides (see for example Mott and Davis *Electronic Processes in Non-crystalline Materials,* Clarendon Press, Oxford, 1971) is of a very different form from that observed

The model proposed also postulates a significant density of surface states The figures for density are compared with the estimates made by Egerton and by Fritzsche in Table 1 The values given for certain samples in this latest work are seen to be considerably lower than in the earlier efforts—possibly a hopeful sign that we are learning better control of the preparation of glassy semiconductors

These results, while not constituting a definitive disproof of the commonly accepted peaked energy distribution of the Davis–Mott model show that the field-effect method is a tool which, with perseverance, may provide definitive evidence on this question

Human reproduction and family planning: research strategies in developing countries

Alexander Kessler & C. C. Standley

Human Reproduction Unit, World Health Organization, Geneva, Switzerland

The difficulties of providing family planning care on a world-wide scale have led to considerable emphasis on research in human reproduction How much of this research should, and can, be carried out in developing countries raises many issues in research administration

RESEARCH into human reproduction and family planning has expanded considerably in the past 15 years, and is now in progress in many institutions both in developed and developing countries Rarely, however, has sufficient effort gone into formulating appropriate national policies for such research

Developing countries raise some of the severest problems, frequently, esoteric research done in developed countries is repeated, while opportunities for local clinical investigations which are closer to the health needs of the countries are ignored The nature of research training may be partly to blame, trainees may be exposed to a technique rather than being provided with an approach to research and a broader background in reproduction The same incoherence is often found in the location of facilities new institutes are created where expansion of existing ones would have been sounder and more economic Funds are at times monopolised by small groups of scientists, and a contributory factor has been the multiplicity of funding sources, foreign ones often being the most important

The urgency of this research and the relatively ready availability of funds means that policy issues require serious consideration The World Health Organization recently convened a workshop for this purpose—research administrators from Argentina, India, Pakistan, Thailand, Turkey and the United States met to pool experiences Their problems can be discussed under the following heads

- Should research be done?
- How should priorities be determined?
- What administrative structure is necessary?

Should research be done?

Increasingly, policy makers are asking for clear orientation of research towards specific problems Stephen Toulmin, in *Encounter,* has described this process as " calling in the implied technological IOUs previously issued by the scientists" Policy makers also ask whether better use of existing knowledge and resources, or a simple increase in services would not better solve problems than would more research Do methods of fertility control now available (whether by drugs, devices or surgical procedures) not meet the needs of the great majority of couples? Is not the need now to make these methods more widely available?

We believe there is still a need for research The low initial acceptor rates and high discontinuation rates for present methods in almost all family planning programmes of developing countries are undoubtedly due in part to a lack of services, often, however, they are due to the wrong service approach At the same time contraceptive technology still leaves room for improvement Although more methods are now available, they remain relatively crude At times they are associated with undesirable side effects, and they often fail to meet the needs posed by differences in culture, education, and service-structure Moreover, many forms of contraception are still not available a male pill, a post-coital pill, a once-a-month pill, a vaccine against pregnancy and so on

Fertility regulation presents special problems for research techniques require an assessment well beyond that required for other therapeutic modalities because of their extremely wide, long term and frequently unsupervised use Further, expected users differ in genetic constitution and environment In most cases return of fertility must be allowed and methods are usually self selected, not prescribed Even conceding the need for more research, the role of developing countries in such research must still be clarified

- For established methods, dosages appropriate for women of a high level of nutrition may not be applicable Side effects of concern in the West may not manifest themselves, while new side effects may appear arising from disease and deficiency states in developing countries
- For new methods, developing countries should be involved at an early stage of the research to determine acceptability They must also be involved in testing at all stages of development so that safety and effectiveness data can be acquired rapidly for different populations
- As far as services are concerned, the argument that family planning programmes can go forward on a common sense basis, without any service research, does not stand scrutiny We have no precedent for providing health services on a continuing basis to most couples of reproductive age in a community Sensible studies and small experiments are needed on the major components of family planning activities in a local context information, education, and provision of clinical services For instance, inappropriate presentation of educational material may spoil an otherwise well-designed programme Local research is also essential in determining the right location of facilities, personnel, frequency and timing of clinics, schedules for follow-up care and provision of methods

How should priorities be determined?

Data are frequently lacking on how to identify specific problems, how to rate their relative importance, how to determine their susceptibility to solution through research, what manpower and facilities are needed, what is the potential pay-off, and what is the likely duration and cost On the other hand, fundamental questions of strategy have to be settled, such as the balance between goal-oriented and non-directed research, between research and research training, and between research in universities, government institutes and industry

The usual guidelines for setting priorities in biomedical research are the levels of unresolved morbidity and mortality, and indices of general welfare The same criteria hold here Initially, broad problem areas must be identified and ranked in importance pregnancy, labour, development, family planning and sterility Then specific topics for study and research approaches must be ranked For instance, should the emphasis be on development of new therapies or on service research?

The contribution of research to reducing morbidity and mortality has already been demonstrated in some fields, such as pregnancy and labour, beginnings have been made in research on the biology and health of the foetus and the foeto–maternal complex This research has generally been in developed countries Malnutrition and infectious diseases in developing countries are likely, however, to lead to great incidence of pathology and different forms of conditions associated with pregnancy, labour and foetal development

In ranking family planning research, account must be taken of indices both of morbidity and mortality and of 'welfare' Birth control prevents death and disease that result from unwanted pregnancy, short birth intervals, or illegally induced abortions, whilst the advantages of determining family size need little elaboration at the family level and will accord, in many communities, with population policies

Problems of local importance undoubtedly have first priority in developing countries The epidemiological, clinical, and service research required clearly cannot be carried out elsewhere Amongst such problems are the effects of hormonal contraceptives in women infected with *Schistosoma haematobium*, foetal development in communities with a high incidence of thalassaemia and prenatal care in protein-deficient pregnant women

More controversial are the priorities for problems that could be investigated in a developed country, for example, development of new contraceptives Ideally, as we have said, any new drug should be investigated in developing and developed countries simultaneously, using a common protocol This, however, demands highly specialised manpower and equipment Should scarce resources be expended on the earlier stages of development, such as those that precede testing on human subjects, for instance, identification of reproductive processes susceptible to regulation, synthesis or isolation of suitable chemicals, screening for effectiveness and toxicological studies in animals?

Several arguments can be made for not automatically excluding from developing countries any aspect of research needed to resolve important problems One is that it would make little sense and detract from the intellectual challenge if there were arbitrary cutoff points to research Another is that the whole range of scientific expertise must be available in a developing country, since scientists and institutions in developed countries are often not interested in the problems of the developing country An example is the lack of research on injectable contraceptives—a modality that meets many of the needs of developing countries An artificial limitation would further deprive the scientific community of talent and would preclude scientists in these countries from pursuing freely their choice Finally, university teaching is improved by the presence of an active research programme

Should public funds support research that is left entirely to the choice of the individual? A comparison of non-directed with directed research is difficult to make, and the level of funding for non-directed research cannot yet be determined on the basis of general principles

Feasibility of research on priority problems

A problem may be important and it may be seen to be amenable to solution through research, but it will have to be ranked in terms of the manpower and facilities that it would tie up Work can sometimes start immediately on a problem not of the highest priority, while a more important one must await the necessary resources A 10–20 yr plan, regularly reviewed, is needed

A representative ranking of research areas in many developing countries could take the following form First, the health rationale for family planning (for example, studies of effects on health of different patterns of family formation, identification of women particularly requiring family planning care because of their health status), second, clinical trials of contraceptives at the community level, third, the effects of widely-used contraceptives in the presence of conditions such as malnutrition, diseases, use of other drugs, fourth, the acceptability and service implications of different methods of contraception, fifth, sterility, and, sixth, the in-depth, pharmacological studies in humans of new contraceptives

Some developing countries may be able to start rapidly on the first item as they may already have manpower in the required disciplines such as obstetrics and gynaecology, maternal and child health, sociology, biostatistics Specialised technicians may need to be trained for field work, computer analysis, and clinical laboratory measurements This might take about three years If centred around one or two good investigators, a research nucleus would have been created which could then, if required, move into research projects in almost all of the priority areas

In contrast, item six demands manpower and facilities unlikely to be present in many countries Several years may be needed to train specialists with skills in steroid assays, peptide chemistry, radioisotope use, pharmacology, metabolic studies and so on Technicians are also essential as is the availability of specialised clinical facilities

One issue that repeatedly comes up is the proportion of funds to be spent on defined projects as opposed to longer-term more comprehensive 'institution-building' ones Assurance of financial support over a number of years is of importance to all investigators, but particularly so in the case of institution-building

A shortage of qualified manpower may make it difficult to bring together experts, other than the applicants themselves, to review research proposals for scientific merit, so foreign assistance may be necessary The low level of literacy in a population may pose problems in ensuring that 'informed consent' has been obtained

Should research training be restricted, for instance, to clinical trial methodology, or widely based in clinical pharmacology? The narrow approach quickly produces an investigator able to apply himself to an important problem, the more broadly educated scientist is potentially more versatile During his training, however, he may find his interests shifting away from clinical trials Western research training for scientists from developing countries has been problematical we may mention the 'brain drain' and the lack of orientation of the research training either to problems or conditions the scientist will encounter on his return home Failure to provide a research position for the investigator on completion of his training, to ensure attractive career opportunities regularly leads to loss of talent to the developed countries, some countries are now trying to remedy these shortcomings

Keeping up with rapid advances presents a technical and financial problem Airmail subscriptions to journals, access to computer retrieval of bibliographies, participation in international meetings go some way to help Less attention has been given to ensuring that research results rapidly reach policy-makers, administrators and service personnel in a form appropriate to their needs

What administrative structure is necessary?

The number of agencies with interests in research in this field is probably greater than in most other areas of biomedical research The concerns of such bodies as the Ministry of Health, the national Family Planning Authority, the Ministry of Education, the Medical Research Council (MRC), the Council for Science and Technology, the government offices responsible for the national drug industry, the national drug regulatory agency and so on, may be difficult to unite in a common policy It may be even harder to bring in the private drug industry whose orientation is primarily commercial Yet another factor is the aggressive attitude sometimes taken to family planning, including its research aspects, by foreign aid assistance agencies, whose priorities may not necessarily coincide with national ones

The national MRC sometimes offers a plausible focus it has experience in formulating biomedical research policy, could place research in reproduction and family planning within the overall context of the country's biomedical research programme, and could use its existing mechanisms for administration In many developing countries, however, there may not be an MRC capable of assuming these responsibilities, a ready focus may then exist in the Ministry of Education in whose institutions much of the research will be carried out anyway Another approach creates a body within the national family planning authority for the administration of research This should ensure a research policy directed to the problems encountered in the family planning programme and ensure rapid transmission of research results to field workers, unfortunately, such bodies may have little tradition of research, encounter resistance from older established ministries, and restrict themselves to a narrow and short term view of research

External aid has often been forthcoming, but on occasions not so much to support research efforts as to influence family planning policies, or even to gain access to subjects to test drugs under less stringent regulatory conditions than those prevailing in the industrialised countries The magnitude of the funds offered has at times led to this assistance being accepted in spite of the distortion it brought to nationally selected priorities Some countries now place rigid embargos on accepting assistance from any other than multilateral sources

The most neglected use of foreign assistance has been in the areas of policy and research organisation Few donors have wished to support activities that have little visibility and no quick returns, and few recipients have insisted on using research funds for this preliminary ground work

Compositional variation in recent Icelandic tholeiites and the Kverkfjöll hot spot

G. E. Sigvaldason, S. Steinthorsson, N. Oskarsson & P. Imsland

Science Institute, University of Iceland, Geoscience Building, Reykjavik, Iceland

Geochemical studies of recent igneous rocks from Iceland lend support to the 'hot spot' theory There is a geographical variation in basaltic composition between Iceland and the submerged parts of the Reykjanes Ridge and Mid-Atlantic Ridge, which suggests that the single-source model for basalts of this region may be correct

THE puristic mantle plume hypothesis[1–3] holds that all ocean ridge volcanism is fed by the plumes The plate systems drift passively across the Earth's surface relative to the plumes, as shown by the universal symmetry of magnetic anomaly patterns about the ocean ridges Thus, the position of the ridges is not fixed by subcrustal agencies such as convection cells in the mantle Outside the mantle plumes there are no heat sources other than the plume overflows All the heat flow in the ocean bottom can be accounted for by the loss of heat from the cooling plates as they drift away from the ridges[4]

The single-source theory has been challenged by Schilling[5] on geochemical grounds, particularly with reference to Sr-isotope variation[6] We propose to show that geochemical variations in Iceland and the North Atlantic may be consistent with the one-source model, both as regards petrochemistry and isotope geochemistry

We have collected and analysed 182 samples that are considered to cover volcanic activity in the tholeiitic rift zones of Iceland[7] during the last 10^5 yr The geological formations represented are the 'grey dolerites' from the last interglacial, pillow lavas and breccias of the subglacial moberg (palagonite) formation, and postglacial lava flows The volumes of the individual lavas vary greatly monogenetic shield volcanoes range from 1–15 km^3, whereas lavas produced on fissures and isolated scoria cones are much smaller—generally less than 1 km^3

The samples have been divided into three groups on a geographical basis (Fig 1) representing the western rift zone (WRZ, 126 samples), the northern part of the eastern volcanic zone[8] (NEZ, 26 samples), and the Kverkfjoll area (30 samples), a relatively small area in the vicinity of the Kverkfjoll volcanic complex in central Iceland (K Albertson, unpublished)

The Kverkfjoll area is the hot spot of the North Atlantic Away from that area the maximum content of potassium in basalts on the volcanic rift zones decreases continuously with distance (Fig 2) The minimum K$_2$O content remains constant, at about 0 05–0 1%, in the Kverkfjoll area and probably along the entire adjoining ridges A pro-

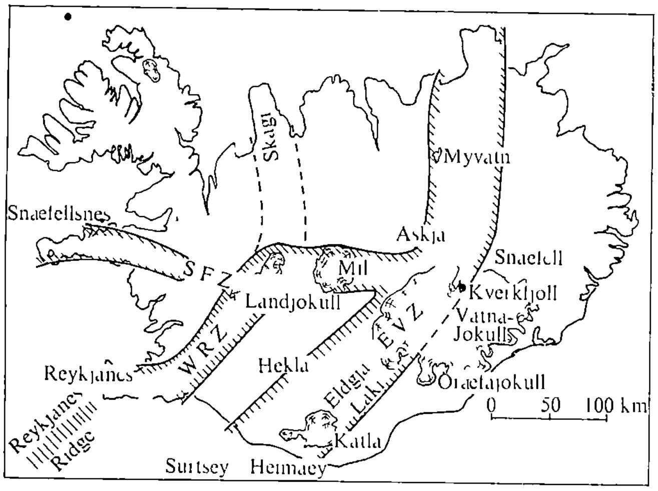

Fig. 1 Neovolcanic areas in Iceland The Snaefellsnes and the southern part of the eastern zones are alkaline in character, the others tholeiitic WRZ, Western Rift Zone, EVZ, Eastern Volcanic Zone, SFZ, Snaefellsnes Fracture Zone

nounced positive correlation exists between K_2O, TiO_2 and P_2O_5 whereas K_2O and Rb show insignificant covariation In central Iceland basalts with a high Rb content exist side by side with basalts highly depleted in Rb Away from the Kverkfjoll area the basalts show gradual depletion of Rb towards the ocean ridges together with increasingly narrower spreads in K_2O values At a distance of 500–600 km from central Iceland the K_2O content of the basalts reaches a value of 0 1%, with very little spread around that figure

The samples from the NEZ have been discussed in detail by Sigvaldason[8] A model was proposed to explain the large compositional spectrum in Icelandic basalts as compared with the narrow range observed in the bulk of ocean ridge basalts The analyses presented here corroborate those results In the model it is assumed that the Icelandic mantle plume feeds all volcanism in the North Atlantic The thermal gradient within the plume centre increases continuously to great depths in the mantle, providing a thermal environment for partial melting over a large depth range Conversely, as the plume overflow spreads below the crust along the volcanic rift zones in Iceland and the adjoining ridges, the thermal gradient goes through a temperature maximum at which partial melting occurs With increasing distance from the plume centre, the thermal maximum becomes better defined at a depth which happens to be appropriate for the formation of ocean tholeiites As that represents relatively low-pressure partial melting, all chemical types formed by partial melting at higher pressure gradually disappear (Fig 2) Thus, two processes are in evidence partial melting at varying depths, and progressive depletion of dispersed elements at the source

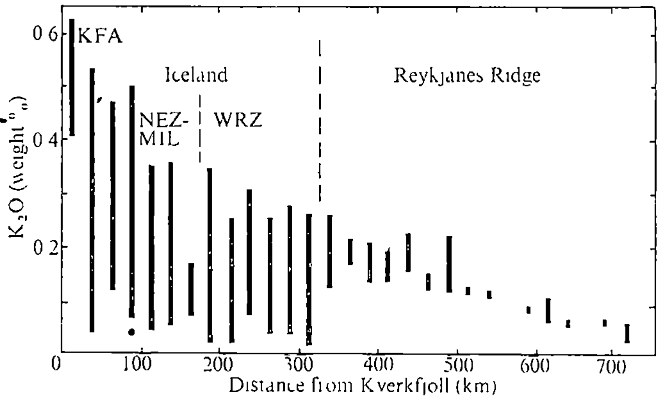

Fig 2 Range of K_2O values plotted against linear distance from Kverfjoll, central Iceland Each column represents the range obtained in a 25 km sector KFA, Kverfjoll area, NEZ, northern part of Eastern Volcanic Zone, MIL, Mid Iceland, WRZ, Western Rift Zone, (see Fig 1)

The Icelandic tholeiites span almost the entire spectrum of observed compositions of oceanic tholeiite To illustrate this is a plot of MgO against iron (Fig 3) compares the Icelandic tholeiites to analyses of oceanic tholeiites[9–11] In spite of this great compositional span, however, the bulk of the Icelandic analyses tends to fall on the iron-rich side of the oceanic analyses This is in keeping with the fact that, as regards volume and frequency, Icelandic tholeiites are distinguished by high alkalis and iron magnesium ratios[12] relative to oceanic basalts The Juan de Fuca[11] analyses resemble the Icelandic suite most (Fig 3), which is in accord with the idea that the Juan de Fuca ridge is the site of a mantle plume[2]

Within the Icelandic group the enrichment of iron and potassium, together with other related chemical variations, seems to bear an inverse relationship to lava volume[8] This effect could be attributed to fractional crystallisation[11] The Ti concentration, however, which has been shown to be sensitive to pressure[13], shows close positive covariation with K, and could be explained equally well by a degree of partial melting (compare with Fig 2) The basaltic liquids may have formed over a relatively large depth range in the mantle Frequent eruptions of small batches of lavas which have undergone only a low degree of partial melting, and which have been derived from a considerable depth, result in large total volumes of high alkali, high iron/magnesium tholeiites, relative to low potassium tholeiites which are produced at shallower depths by a higher degree

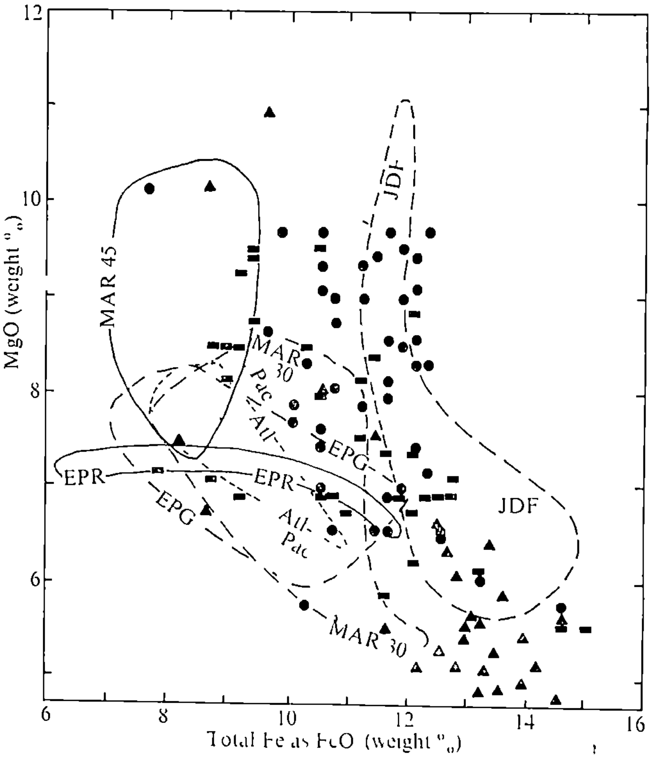

Fig 3 MgO plotted against total iron in the samples, showing the relatively iron rich nature of Icelandic tholeiites The range of values observed in oceanic tholeiites is shown for comparison Atl, Atlantic Ocean[9], Pac, Pacific Ocean[9], EPR, East Pacific Rise[11], EPG, Gorda ridge (41° N)[11], MAR 45°, Mid-Atlantic Ridge (45° N)[11], MAR 30°, Mid Atlantic Ridge (30°N)[11], JDF, Juan de Fuca Ridge (44°N)[11], ▲, Kverkfjoll Area, ■, North-eastern Zone, ●, Western Rift Zone

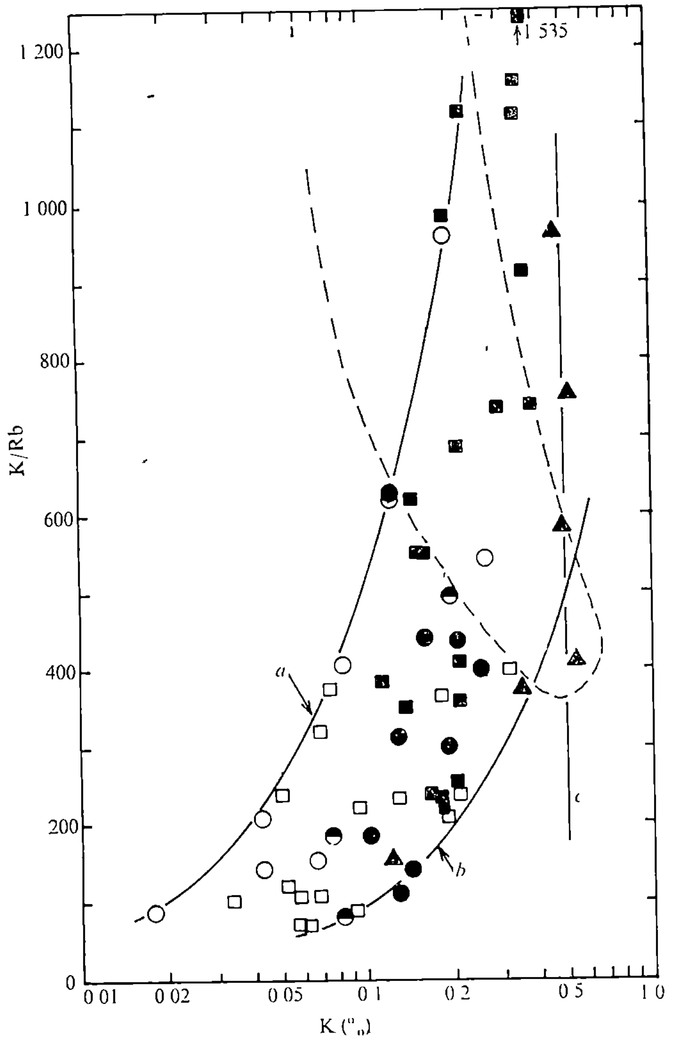

Fig. 4 The K/Rb ratio plotted against log K. Lower part of the field of oceanic tholeiites[11,16] enclosed by dashed line. *a*, Rb=2 p.p.m.; *b*, Rb=10 p.p.m.; *c*, K=0.5%; □, NEZ shield volcanoes and table mountains; ○, WRZ shield volcanoes and table mountains; ■, NEZ fissures and minor eruptions; ●, WRZ fissures and minor eruptions; △, KFA fissures and minor eruptions. The Rb values were obtained by XRF analysis. Although this has a distinct disadvantage at low Rb values this was overcome partially by adding a fixed amount of 20 p.p.m. Rb to the samples. The precision is considered to be better than ± 1 p.p.m.

of partial melting. The volume relationships between products of partial melting of high and low degree in Iceland are, therefore, entirely different from those of the ocean ridges. Along the Reykjanes ridge, in a direction away from Iceland, the low degree partial melting products disappear, giving an impression of an increase in the degree of partial melting at the same time as volcanic productivity decreases. This seems to explain adequately the apparent decrease in light rare earth elements south of Iceland[5].

Figure 4 shows the K/Rb ratio plotted against K for some of the samples, with the field of ocean ridge basalts[11,16] shown for comparison.

Several features of the diagram are worthy of discussion. The K/Rb values are generally lower than previously observed for tholeiites[11]. Analyses of plagioclase separates from porphyritic basalts show K/Rb ratios in the range 50–300. There is no consistent relationship between the K/Rb ratios of phenocrysts and groundmass. Furthermore, REE analyses of Icelandic tholeiites[14,15] do not show Eu anomalies, suggesting that there has been no plagioclase differentiation. These low ratios, therefore, may be derived from the mantle and could indicate a higher content of Rb (phlogopite for example) in the plume than has been assumed previously[17].

The K/Rb–K field is defined by three curves (Fig. 4): its low K side is bounded by the curve Rb=2 p.p.m., whereas for the high K side, at K/Rb ratios below 400, the curve Rb=10 applies, and for higher values the line K=0.5% (Fig. 4). The values for the shield volcanoes tend to fall on the diagram to the left of those of other type of volcanoes. As a group the shield volcanoes show the lowest K and Rb values in Iceland even if the K content may be higher, and the Rb content is much higher, than in the depleted ocean ridge basalts. The voluminous shield eruptions occurred in the specific volcano-tectonic environment found during the isostatic rebound of Iceland immediately after the Pleistocene glaciation. The prevailing conditions of pressure and temperature were suddenly disturbed towards lower pressures, resulting in the melting of large batches of mantle material that had already gone through an earlier stage of melting. They are the most depleted basalts in Iceland.

Schilling[5], chiefly on the basis of Sr isotopes[6], has advocated two primary magma sources in the North Atlantic. Magmas derived from the Icelandic plume have high (~ 0.7032) ^{87}Sr/^{88}Sr ratios[6,15,18], show an undepleted REE pattern, and have generally high contents of K, Ti, P, and high Fe/Mg ratios. The oceanic source yields lavas with a much more depleted chemistry and lower (0.7026–0.7028) Sr isotope ratios[6]. The gradient in composition, from Iceland along the ridge, results, according to that theory, from the mixing of the two magmas. The observed variation in Sr isotopes can possibly be accounted for in terms of the single source model. At the depth at which magma segregation is supposed to take place the upper mantle consists of olivine, two pyroxenes, plagioclase and minor phases, including phlogopite[19] and amphibole[20,21]. The K and Rb enrichment of the basalts in central Iceland results from the important contribution of phlogopite to the early partial melts of the plume. Phlogopite contains about 7% K, 250 p.p.m. Rb, and 18 p.p.m. Sr (ref. 17). The other components in the upper mantle contain between 1 p.p.m. and 0.1 p.p.m. Rb. The high Rb content of the phlogopite results in an increased ^{87}Sr/^{86}Sr ratio relative to the rest of the mantle. Using the values of Rb and Sr already given for phlogopite the ^{87}Sr/^{86}Sr ratio would increase by 7×10^{-5} every million years. Conversely, the highest Rb/Sr ratios observed in Iceland tholeiites increase by 2×10^{-6} every million years, whereas the Sr isotopic ratio of the depleted ocean tholeiites has very little capacity for change with time and probably reflects that of the bulk of the upper mantle.

The implication of possible isotope disequilibrium between mineral phases in the upper mantle may be far reaching as regards the interpretation of isotopes in partial melts. As long as a given mineral assemblage remains stable, however, each mineral may develop its own isotope ratio—which is the basis for the isochron method of radiometric dating[22]. Unless recrystallisation occurs there seems little impetus for isotope re-equilibration between phlogopite and the mantle phases with a low Sr content. In general, because Sr is produced in phlogopite by radioactive decay it should tend to migrate one way only—away from the phlogopite.

There is, as yet, insufficient documentation of the relationship between precisely measured Sr isotope ratios and the petrochemistry of Icelandic rocks. Preliminary work[6,15] indicates, however, that, in general, rocks from the alkalic provinces in Iceland possess slightly higher Sr isotope ratios than the tholeiites. That is consistent with their supposed nature as lower degree partial melts[19].

On the basis of the available data we therefore conclude that there is no well established geochemical evidence to contradict the single-source model for the North Atlantic There is a continuous gradational variation between basalts erupted in Iceland and basalts on the submerged part of the Reykjanes and Mid-Atlantic Ridges This compositional gradient probably results from the combination of a changing environment of pressure and temperature in an upwelling and radially spreading mantle plume system, and from a progressive depletion in the low temperature melting fraction at the source

Note added in proof Unknown to us at the time of writing, similar ideas on isotope disequilibrium in the mantle have been published[23]

Climatic significance of deuterium abundance in growth rings of *Picea*

W. E. Schiegl

Institut fur Radiohydrometrie der Gesellschaft fur Strahlen- und Umweltforschung GmbH, Munich, Germany

Deuterium variations in growth rings of a Picea *from southern Germany are essentially a function of annual air temperature Short term isotope variations are partly influenced by changes of relative humidity, but it is the long term annual temperature fluctuations which are mainly responsible for the deuterium variations in the rings Long term deuterium variations in* Picea *record climatic changes of the past and also reflect the deuterium content of the annual precipitation*

NATURAL, stable isotopes are used more and more frequently in the field of palaeoclimatic research Apart from ^{18}O thermometry[1,2] on sea cores, measurement of the deuterium content of plants opens new aspects for palaeoclimatic investigations

The basic idea of the deuterium method is that the natural deuterium content of chemically bound hydrogen in plants is correlated with that in precipitation[3] As the deuterium content of precipitation in middle and high latitudes depends mainly on the climate and decreases with annual mean temperature[4], the deuterium content in plants is closely related to climate[5], and tree rings should therefore bear information on past climates

Sample preparation and mass spectrometric deuterium determinations have already been described[3] The overall measuring accuracy is ± 2‰ and the results are reported in per mille deviation from Standard Mean Ocean Water (SMOW)[6]

During evapotranspiration of the leaves, complicated isotopic interactions occur between atmospheric vapour and water which is replenished from the soil The hydrogen component of the water is transformed by photochemical processes into woody matter and so evapotranspiration is a process which is important. in the development of the deuterium content of plant material

Isotopic equilibria in these interactions can be described mathematically[7]

$$\delta_l = \delta_s\,(1-h)+h\delta_v+\varepsilon_p+\varepsilon_k\,(1-h), \qquad (1)$$

where δ_l is the deuterium content of the leaf sap, δ_s that of soil water, and δ_v that of atmospheric vapour ε_p is the equilibrium separation factor which increases with decreasing temperature, ε_k is the kinetic separation factor, and h the relative humidity This formula describes the isotopic processes during evapotranspiration in leaves to a good degree of approximation[8]

The average deuterium concentration in leaves from a *Picea* was calculated for the period 1881–1970 For the calculations I used meteorological data from the Hohenpeissenberg Observatory (unpublished information and ref 9), which is 16 km east of Sachsenried, the place where the tree grew Measurements of the deuterium content of precipitation and ground water of this area indicated that $\delta_s \approx 70‰$ Because atmospheric vapour in Central Europe, contains on average, 75‰ less deuterium than does precipitation $\delta_v \approx \delta_s - 75$ (ref 10) ε_p is temperature dependent and is +93‰ at 15° C (ref 11), and ε_k (= 16‰) is independent of temperature The relative humidity in the area around Sachsenried is about 75‰, and

Table 1 Correlation coefficients between the deuterium content of *Picea* and meteorological and other parameters

	1785–1910	1910–1970	1785–1970	1785–1970

Annual temperature	0 51	0 74	0 47	0 83
Humidity	—	0 47*	0 056*	0.34†
Leaf sap	—	0 57	0 43*	—
δ_{18} ice	—	—	—	0 61

* $r_2\sigma$ = 0 49, † $r_2\sigma$ = 0 7 (beginning in 1881)

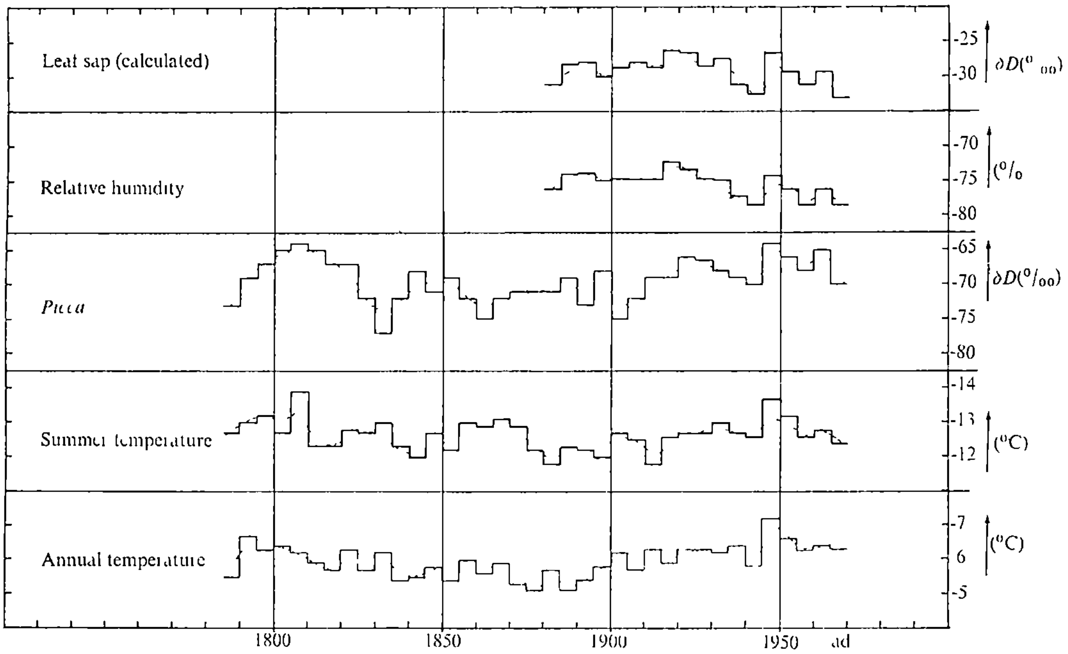

Fig. 1 Comparison between summer temperature (mean May–September), annual mean temperature, deuterium content of *Picea*, relative humidity (mean May–September) and the calculated deuterium content of the leaf sap all in the 5-yr means Dashed lines indicate the trends in the histograms

so equation (1) shows that the influence of the atmospheric vapour is more significant than the influence of the water which the plants take up

Implications of a deuterium content

From equation (1) it follows that the deuterium content should depend essentially upon the temperature and relative humidity during the growing season In order to test this conclusion the deuterium content of growth rings of a *Picea* from Sachsenried (46° 50′N, 10° 50′E), with an age of about 200 yr was determined For the period 1910–1970 each ring was analysed twice for deuterium to diminish any errors which may have arisen from the analysis of an incomplete ring Growth rings formed between 1785–1910 were analysed In each case a block of rings formed in five consecutive years was analysed and care was taken to burn the same amount of wood from each block, so that a weighted mean was not obtained

The deuterium content of each block has been compared with the summer temperature (mean May–September), the annual mean temperature, the relative humidity (mean May–September) (Fig 1), and the calculated deuterium concentration in the sap of leaves (for the same summer period) using equation (1) In order to be able to compare the results for the various possible combinations in a statistically meaningful manner the correlation coefficients for the various periods with different measuring accuracies have been calculated (Table 1) The maximum error of the correlation coefficient for the 2σ limit is given as $r_{2\sigma}$ in Table 1

In the 5-yr mean, there is a reasonable correlation between the deuterium content and the summer temperature ($r = 0\ 52$, $r_{2\sigma} = 0\ 6$) in contrast to the poor correlation with mean annual values In particular, the deuterium trend is distinctly indicated by the trend of the temperature curve A perfect correlation cannot be expected in any case, because the meteorological parameters are averaged continuously over five months—that is not the case for the deuterium content of wood On overcast days there is hardly any assimilation because of insufficient intensity of solar radiation Furthermore, the humidity still shows some fluctuations in the 5-yr mean, so some degree of influence of the humidity on the deuterium content is evident On the long term mean the humidity variations level off and the trend of the deuterium curve follows more perfectly that of the temperature curve (Fig 1)

The measuring accuracy is best for the period 1910–1970,

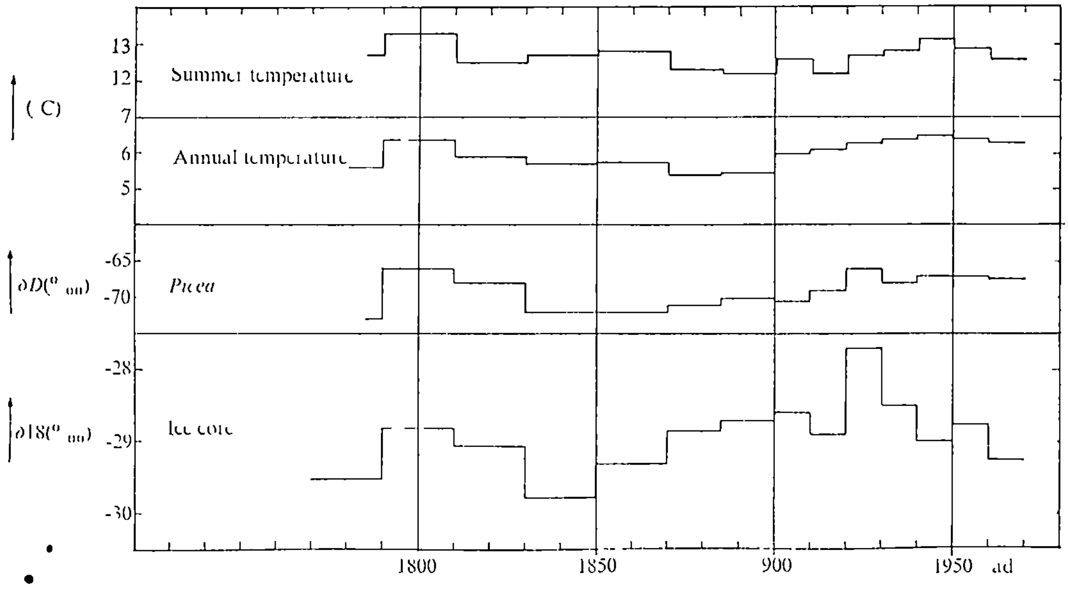

Fig 2 Comparison between the ^{18}O content of an ice core from Camp Century on Greenland and the deuterium content of the growth rings of a *Picea* from Sachsenried The upper graphs show the summer and the annual mean temperatures from the Hohenpeissenberg, Meteorological Observatory near Sachsenried

SCIENCE CO[illegible]
[illegible]

because the average of 10 single measurements is used In the period 1785–1910 the accuracy is poorer because only two single analyses are averaged (Table 1) and the time scale for the older year rings becomes increasingly inaccurate because some rings are missing

The deuterium variation of the leaf sap is smaller than that of the growth rings Presumably, that is because the calculation is based on a constant correlation between the deuterium content of atmospheric vapour and the atmospheric temperature (3‰ ° C^{-1}) for Central Europe Such a relationship, however, is an idealisation of the natural conditions, because at any one temperature, depending on the meteorological conditions, substantial variations in the deuterium content of atmospheric vapour can still occur

The growing period comprises hardly half a year, and so it must be considered whether the climatic processes during that period really reflect, to any degree, the general climatic trend of the entire year A comparison between summer and annual temperatures shows that similar trends do, in fact, occur The low temperatures of the 19th century, which caused a considerable advance of the mountain glaciers, in temperature latitudes, are indicated clearly In addition to that, a comparison of the correlation coefficients for summer and annual temperatures (Table 1—5-yr means) shows that the annual temperature correlates much better with the deuterium content of the growth rings (r = 0 47, $r_{2\sigma}$ = 0 33) than does the summer temperature (r = 0 04, $r_{2\sigma}$ = 0 33) That observation is further supported by the comparison in Fig 2 In the lower graphs the deuterium content of *Picea* is compared with the ^{18}O result from an ice core from Camp Century on the Greenland ice sheet[12] There is a good relationship, although the ice reflects the isotopic composition of the annual precipitation (r = 0 61, $r_{2\sigma}$ = 0 54) On the long term mean the relationship between the deuterium content again seems better with the annual termperature (r = 0 83, $r_{2\sigma}$ = 0 54) than with the summer temperature (r = 0 41, $r_{2\sigma}$ = 0 54) I therefore conclude that the deuterium concentration in the atmospheric vapour is a function of the climatic history of the whole year and influences the deuterium content of the leaf sap so that, even though only a relatively short growth period is measured, the results reflect throughout a whole year That is important for all palaeoclimatic investigations which use deuterium variations in biogenic material Finally, as two localities thousands of kilometres apart show similar isotopic trends, it follows that essentially global climatic changes must be responsible for the deuterium variations in *Picea*

I thank Oberforstmeister Porsch from Sachsenried, Dr A Aniol (Meteorological Observatory Hohenpeissenberg) and Professor H Moser of the Institut fur Radiohydrometrie in Munchen

Properties of hybrids between *Salmonella* phage P22 and coliphage λ

David Botstein

Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Ira Herskowitz

Department of Biology, University of Oregon, Eugene, Oregon 97403

The temperate bacteriophages P22 of Salmonella typhimurium *and* λ *of* Escherichia coli *form viable hybrids in which the immunity, early control and DNA replication genes of P22 are substituted for the analogous* λ *genes The specificity of the early control and DNA replication genes differs between P22 and* λ, *the immunity of the hybrid is identical with that of the lambdoid coliphage 21 Implications for the evolution of viruses are discussed*

The temperate bacteriophages P22 of *Salmonella typhimurium* and λ of *Escherichia coli* are very similar in functional organisation[1,2] In particular, the regions concerned with control, recombination, integration, DNA replication and lysis functions of both phages are arranged in the same order on their genetic maps (Fig 1) The phages share DNA sequence homology, as measured by DNA–DNA hybridisation[3], most of which occurs in the right arm of λ DNA[4], where the functions listed above are located These similarities are counterbalanced by profound differences between the two phages (1) P22 DNA is circularly permuted and terminally repetitious, whereas λ DNA is not permuted and has single-stranded cohesive ends[5,6], (2) The P22 genetic map is circular, whereas the map of λ is linear[7,8], (3) P22 particles have only a short baseplate structure whereas λ has an elongated tail, (4) P22 adsorbs only to *Salmonella typhimurium* whereas λ adsorbs only to *E coli*, (5) Control of lysogeny differs P22 has two regions essential for immunity and repression whereas λ has but one[11,12], (6) P22 lysogens exclude superinfecting phages in several ways beyond the immunity and repression system whereas λ lysogens display solely the immunity provided by the single repressor[13,14]

These considerations led us to inquire whether hybrid phages containing DNA from both P22 and λ could be constructed, and, if so, which blocks of P22 genes were interchangeable with analogous blocks from λ We show here that P22 DNA can be substituted in the right arm of λ to yield hybrid phages with distinctive properties The construction of P22/λ hybrid phages was accomplished independently by a different method by Gemski *et al* [15] Studies

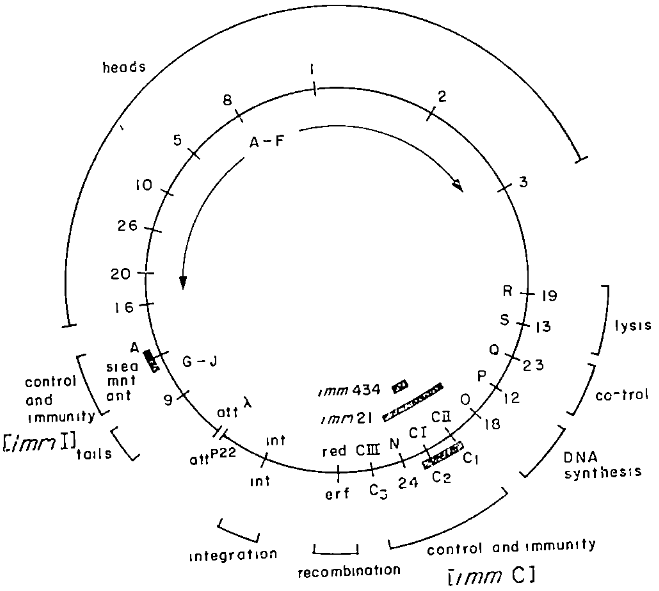

Fig 1 Comparison of the genetic maps of P22 and λ Inside the map are the λ gene designations, outside are the P22 gene designations One-to one correspondence means great similiarity in mutant phenotype The heavy bars outside indicate *imm*I and *imm*C, the heavy bars inside indicate the extent of non-homology between λ and λ*imm*21 and λ*imm*-434 The map is redrawn from Botstein *et al*[1]

with these hybrid phages indicate that P22 and the *E coli* lambdoid phage 21 (ref 16) have repressors and operators with apparently identical specificity, indicating common ancestry, on the other hand, the DNA replication and early gene control systems of P22 and the lambdoid phages are analogous but have significantly different properties

The cross

Phage P22 does not adsorb to *E coli* and phage λ does not adsorb to *S typhimurium* To get both phage DNAs into the same cytoplasm so that they might recombine, we took advantage of the ability of *E coli* episomes to be transferred between the two species of bacteria Roth and Hoppe[17] showed that the $F'lac^+pro^+$ episome of *E coli* carries a prophage attachment site for phage P22 Consequently, P22 was inserted into this episome by infection of an $F'lac^+pro^+$ *Salmonella* strain which was deleted for the P22 prophage attachment site on the chromosome The P22 carried on this episome has a temperature-sensitive repressor (*c*2 gene product), hence, the prophage is induced at high temperature in *Salmonella* strains The $F'lac^+pro^+str^s$ (P22*c*2-*ts*) *Salmonella* strain was mated with an *E coli* lac^-str^r strain, and *E coli* lac^+str^r recombinants selected Most of these recombinants were temperature-sensitive for growth and produced 20–50 P22 phage per cell at high temperature Therefore, it appears that all host components required for P22 growth are present in wild type *E coli* In contrast, it was found that λ^+ will not grow under similar circumstances in *S typhimurium*[18]

The hybrid phages described here are derived from an *E coli* lysogen-carrying P22*c*2*ts*30 prophage, when this lysogenic strain was infected with a marked λ (λ *c*I60) and the culture was shifted to 41° C a small yield of λ and P22 (about 20 of each) was produced Among the progeny were recombinants (about 0 01%) with the host range of λ (that is, adsorption to *E coli*), but which had acquired a new immunity (that is, growth in *E coli* lysogenic for λ) In a parallel infection, nonlysogenic but otherwise identical $F'lac^+pro^+$ *E coli* strain was infected with λ *c*I60 at 41° C, no phages able to grow on *E coli* lysogenic for λ were obtained

Structure of λ*imm*P22

(*a*) The immunity region derives from P22 Since the hybrid phages were selected for their ability to grow on a λ lysogen of *E coli*, it was expected that the hybrids had a new immunity, presumably from the P22 prophage This idea was confirmed by several observations (1) The hybrid phages all have a temperature-sensitive clear plaque morphology, unlike that of the λ parent, but like that of the P22 prophage As expected if the *ts*-clear mutation affects the P22 *c*2 gene, *E coli* lysogens carrying these hybrids as prophages are induced when shifted to 41° C (2) λ phages grow on the *E coli* strain lysogenic for P22 The hybrid phages do not grow on these lysogens, indicating that they have immunity of P22 The hybrid phages grow normally on the $F'lac^+pro^+$ *E coli* strain which does not carry a P22 prophage (Table 3) (3) In other experiments, hybrids were constructed between λ and P22 prophages which carry *amber* or *ts* mutations in the genes near the *c*2 gene, in these cases, the hybrid phages inherit the *amber* or *ts* phenotype (S Hilliker, unpublished work)

These bybrid phages—obtained from the cross of λ*c*I60 with P22*c*2*ts*30—are called λ*imm*P22 by analogy with λ*imm*434 and λ*imm*21, λ hybrids with the immunity specificity of the lambdoid phages 434 and 21 (refs 19 and 20)

(*b*) Tail genes derive from λ Since the hybrid phages can grow on *E coli* strains, the genes determining host range must be inherited from the λ parent As anticipated, the hybrid phages are as sensitive as λ wild type to antibodies raised against λ wild type phage particles Furthermore, mutants of *E coli* lacking the λ receptors for adsorbtion are also resistant to the λ*imm*P22 hybrids (data not shown) λ*imm*P22 hybrids, therefore, have tail genes from λ

(*c*) Prophage insertion specificity derives from λ The hybrid phages can integrate into an *F′gal att*λ episome and be tranferred into another strain by conjugation λ*imm*P22 hybrids, therefore, have the insertion specificity (attachment site and *int* gene) of λ (S Hilliker, unpublished work)

(*d*) The source of other genes in the hybrids is as follows Marker rescue tests were done by plating λ *amber* mutants on su^- (nonpermissive) lysogens of λ*imm*P22 hybrids For comparison, phage were also plated on lysogens of λ*imm*434 (known to substitute none of the essential λ genes tested) and λ*imm*21 (known to substitute only gene *N*)[21] Recombinants with immunity of λ and wild type gene function

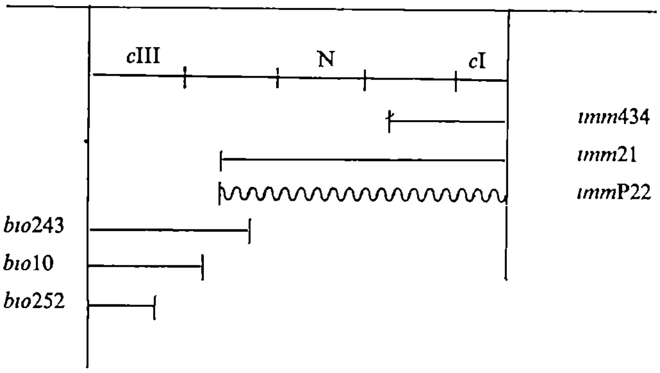
Lysogens were constructed in strain 594 which is strongly nonpermissive for *amber* mutants Phage were plated either for efficiency (numbers) or as a serial-dilution spot test Plates were incubated at 30° C since λ*imm*P22 carries a c_2ts allele λ*imm*21 and λ*imm*434 were described by Herskowitz and Signer[21]

Table 2 Lefthand endpoint of nonhomology region



Frequency of recombinants

	immP22	λimm21	λimm434
λ*bio*243	$<2\times10^{-7}$	$<2\times10^{-5}$	2×10^{-2}
λ*bio*10	2×10^{-3}	4×10^{-4}	—
λ*bio*252	1×10^{-2}	6×10^{-3}	

Crosses were done as standard λ crosses without ultraviolet-irradiation as described by Signer and Weil[33] Recombinants were scored by their ability to grow on *E coli* lysogenic both for P2 (which selects *bio*) and λ (which selects against *imm*λ) None of the parental phages grown in parallel produced progeny capable of growth on the test dilysogen at a frequency in excess of 2×10^{-5} In the diagram, solid line indicates λ DNA replaced

were scored Table 1 shows that functional alleles of mutations in λ genes *Q, S, R, B* and *J* can be rescued, whereas the functional alleles of mutations in λ genes *N, O* and *P* cannot

The appearance of nondefective *imm*λ recombinants in the cases of *Q, S, R, B* and *J* mutants indicates that the λ*imm*P22 prophage contains either (1) the wild type allele from its λ parent, or (2) an analogous and functionally compatible allele from the P22 parent which is separable from *imm*P22

Failure to find functional *imm*λ recombinants in the cases of *N, O* and *P* mutants indicates that the hybrid phage does not carry these genes from the λ parent, and that the analogous P22 genes in the hybrid phage cannot be separated from the P22 immunity region of the hybrid phage

These results suggest that in λ*imm*P22 the immunity region of λ has been replaced by an analogous region from phage P22 (Fig 1) The region of nonhomology (or non-compatible function) between λ*imm*P22 and λ in the hybrid apparently includes genes *N* to *P* on the λ genetic map The analogous region in P22 (*imm*C and its flanking genes) has been found to contain genes with functions analogous to those of λ (gene control and DNA replication in addition to immunity specificity)[1,22,23]

We have performed additional crosses to determine in detail the lefthand endpoint of the nonhomology between phages λ*imm*P22 and λ λ*bio*10*imm*P22 but not λ*bio*243-*imm*P22 recombinants can be formed, indicating that the region of nonhomology extends to between the endpoints of these deletions Table 2 shows that the lefthand endpoint of nonhomology of phage λ*imm*21 falls within same region Since the *imm*21 substitution replaces the λ *N* gene, these crosses provide independent evidence that the *imm*P22 substitution also replaces λ gene *N*

Functional comparisons of λ/P22 hybrids

(a) λ*imm*P22 has the same immunity specificity as λ*imm*21 λ*imm*P22 hybrids establish and maintain lysogeny normally, less than 1% of the cells in a lysogenic culture are cured These lysogens are immune to superinfecting phage of the same genotype We tested various lambdoid phages for the ability to grow in λ*imm*P22 lysogens We also tested the ability of λ*imm*P22 to grow in lysogens of these lambdoid phages As Table 3 shows, λ*imm*P22 grows normally in all lysogens except those carrying prophages with the immunity of phage 21 or P22 Furthermore, λ*imm*P22 lysogens are immune to those phages carrying the immunity region of phage 21 or P22 This result implies that the *imm*C repressor and operators of phage P22 are functionally equivalent to the repressor and operators of phage 21 and different from those of all other lambdoid phages tested It should be emphasised that the *imm*C region of P22 is sufficient to control the hybrid phage λ*imm*P22, even though two immunity regions (*imm*I and *imm*C) control wild type P22 This result means that *imm*C is probably the primary regulator of repression and immunity in P22

(b) We have obtained λ/P22 hybrids with substitutions of regions other than immunity To construct hybrids different from λ*imm*P22, the *F′lac*⁺*pro*⁺(P22) strain was infected with various defective λ mutants For example, this strain was infected with λ carrying *amber* mutations in both genes *Q* and *S* *amber*⁺ recombinants with the host range of λ were selected by plating the progeny phage on *su*⁻ nonlysogenic *E coli*, recombinants were obtained at frequencies between 10^{-3} and 10^{-4} These recombinants have less DNA than the Q^-S^- parent, as judged from their ability to grow in the presence of chelating agents[25] Most of these phages were able to grow in λ*imm*P22 or λ*imm*21 but not in λ lysogens, indicating that they had retained the immunity specificity of the λ parent If these hybrid phages were formed by the minimal recombination event (a double crossover), they should carry the P22 region analogous to the *Q*–*S* region of λ Since both phages in this region confer the specificity of late gene expression[1 25], these hybrids should contain the head and tail genes of λ and the late gene control region from P22 Preliminary studies (P Toothman and

Table 3 Immunity of λ*immP*22

	F′*lac* (P22)	F′*lac*	No prophage	λ*immP*22	λ*imm*21 (b_5)	λ*imm*434	λ+

These experiments represent serial-dilution spot tests + indicate an efficiency of plating of near 1 and 0 represents no plaques seen, to a sensitivity of less than 1 in 10^5 The F′*lac* strains are the same as those used to isolate λ*immP*22, the other lysogens are in strain 594 The λ*imm*21 phages are derived from 21*hyc*I (ref 20) or from λ *b*5 where indicated

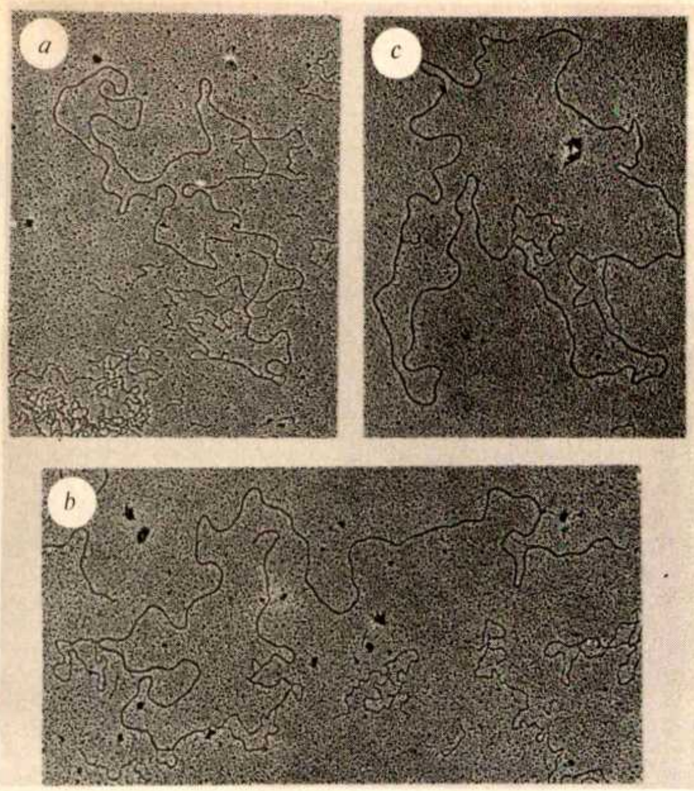

Fig. 2 Electron micrographs of DNA heteroduplexes prepared by the formamide method[34] from purified phage DNA. The b_2 deletion serves as a position and informal calibration marker. *a*, λb_2/λ*imm*P22 heteroduplex molecule; *b*, λ/λ*imm*21b_2 heteroduplex molecule; *c*, λ*imm*21b_2/λ*imm*P22 heteroduplex molecule.

S. Hilliker, unpublished work) indicate that the λ late gene positive regulator (*Q* gene product) can turn on late genes from such prophages. The *Q* genes of λ and P22 may, therefore, have the same specificity.

Physical mapping of λ*imm*P22

The genetic tests presented above indicate that the λ*imm*P22 chromosome is essentially a λ chromosome in which the region from the left of gene *N* to some point beyond gene *P* of λ has been substituted by DNA encoding the analogous functions of phage P22. In addition, λ*imm*P22 and phage 21 have the same immunity specificity, suggesting that 21 and P22 share sequence homology in their immunity regions. To test these views directly, we constructed DNA heteroduplexes between all combinations of wild type λ, λ*imm*21 and λ*imm*P22. Each pair of DNAs differed also by a deletion (*b*2, in the central region of λ DNA) in order to orient the heteroduplex molecules and to provide an internal calibration for measurements. As Figs 2 and 3 show, the heteroduplexes confirm the genetic results; clearly λ*imm*P22 has a DNA substitution in the right arm of λ; λ DNA sequences are replaced by nonhomologous sequences from P22.

The regions of nonhomology between the three pairs of phages (λ/λ*imm*21, λ/λ*imm*P22 and λ*imm*21/λ*imm*P22) all begin at about the same point at the left (14.1—14.6 units from the *b*2 deletion). The *imm*21 and *imm*P22 substitutions therefore have approximately the same lefthand endpoint of nonhomology with respect to λ DNA. Since the *imm*21 substitution replaces the *N* gene of λ, the *imm*P22 substitution must likewise remove the *N* gene of λ. These conclusions confirm the results of recombinational studies shown above (Table 2).

The region of nonhomology between λ and λ*imm*21 is known to end to the left of λ genes *O* and *P* (ref. 26). The righthand endpoint of the major region of nonhomology between λ*imm*P22 and either λ or λ*imm*21 extends well beyond the point of nonhomology between λ and λ*imm*21 (Figs 2 and 3). Comparison with the physical map of Davidson and Szybalski[26] indicates that λ*imm*P22 must have DNA nonhomologous with λ extending to the right of λ gene *P*. Therefore, as suggested by earlier genetic results, λ*imm*P22 has a substitution covering the λ DNA replication genes and origin of replication. We show below that λ*imm*P22 behaves as if it has a *P* gene different from that of λ.

Three small regions of nonhomology between λ*imm*P22 and either λ or λ*imm*21 are found at the far right of the DNA heteroduplexes. The last of these is about 10.0 λ units from the right end of the DNA. If λ*imm*P22 were formed by only two crossovers between λ and P22 DNA, then the crossover on the right must have occurred somewhere to the right of this point. If this be the case, the existence of homology to the left of this point (between the small bubbles) suggests that there is natural homology between P22 and λ DNA in this region. Alternatively, λ*imm*P22 may have been formed by multiple crossovers between λ and P22 DNAs, such that only the three small nonhomologous regions are from P22. We favour the view that λ*imm*P22 resulted from two crossovers, since DNA–DNA hybridisation measurements[4] indicate that λ and P22 DNAs share 18% homology in the right arm.

Whereas the heteroduplex between λ and λ*imm*P22 shows a large region of nonhomology beginning at λ gene *N*, the heteroduplex between λ*imm*P22 and λ*imm*21 shows only a short region of nonhomology. To the right of this region is an equally short region of homology followed by another large region of nonhomology. The existence of a homologous region implies that the *c*I region of λ*imm*21 and the *c*2 region of λ*imm*P22 are not only functionally similar, but are also coded by homologous sequences in the DNA. In support of this placement of the homology to the repressor genes of the two phages, recombinants have been obtained with crossovers between the operators (S. Hilliker, personal communication). The repressor gene sequence homology suggests that the repressors of phages P22 and 21 have a common ancestry.

Control and replication genes

Physical and genetic mapping indicates that the *imm*P22 substitution replaces λ genes *N*, *O* and *P* with analogous genes (24, 18 and 12) of P22 (Fig. 1). This phage can, therefore, be used to study the behaviour of these P22 genes in an *E. coli* host. We have found that λ*imm*P22 hybrids grow normally in certain *E. coli* mutants (*gro*P$^-$, *gro*N$^-$, and *nus*$^-$) which fail to support λ growth (Table 4).

*Gro*P$^-$ mutants of *E. coli* have alterations of a host replication function (*dnaB*) which apparently must interact with the λ *P* gene product for successful λ replication[27]. Since λ*imm*P22 grows in these mutants, the P22 gene product analogous to *P* gene product either interacts with *dnaB* in a different manner or perhaps not at all. It should be noted that *groP*$_{A}$ and *groP*$_{B}$ mutations, known to lie in the

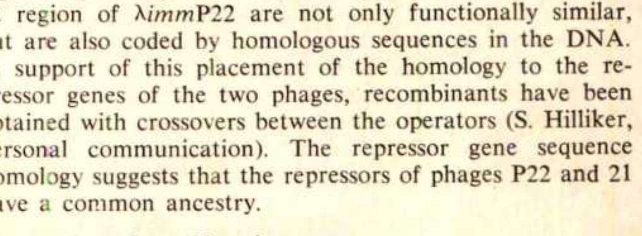

Fig. 3 Summary of measurements of DNA heteroduplexes. All the numbers are averages of at least eight molecules and are normalised to the total length of λ DNA. The locations of the λ genes are taken from Davidson and Szybalski[26].

Table 4 Efficiency of plating on bacterial mutants unable to support growth of λ

Host	λ+	λ*imm*P22	λ*imm*21
gro$^+$	(1)	(1)	(1)
groP$_{A15}$ (*dnaB*)	2×10^{-6}	1.1	5×10^{-6}
groP$_{B560}$ (*dnaB*)	2×10^{-6}	0.7	3×10^{-6}
groP$_{AB756}$	2×10^{-6}	0.07	3×10^{-5}
groN$_{785}$	2×10^{-6}	1.1	0.9
nus$^+$ (42° C)	(1)	(1)	(1)
nus (42° C)	2×10^{-6}	1.0	1.0
nus (30° C)	1.0	0.7	0.7

The *groP* and *groN* mutants are described in refs 27 and 29. *nus* strains are described by Friedman [30]. Figures in parentheses indicate normalisation to this value. All strains are nearly isogenic with either *gro*$^+$ or *nus*$^+$. Two independent λ*imm*P22 hybrids were tested.

dnaB gene[28], do not affect growth of λ*imm*P22, whereas the *groP*$_{AB}$ mutation, which is known to lie outside *dnaB*. (I.H., unpublished result), might have some effect on growth of the hybrid phages.

E. coli mutations *gro*N$^-$ or *nus*$^-$[29,30] block early λ transcription, probably by affecting the function of the early gene positive regulator, N protein. λ*imm*21 is able to grow in these bacteria (Table 4); λ*imm*P22, likewise, grows normally in *gro*N$^-$ and *nus*$^-$ mutants under conditions completely restrictive for λ growth, indicating that the early genes are regulated differently from λ.

From the behaviour in these *E. coli* mutants, it is clear that the early gene control and DNA replication genes of P22 have specificities distinctly different from λs when assayed in the same genetic background.

Implications for virus evolution

The formation of viable hybrids between coliphage λ and the *Salmonella* phage P22 shows that the similarity between these two phages in the arrangement of functions on their genetic maps is the result of a substantial degree of common evolutionary ancestry. We imagine that the hybrid phages were formed by phage-specified or bacterial recombination rather than "illegitimate recombination"[31] because of the relatively high frequency with which they are formed. Not only are viable hybrids formed, but the immunity specificity of P22 and phage 21 are identical, both in function and, to the resolution afforded by heteroduplex mapping, in nucleotide sequence. Similarly, the *Q* gene of λ and the analogous gene (gene 23) of P22 seem to be functionally identical.

A second striking fact about these hybrids is the extent to which nonhomologous genes controlling DNA replication, regulation and immunity of phage P22 remain fully functional when inserted into the chromosome of phage λ. Also notable is the retention of regions of homology flanking nonhomologous segments of DNA which contain nonidentical genes such as those controlling DNA replication. The conclusion which emerges is that evolution of the lambdoid phages (which must now include P22) appears to have proceeded within regions of function which have been selected for the ability to form viable combinations with functional segments from other members of the lambdoid phage group. Since P22 and λ have different bacterial hosts, selection must have maintained this functional and recombinational compatibility for at least the time in evolution since *E. coli* and *S. typhimurium* diverged. It should be noted that *Salmonella* and *E. coli* can exchange genetic material and have similar genetic organisation[35]. Perhaps the enteric bacteria have themselves evolved by a mechanism similar to that suggested for bacteriophages.

Our view of bacteriophage evolution depends on the clustering of related functions on the genetic map[31-34]. The idea that such clustering might be selected through hybrid formation has been advanced as well. But, the idea that the lambdoid phage "races were derived from still other races by re-assortment of unlike segments" the concomitant idea that "presumably both the diversity [of the functional segments] and the capacity to form hybrid recombinants have served a joint evolutionary purpose" was first clearly formulated by Hershey[32]. This idea must now be taken to extend across the species lines of the enteric bacteria.

Heteroduplex studies of the DNA of the lambdoid phages[36,37] and of the lytic T series of coliphages[38,39] support this view of bacteriophage evolution. One can see in the heteroduplexes the whole range of evolutionary divergence: at some points, entire regions of function are nonhomologous and at other points the region of nonhomology may involve only a single gene or even a part of a gene[40]. Although the principle of exchange of functional regions might apply to all bacteriophages, not all phages seem to be in the same group. For example, the temperate coliphages P2 and 186 form viable hybrids with each other (unpublished results of B Egan, H. Younghusband and R. B. Inman) but not, thus far, with the lambdoid phages; similarly, the lytic coliphages T3 and T7 appear to belong to a group separate from that containing phages T2, T4 and T6.

In conclusion, we suggest that evolution proceeds by diversification within segments encoding particular functions: each segment retains functional compatibility and recombinational homology so that reassortment among them is easy and frequent. We imagine that this idea might apply quite generally to bacteriophages, and, indeed, to all viruses, including those of mammals. One might expect therefore that functional hybrids among viruses of quite divergent host species might frequently be encountered.

We thank Sandra Hilliker and Penny Toothman for allowing us to use unpublished results, Bik-Kwoon Tye for initiating work on the heteroduplex, David Friedman and Bill Dove for phage and bacterial strains and Van Jarvik for technical assistance. LETTERS TO NATURE

Distance to Cygnus X-1

THERE has been much discussion concerning the X-ray object Cygnus X-1 and its optical counterpart, HDE226868, a highly reddened star of type O9 7 Iab (ref 1) The O star is a single-lined spectroscopic binary, and various assignments of the minimum mass of the secondary, taken to be the X-ray object, suggest that the latter is a black hole These conclusions are dependent on the mass of the O star being ~ 20–30 $M_{\odot}$, as would be the case if the star were 'normal' for its luminosity class But the possibility of heating of the primary by the nearby X-ray object, and the spectroscopic indications of mass loss[2], indicate that such an assumption is unsafe In order to determine the mass of HDE226868, a more complete spectroscopic analysis, in which the effective temperature and surface gravity are deduced, and a determination of luminosity (from the distance to the object) are necessary The distance to the object is crucial to the problem, because once the effective temperature and gravity of the O star are known, the mass will vary as the square of the distance An error in the distance by a factor of about two means that the model for the X-ray source need not include a black hole

Accurate estimates of the distance to HDE226868 have recently been claimed by Margon *et al*[3] and Bregman *et al*[4] who give 2 5 kpc Such a large distance favours the black hole model Both works used the reddening produced by interstellar dust as a distance indicator A consistent distance–reddening relationship has been assumed for this region of the sky The evidence for this needs to be examined closely

Interstellar reddening is particularly irregular in the Cygnus region The absorbing clouds of dust collectively form the Cygnus Rift, in which there are many highly reddened OB stars Bregman *et al* showed that HDE226868 is highly reddened compared to the objects—mostly F stars—in their small field of view Apart from the fact that HDE226868 is located extremely near, or actually within, the Great Rift, it is clear that it has photometric properties very similar to reddened O stars in this same region surveyed by Johnson and Morgan[5] This, of course, does not necessarily imply that the object is a normal O star close to the main sequence Plotting the colours of HDE226868 measured by Bregman *et al* ($B-V=+0\ 81$, $U-B=-0\ 30$) on a reproduction of Johnson and Morgan's two-colour diagram (Fig 1), shows that it is not anomalous there are many O stars in this area which are more highly reddened

The relationship between total extinction, A_V (commonly taken to be $3E(B-V)$), and distance for fields in the vicinity of the Milky Way has been investigated by Neckel[6] Neckel was unable to deduce any relationship between A_V and distance within a region centred on $l^{II}=73°$, $b^{II}=0°$, which is extremely close to HDE226868 That survey is, however, considered by Margon *et al* to be inapplicable because Neckel's fields were wide enough to include regions where large changes of absorption could occur over small angular scales Margon *et al* attempted to overcome this difficulty by selecting stars within 50′ of

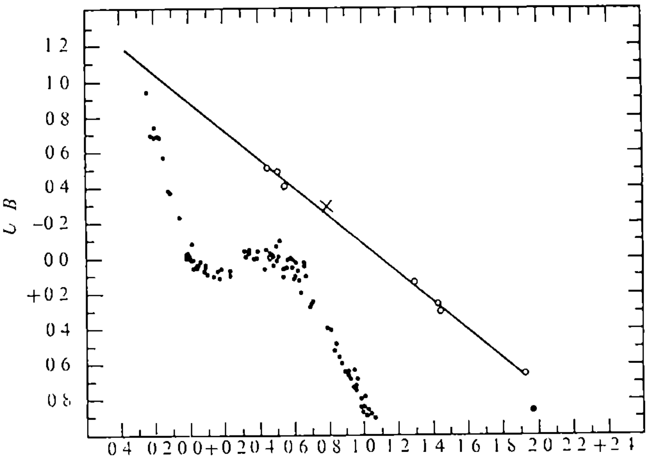

Fig 1 Two-colour plot for reddened O stars in Cygnus from Johnson and Morgan[5] ●, unreddened main sequence stars (from types B1 to K3), ○, O stars in the Cygnus Rift Region, × HDE226868, from the colours of Bregman *et al*[4]

HDE226868 This procedure was clearly not successful, because even at distances below 1 kpc there is an extremely large scatter of points in their plot The extrapolation of such data to greater distances is thus hardly justified The same applies to the plot of $E(B-V)$ against distance for the survey of stars[4] within 30′ of HDE226868 In this case, an independent distance check is provided by the Cepheid V547 Cyg, for which $d=6\ 6$ kpc, about two and a half times greater than would have been estimated from the assumed $E(B-V)$ against d relationship

We therefore conclude that this region is extremely patchy over angular scales as small as 1° This is confirmed by Lynds'[7] survey of dark nebulae which shows not only general patchiness but also the presence of extremely small, dark nebulae The space density of these tiny nebulae may, moreover, be underestimated because of the lack of sufficient background illumination If these objects are representative of the familiar 'Bok globules', then many may have linear dimensions of only 0 05 pc (ref 8), and would therefore subtend only 10″ at a distance of 1 kpc As the reddening produced by the globules is as high as $A_v \sim 5$ magnitudes, large extinction changes can occur over areas of sky which are very much smaller than those covered by either Margon *et al* or Bregman *et al*

Because of the extremely complex nature of the Cygnus region, and the fact that the only independent distance check is so widely in error, the quotation of a distance to ± 16% by Margon *et al* cannot be taken seriously At present we consider that it is over-optimistic to expect reddening measurements to be able to provide the distance of HDE226868 to the required accuracy Until there is a far more accurate determination of the distance of this object it seems premature to suggest that the X-ray source is a black hole

High energy radiation from white holes

COMPARED to black holes, their time-reversed versions, white holes have attracted little attention from theoreticians Here we point out possible ways in which white holes may be useful to high energy astrophysics

Basically a white hole is an object exploding from a highly dense or a singular state It may be a case of delayed big bang[1] in a Friedman universe, or it may be an instance of a collapsing object reversing implosion to explosion For the latter possibility unconventional equations of state[2] or negative energy fields[3] are required if the theoretical framework is that of general relativity[4] We will take the white hole to be an object exploding from a singularity and obeying Einstein's equations of gravitation subsequent to the singular event Before turning to the astrophysical implications we calculate the spectral features to be expected from a white hole

For simplicity we make the following assumptions (1) The white hole emerges from the singularity as a spherical object of uniform density and zero pressure in the comoving frame of the outward moving particles, (2) the light emitted by the white hole is monochromatic and is being emitted radially outwards from the surface at a uniform rate in the comoving frame of reference, (3) the space-time exterior to the object is empty

The comoving frame of reference in the interior will be denoted by coordinates (r, θ, Φ, t) in terms of which the line element within the object is given by

$$ds^2 = c^2\,dt^2 - S^2(t)\,[dr^2/(1-\alpha r^2) + r^2\,(d\theta^2 + \sin^2\theta\, d\Phi^2)] \qquad (1)$$

where c = speed of light, $S(t)$ is the expansion factor and α a parameter related to the mass M and the comoving radius r_b of the object by

$$2GM = \alpha r_b{}^3\, c^2 \qquad (2)$$

The similarity of equation (1) to the Robertson–Walker line element of cosmology is well known Also, if we change t to $-t$, equation (1) represents a freely collapsing ball of dust

For convenience we will measure t from the instant of explosion so that $S(0) = 0$ For $t>0$, $S(t)$ satisfies the equation

$$S\dot{S}^2 = \alpha c^2\,(1-S) \qquad (3)$$

so that it attains its maximum value $S = 1$ at

$$t = t_0 = \pi/(2c\sqrt{\alpha}) \qquad (4)$$

We will investigate light emission from the white hole in the interval $0<t<t_0$

The space exterior to the white hole is described by the Schwarzschild line element

$$ds^2 = [c^2-(2GM/R)]\,dT^2 - dR^2/[1-(2GM/c^2R)] - R^2\,(d\theta^2+\sin^2\theta\, d\Phi^2) \qquad (5)$$

A typical Schwarzschild observer has R = constant, θ = constant, Φ = constant We wish to calculate the spectrum of radiation from the white hole as seen by a Schwarzschild observer with $R = R_1 \gg 2GM/c^2$. In accordance with our assumption (2) we will take the luminosity spectrum of the white hole as $L\,\delta(\nu-\nu_0)$, where L = constant

To calculate the spectrum received at R_1, define

$$S = \sin^2\theta,\ 0 \leqslant \theta \leqslant \pi/2 \qquad (6)$$

Then θ as a function of comoving time coordinate t is given by

$$t = (2t_0/\pi)\,(\theta - \sin\theta\cos\theta) \qquad (7)$$

The white hole bursts out of the Schwarzschild radius at $t = t_c$, $\theta = \theta_c$, where

$$\sin\theta_c = (\alpha r_b{}^2)^{\frac{1}{2}} \qquad (8)$$

Suppose two successive light signals are sent out from the surface at comoving instants t and $t+dt$ and are received by the observer at R_1 at instants T and $T+dT$ measured in the Schwarzschild coordinate Then a straightforward calculation shows that

$$dT/dt = \sin\theta/\sin(\theta+\theta_c) \qquad (9)$$

So an electromagnetic wave of frequency ν_0 emitted from the surface appears to the receiver to have the frequency

$$\nu = \nu_0 \, [\sin(\theta+\theta_c)/\sin\theta] \qquad (10)$$

A result of this type but in different forms had been obtained earlier by others[5,6] but the above form is suitable for working out the spectrum of the radiation as seen by the Schwarzschild observer Under our assumption (2), $L/h\nu_0$ photons of frequency ν_0 are being emitted per unit t-time from the surface The number emitted in the interval $[t, t+dt]$ is therefore $L dt/h\nu_0$ The same number must be received in the interval $[T, T+dT]$, but with frequencies in the range $(\nu, \nu+d\nu)$ where $d\nu$ is related to dt through equations (7) and (10)
A simple calculation gives

$$dt = (4t_0\nu_0^3 \sin^3\theta_c \, d\nu)/(\pi \, (\nu^2+\nu_0^2-2\nu\nu_0 \cos\theta)^2) \qquad (11)$$

Writing $E = h\nu$, $E_0 = h\nu_0$, the number of photons in the range $[E, E+dE]$ received from the white hole per unit area at $R = R_1$ is given by

$$N(E)dE = (Lt_0/\pi^2R_1^2)E_0^2\sin^3\theta_c dE/(E^2+E_0^2-2EE_0\cos\theta_c)^2 \qquad (12)$$

For $E \gg E_0$

$$N(E) \, dE \cong Lt_0 \, E_0^2 \, (\sin^3\theta_c/\pi^2 \, R_1^2) \, dE/E^4 \qquad (13)$$

The energy spectrum $I(E)$ is given by

$$I(E) = EN(E) \propto E^{-3} \qquad (14)$$

This is the spectrum at the high energy end under the simplifying assumptions made here More general (and perhaps more realistic) assumptions can lead to different types of spectra which we have also worked out We now wish to indicate possible fields in high energy astrophysics where white holes may find applications

(i) The hard electromagnetic radiation from white holes situated at the centres of, say Seyfert galaxies, can be a source of background X and gamma radiation The energy spectrum (14) seems, at first sight to be too steep compared to the observed[7] spectrum $\propto E^{-1\ 2}$ But absorption effects in the gas present in the nuclei surrounding the white hole tend to flatten the spectrum given by equation (14) Detailed calculation with available data[8,9] shows that these absorption effects can in fact flatten the E^{-3} spectrum to $\sim E^{-1}$ form in the range 0 2 keV to 1 keV At lower energies, the ultraviolet radiation seems to be of the right order of magnitude to account for the infrared emission of $\sim 10^{45}$ erg s^{-1} through the dust grain heating mechanism[10]

(ii) The transient nature of X-ray and gamma-ray bursts[11] suggests a white hole origin The shape of the spectrum at the emitting end is likely to be more complicated than the very simple form assumed in the above example In general, however, the spectrum should soften with time

(iii) Although we have worked out the spectrum of photons, it is not difficult to see that similar conclusions will apply to particles of non-zero restmass provided they have very high energy It is possible therefore to think of white holes in the Galaxy on the scale of supernovae, yielding high energy cosmic rays right up to the highest energy observed

Spectrum of the cosmic background radiation between 3 mm and 800 μm

WE report the successful flight of an experiment designed to measure the spectrum of the cosmic background radiation from $\sim$3 mm to wavelengths shorter than the Planck peak for a temperature of 2 7 K The experiment was launched, to an altitude of 40 km, on March 13, 1974, from Palestine, Texas Because of an on-site computer fault, the complete data were not available to us until May 7, 1974 The instrument has been described previously[1,2] and will be discussed in detail in a future paper, we present here the results of preliminary analysis of the flight data

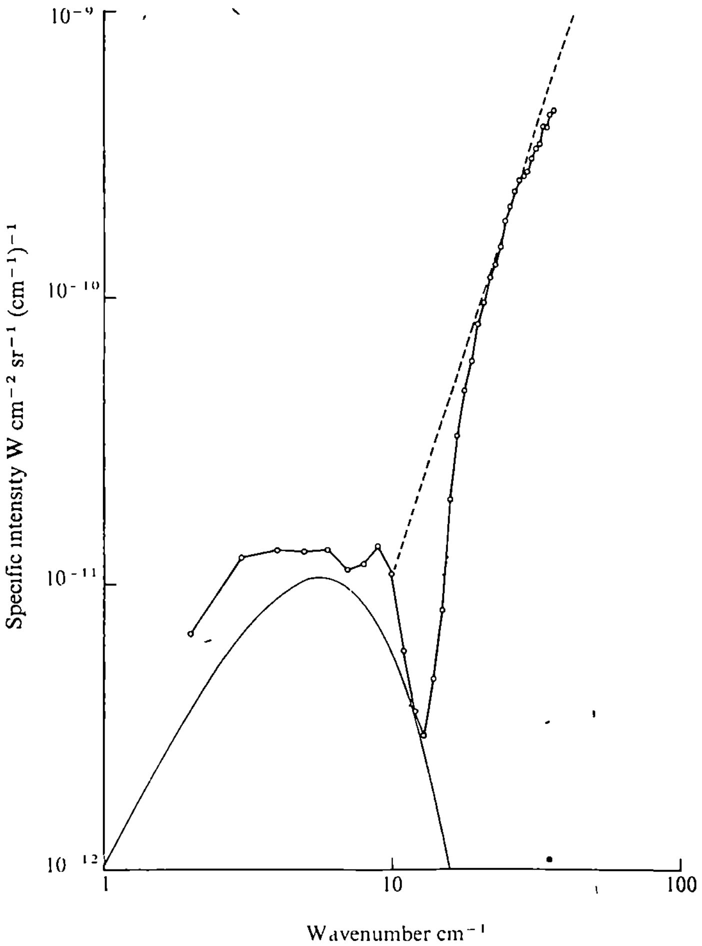

Fig 1 Cosmic background spectrum at 1 cm^{-1} resolution ——o——, Observed spectrum, — — — —, predicted window emission, , window emission using the results of Chantry *et al*[4] Smooth solid line denotes 2 7 K minus 1 4 K curve

The instrument consists of a polarising Michelson interferometer[3] cooled, by a liquid helium bath, to a temperature of 1.4 K. The processed output of the interferometer is the difference between the spectrum of radiation entering the cryostat and the spectrum of the radiation within the cryostat cavity. The interferometer received radiation at a zenith distance of 50° within a cone of semi-angle 3°, the zenith distance of the extremity of the balloon, as seen from the package, was 27°. The interferometer operated in vacuo, separated from the atmosphere by a 50 μm thick window of polyethelene, the measured spectrum should therefore consist of the cosmic background radiation plus emission from the atmosphere and the window. The designed (unapodised) spectral resolution was 0.25 cm^{-1} (Rayleigh criterion). The instrument was calibrated in the laboratory using simulated black body sources at room, liquid nitrogen, liquid hydrogen and liquid helium temperatures, for in flight calibration, we decided to use the emission from the window. The efficiency of the instrument, as a function of frequency, was deduced from the observed room-temperature laboratory spectrum.

One hour of useful time was achieved at float altitude (reached at 0145 CDT), giving 16 interferograms. Total integration time for each sampled point was 19 s. The spectra obtained from these interferograms were averaged at 1 cm^{-1} resolution, the result was divided by the instrumental efficiency function and the high frequency part fitted to the expected window emission between 20 and 30 cm^{-1} to establish a vertical scale. The fitted spectrum is shown in Fig. 1. Also shown is the spectrum of a 2.7 K black body (representing the supposed cosmic background) minus the spectrum of a 1.4 K blackbody (representing the interior of the interferometer cavity).

It is not clear why, below 20 cm^{-1}, the observed spectrum of emission from the window departs radically from that predicted. The prediction of emission, however, is difficult because of the problems of measuring absorption in thin samples. Estimates of absorption vary between experimenters, for example, we show in Fig. 1 the predicted window emission using the absorption figures of Chantry *et al.*[4] We believe, however, that the measured values (E. I. Robson and B. Carli, to be published) used for fitting are correct to (+20, −60)%. It is seen that, if the predicted emission were decreased appreciably, the measured low frequency spectrum would fall below that of 2.7 K minus 1.4 K blackbodies. We have tried the effect of assuming higher temperatures for the interferometer cavity, but to obtain any significant reduction in the height of the predicted background curve requires that the peak emission be displaced to such high frequencies as to exceed the measured values. We are therefore satisfied that the calibration is substantially correct.

Our measured spectrum is a factor less than ~2 higher than that of a 2.7 K background at frequencies below 10 cm^{-1}. A temperature ~$2^{1/3}$ higher than 2.7 K is ruled out, however, by the position of the peak. The excess may well be due to unresolved atmospheric emission[5]. In any case, this first direct spectral measurement shows very clearly the sharp decline in the spectral intensity above 6 cm^{-1}, and it would be very difficult to reconcile our observation with a background temperature higher than ~2.9 K.

We thank our colleagues at Queen Mary College who have contributed to this experiment and the staff of the National Center for Atmospheric Research Balloon Facility for their expert assistance. The project was supported by a grant from the Science Research Council. E. I. R. and J. S. H. acknowledge an SRC Associateship and Studentship respectively.

A new solar–terrestrial relationship

RECENT suggestions of interrelationships between solar activity, the Earth's magnetic field and the weather[1–3] make more urgent the need to have a reliable method of predicting sunspot activity.

Most attempts to develop prediction techniques have been associated with empirical relationships derived from the preceding behaviour of many sunspot cycles, but none of these has been really successful over any extended period. Wood[4] has re-opened consideration of the possibility[5] that solar activity may be controlled by the tidal influence of the planets. In the course of a detailed study[6] of 25 yr of geomagnetic data it was found that the phase of the solar diurnal variation of the horizontal field on quiet days, Sq(H), exhibits a marked solar control: the variability of the phase is most marked in winter and at sunspot minimum epochs. The solar cycle behaviour has now been studied over an 89-yr period from 1884, the earliest year for which International Quiet Days have been designated, and a consistent tendency has been found for the magnetic data at sunspot minimum to anticipate the magnitude of the subsequent sunspot maximum.

Both the amplitude and phase of the Sq variation vary considerably from day to day, even on very quiet days. The variability in the amplitude has been well studied, but relatively little work has been published on the variability in the phase. Here, the phase variability is discussed. Figure 1 shows the diurnal variation of the occurrence of the time of daily minimum horizontal field for all the international quiet days in the period 1884–1972. Although the most common time of H-min is between 1030 and 1130 LT, there is a wide range of appropriate times. Days for which H-min occurred within 2½ h of 1100 LT

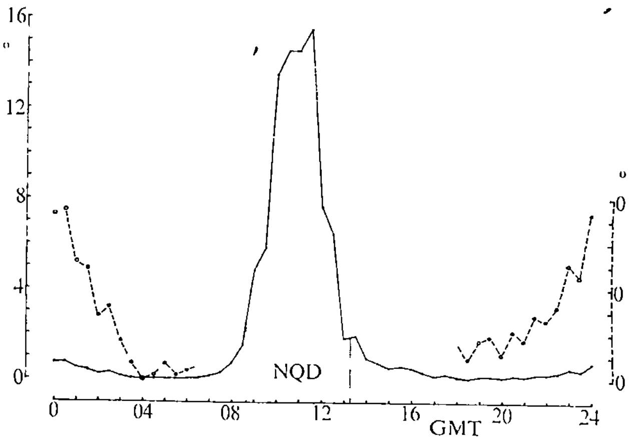

Fig. 1 Diurnal variation of the percentage number of international quiet days of the period 1884–72 for which the daily minimum horizontal magnetic field occurred within each half-hour of the day at Greenwich/Abinger/Hartland. Dashed curve is for night-time data plotted on a ×10 ordinate scale, indicated on the right-hand side.

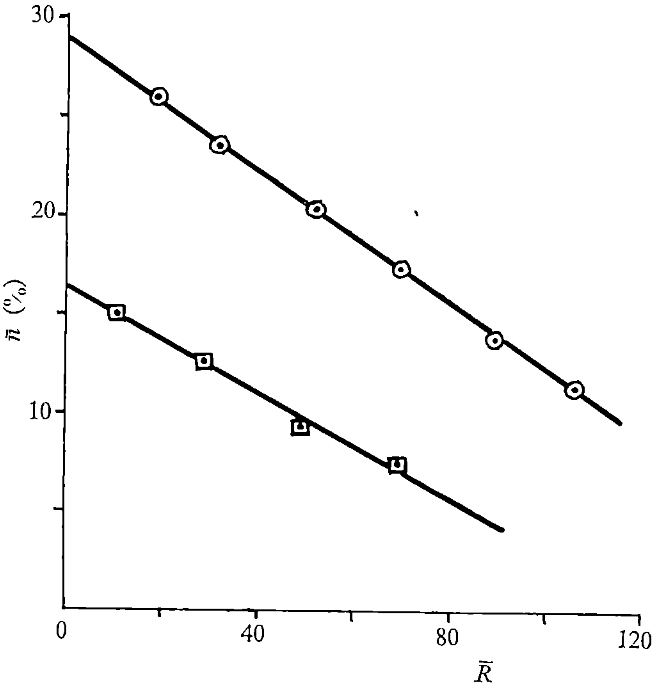

Fig 2 Average percentage occurrence of AQDs ($\bar{n}$) as a function of average sunspot number ($\bar{R}$) derived from annual mean 3-yr smoothed data averaged over increments of 20 in R Data are the same as in Fig 1, subdivided into two periods moderate activity, 1885–1936 (squares), strong activity, 1937–71 (circles)

are styled 'normal quiet days' (see ref 6) These are included within the shaded region marked NQD in Fig 1 All days outside this region are defined as 'abnormal quiet days' (AQD)

The dashed curve in Fig 1 represents a replot of the points for the night-time period on a × 10 ordinate scale, it seems that within the AQD category there is a subsidiary maximum occurrence of near-midnight minima in H At such times the conductivity of the E region of the ionosphere is so low that essentially no electric current flow can occur, so that the reduction in the horizontal magnetic field cannot be ascribed merely to positional changes of the atmospheric Sq current loops Evidence is presented elsewhere[7] for a connection between the occurrence of the more moderate AQDs and changes in the structure of the terrestrial atmosphere and the orientation of the Sq current loops, but it seems likely that the more extreme types of AQD have an extraterrestrial (probably solar) cause

It was previously found[6] that the occurrence of AQDs is primarily a winter phenomenon, and examination of the detailed seasonal variation over the period 1884–1972 shows that the most extreme AQDs occur exclusively in winter Confirmation of this inverse relationship to solar radiation is provided by the negative correlation between AQD occurrence and sunspot number, illustrated in Fig 2 In this diagram the data have been smoothed over 3 yr and the mean AQD count determined for each successive interval of 20 in sunspot number

For each group of data in Fig 2 (1885–1936 and 1937–71) there is a remarkably linear increase in the occurrence frequency of AQDs with decrease in solar activity, such that the occurrence is primarily confined to times near solar minimum Extrapolating the Fig 2 data shows that the mean occurrence frequency of AQDs for 'zero sunspots' for the 1885–1936 cycles is 16 5%, and for the 1937–71 cycles it is 29% These differences probably emphasise the relative crudity of the sunspot number as an index of solar activity The earlier group is for a period of relatively low sunspot maxima and low minima, the later group has high sunspot maxima and relatively high sunspot minima, and it seems likely that the bodily displacement of the lines in Fig 2 is conditioned by varying thresholds of solar activity which are not apparent in the values of sunspot numbers themselves The 'AQD count' parameter is interesting since it is an index which maximises at sunspot minimum, and it is conceivable that it thereby provides a rather sensitive measurement of the depth' of solar minimum not evident in the conventional sunspot number

Further insight into the solar cycle control of AQD occurrence is provided by an examination of the long-term behaviour over the eight separate solar cycles investigated Figure 3 shows a 3-yr running mean of the average quarterly values of AQD count (solid curve) and sunspot number (dotted curve) The inverse correlation between the two curves corroborates the result of Fig 2, a new feature is the striking variation in the amplitude of the maxima of the AQD count (at sunspot minima) such that the change from one cycle to the next is always in the same sense as the change in amplitude of the subsequent sunspot maxima This effect is better illustrated in Fig 4 which shows 3-yr running mean curves of the annual values of both parameters, plotted so that the time scale for sunspot number is 6 yr ahead of that for the AQD count The effect is consistently observed over the ups and downs of the past eight solar cycle maxima, and is particularly evident over the period 1920–72 when after three consecutive increases in the size of the AQD count and the subsequent solar maxima (culminating in the record IGY maximum) the following maximum was significantly smaller for both parameters

It is now possible to rationalise the two lines obtained in Fig 2 when concurrent values of AQD count and sunspot number are plotted against each other Figure 5 shows a plot of the amplitudes of the cycles in each parameter, read from Fig 4, using both the ascending and descending parts of each cycle, where each AQD count amplitude is associated with the corresponding sunspot number amplitude one half-cycle ahead The approximately linear relationship shows that each change in AQD count is approximately mirrored by a proportional change in sunspot number during the corresponding part of the subsequent cycle

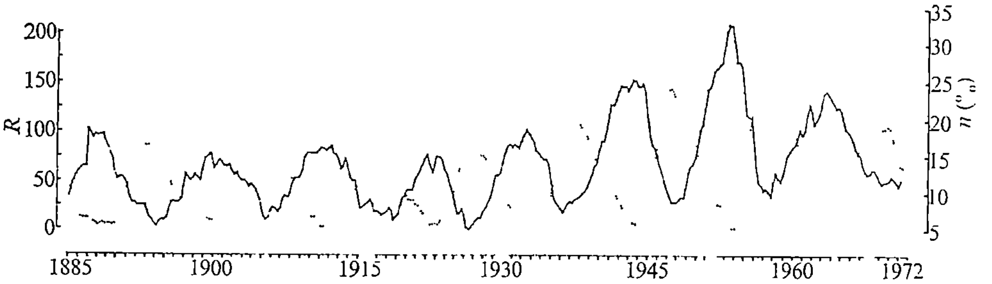

Fig 3 Three-yearly running mean of the quarterly occurrence of AQDs (n, solid curve) and of sunspot number (R, dotted curve) for the data as in Fig 1

If this relationship proves valid it implies that the Sun 'breathes' with an 11-yr period, such that the size of a solar activity maximum is determined at the very beginning of a cycle, or perhaps the very end of the preceding cycle, from the 'depth' of the solar minimum This quantity is essentially unmeasurable by the conventional sunspot number, and may be insensitive of detection by other indices of solar activity which decrease at this time The AQD count index, based on a simple analysis of the variation of the Earth's magnetic field on quiet days in winter, seems to provide a highly sensitive index of the extent of solar minima Detailed examination of the various cycles in

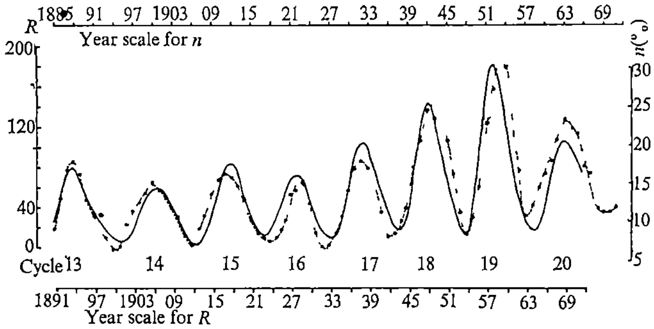

Fig. 4 Three-yearly running mean of the annual occurrence of AQDs (*n*, dashed curve, upper abscissa scale) and of sunspot number (*R*, solid curve, lower abscissa scale) for the data as in Fig 1 Note the 6-yr displacement of the time scales

Fig 3 reinforces the conclusion that an apparently close relationship exists between the two parameters separated by an interval of 5–6 yr For example, there is a marked tendency for some maxima in AQD count to be double-humped, with peak separations of about 2 yr Double maxima are a feature[8] of the solar cycle (although not always evident in sunspot number) and have been interpreted as the result of the superposition of two processes having different physical properties It is tempting to suggest that the extra large and single-humped sunspot maximum of 1957–58 arose from a coincidence of the two peaks, and it is noteworthy that the preceding AQD count maximum in 1953–54 also exhibits a single sharp peak

There are obvious difficulties in accounting for a time constant as long as 5–6 yr from the solar side But it is now evident that the solar cycle is a much more complicated periodicity than that indicated by the variation of any one index of activity The cycles in solar wind intensity and velocity, coronal green line intensity and coronal shape, and sunspot number all differ in phase from one another, with a maximum difference of at least 3 yr (ref 9) One model[10] of the Sun's magnetic field proposes that the magnetic polarity of solar polar regions changes sometime during the decline from sunspot maximum to sunspot minimum, and a solar activity centre is considered to have a 'history' related to solar happenings during the preceding years The interplanetary field near the Earth is largely controlled by the solar polar field and, in keeping with the above result, the phase of the annual variation of the interplanetary field changes about 2 7 yr after sunspot maximum[11]

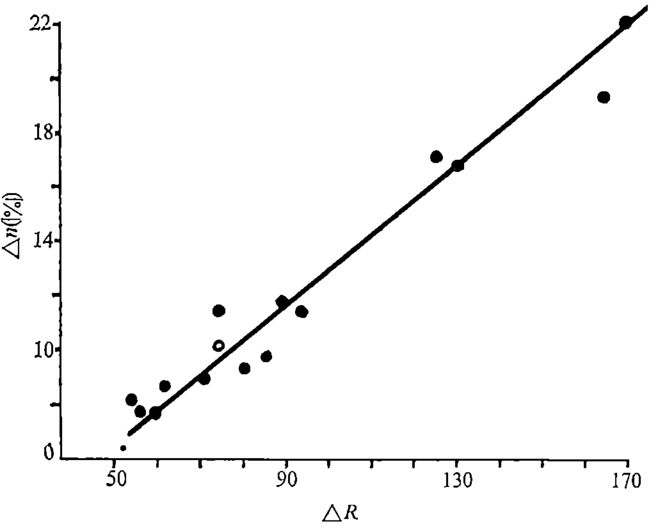

Fig 5 Amplitudes of the cycles in AQD occurrence (Δn) and sunspot number (ΔR) one half-cycle ahead, read from Fig 4 (Open circle is for the ascending part of cycle 13 and involves an estimate of the value of Δn, since no magnetic data are available for the time of the AQD minimum)

From the terrestrial magnetic side it is difficult to speculate on possible mechanisms while the essential cause of the AQD phenomenon remains obscure Comparison of Sq data for observatories spaced 1,000 km apart has shown[6] that 80% of the AQDs are common at the two sites in winter and at sunspot minimum, the agreement falls to 35% in summer and sunspot maximum This suggests that when the most variability is encountered it influences larger areas of the Earth Thus, although the AQD index, as presented, is derived from data for one station only, it reflects a regional or planetary phenomenon The unusual minima in the horizontal magnetic field at a station tend to occur around 0000 UT and are generally additional to the normal minima around 1100 LT which are associated with the ionospheric Sq current system[12] So it seems very likely that the cause of the AQD incidence is extraterrestrial, and is probably solar in origin A likely line of communication between the Sun and Earth seems to exist in the interplanetary field The varying 'sector structure' of this field, which is related to the solar magnetic field, can be seen clearly in the behaviour of the geomagnetic field at high latitudes[13] It has also been proposed[14] that during quiet days the magnitude of the total interplanetary magnetic field is partly responsible for the day-to-day variability of Sq (range rather than phase) at low latitudes Furthermore, the sector structure of the interplanetary field shows a solar cycle variation[15], and exhibits a particularly stable structure at sunspot minimum[16]

There remains the possibility that the relationship reported here is fortuitous, albeit being obeyed for a tantalisingly long period The ultimate test must await much more extensive data, or the realisation of a sound scientific basis for such a connection along the lines suggested above Meanwhile, the index could probably be refined considerably by basing it on magnetic data from several geographically separated stations, and by defining the incidence of an AQD more precisely It seems (Fig 4) that there is a long term secular trend in AQD occurrence, evidenced by the almost continual increase in the size of the minimum count of each cycle over the period covered

Rainfall, drought and the solar cycle

THE present drought devastating the Sahel, India and Ethiopia has been ascribed to long term climatic changes Winstanley[1] and Lamb[2] suggest that the general circulation of the atmosphere is slowly changing, resulting in an equatorward shift of the principal climatic belts If these shifts are part of a 200-yr cycle, as Lamb suggests, severe droughts should become more common during the next 60 yr But at Addis Ababa the 11-yr solar cycle seems to have a greater influence on rainfall variations and so the timing of droughts, than does the long term cycle

In Fig 1 we compare the variation of annual rainfall recorded at Addis Ababa during the past 72 yr (refs 3–5 and unpublished data from Addis Ababa Geographical Observatory) with the Zurich sunspot number Both sets of data have been smoothed by plotting 3-yr running means The rainfall clearly follows a cyclic pattern in which rainfall peaks and troughs precede the sunspot peaks and troughs by a few years This agreement is not caused by the smoothing technique used comparing each year's unsmoothed rainfall and sunspot values the correlation coefficient, *r*, is 0 21 (significant near the 5% level) If each year's sunspot value is compared with the previous year's rainfall, $r=0\ 29$ (significant near the 1% level) and if compared with the rainfall 2 yr before, $r=0\ 33$ (significant at better than the 1% level) Thus, there is a strong statistical correlation between Addis Ababa rainfall and sunspot number, the rainfall peaks leading the sunspot peaks by an average of 1 3 yr, the actual values for the 7 cycles being 1, 2, 3, 2, 1, 1, 0 yr It is noteworthy that, in a reported correlation between atmospheric ozone content and sunspot values[6], the ozone troughs preceded the sunspot peaks by 1 5 to 2 yr

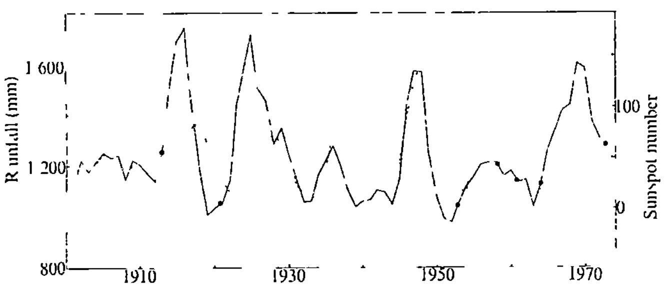

Fig. 1 Three-year running means of Addis Ababa rainfall (———) and three-year running means of Zurich sunspot numbers (— — —) ●, Known Ethiopian drought years In cases where discrepancies occur between rainfall data from refs 3 and 5 preference has been given to ref 3

The phase relationship of the two curves of Fig 1 is well maintained, but the amplitude relationship is more complicated There is a tendency for the magnitude of the rainfall peak to be inversely related to the magnitude of the sunspot peak (Fig 2*a*) A similar relationship appears for the trough values (Fig 2*b*) But since two of the data points on each graph disagree with this trend there is not sufficient evidence to state this relationship definitely

If this rainfall/sunspot cycle relationship continues then, using King-Hele's[7] prediction of 1978 as the peak year of the next solar cycle, we would expect Addis Ababa rainfall to increase until about 1976–77 and then decline to a minimum about 5 yr later Further, if the relationship shown by Fig 2*a* holds, then the predicted value of 110 for the next sunspot number peak[7] gives a value of about 1,600 mm for the next rainfall peak

It is important to find whether such a relationship applies for Ethiopia as a whole, and for other drought afflicted areas of Africa Instrumental rainfall records have been obtained only recently in most areas of Ethiopia, but a 70-yr record exists for Asmara A preliminary study of this shows little correlation with solar cycle before 1930, but a negative correlation after that date

To support the scanty instrumental data on rainfall, an indication of past rainfall troughs can be obtained from historical records of drought, and drought-induced famines To be recorded by travellers or historians a drought would have to have been severe enough, and lengthy enough, to affect seriously the life of the country, and not have been merely an isolated year of poor rainfall Figure 3 is a histogram of presently known Ethiopian drought years, since 1540 AD, as a function of years from sunspot minimum Droughts have occurred in each of the years of the sunspot cycle, but 14 of the 27 drought years occurred in the 3 yr centred on sunspot minimum Six more occurred in the years following minimum, possibly representing droughts caused by an accumulation of bad years (the effects of a long deficiency of rain persist during the first years of improved rainfall) Thus, there is some evidence that the rainfall/solar cycle relationships observed at Addis Ababa has applied for the past few hundred years over highland Ethiopia as a whole

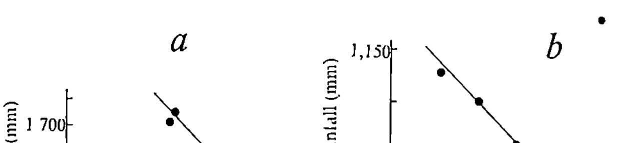

Fig 2 *a*, Rainfall cycle peak values against corresponding sunspot cycle peak values The line is a least squares fit to the solid points only *b*, As for *a* but for corresponding trough values

It may be significant that the early 1930s coincided with several changes in climate/solar cycle correlations From this time the Asmara rainfall shows some solar correlation, and for Addis Ababa, the time lag between rainfall and sunspot peaks decreased There was, at the same time, a phase change in the relationship between sunspot values and 8 m depth earth temperatures in the UK, and also phase changes in equatorial pressures and temperatures[8] Additionally, the level of Lake Victoria showed high solar cycle correlation from 1890 to 1930, but the relationship broke down after that time[8] These changes may be related to the proposed 200 and 700-yr climatic cycles which peaked at that time[1]

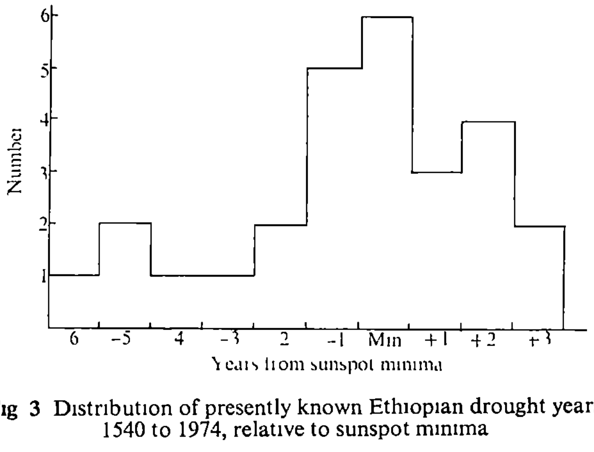

Fig 3 Distribution of presently known Ethiopian drought years, 1540 to 1974, relative to sunspot minima

An intensive study of the Indian monsoon rains[9], based upon the 50-yr records of many stations, has found significant correlations with solar cycles In regions of orographic rainfall near the Himalayas, strong, positive correlations are found, whereas in some other regions there are negative correlations Zones of positive and negative correlation are separated by areas of little correlation The Indian data illustrate that the solar influence on rainfall is spatially modulated, in unknown ways, resulting in systematic variations of the sign and degree of correlation Similar solar cycle influences should be looked for in the rainfall records of the Sahel and elsewhere

If this sunspot–rainfall relationship is substantiated by data from other stations in the Sahel and India, governments and relief organisations will have a valuable warning of periods of greatest drought danger

Dynamic implications of mantle hotspots

MOVEMENT of lithosphere plates over hotspots which are fixed relative to the mantle could explain the origin of island chains and aseismic ridges[1-4] Observations of phase velocities against epicentral distances for Tonga–Samoa earthquakes[5] show anomalies which can be interpreted as a radial and lateral inhomogeneity in the lower mantle beneath Hawaii That indicates the possible existence of deep mantle plumes

Here, I consider some implications of the mantle plume hypothesis on the basis of a simplified flow model I represent the flow of the plume by viscous flow through a pipe The Navier–Stokes equations, assuming steady state, fluid incompressibility and uniform viscosity, reduce to a simple form for the case of pipe flow The maximum flow velocity, V_z, given by the exact solution of these equations, is

$$V_z = (dp/dz)\,(a^2/4\eta) \qquad (1)$$

where a is the radius of the plume, the flow is along z axis and η is the coefficient of viscosity

$$\text{The volume flux} = (\pi a^2/2)\ V_z \qquad (2)$$

The associated energy equation, based on the same assumptions as for Navier–Stoke equations, also yields an exact solution for pipe flow, giving the temperature δT, generated by the flow

$$\delta T = \eta\ V_z^2/4K \qquad (3)$$

where K is the coefficient of thermal conductivity

Table 1 lists the temperature differences and the volume flux for a range of velocities of plume flow

The values used in computing Table 1 are $\eta = 3 \times 10^{21}$ g cm^{-1} s^{-1}, $K = 10^{-2}$ calorie °C^{-1} cm^{-1} s^{-1}, and the plume radius, a, = 75 km The most frequently quoted[2] vertical velocities of plume flow are 2 myr^{-1} It is clear that such velocities will generate unacceptably high temperatures if the frictional viscosity is of the same order of magnitude as present estimates of the mantle viscosity

With a speed of flow of 2 m yr^{-1} each plume would bring up about 18 km^3 yr^{-1} of mantle material Twenty plumes will bring up a total of 360 km^3 yr^{-1} That would be the total flux of the material moving away from the rise crests Lithosphere is created at a rate of about 170 km^3 yr^{-1}, which is the flux of counterflow towards the ridge crests The resultant drag exerted by the flow on the lithosphere will be in the direction of plate motion, that is, away from the rise crests[2] The drag can be increased by increasing either the number of plumes, or their vertical flow speeds or dimensions

If, however, the flow speed is reduced to, for instance, 3 cm yr^{-1}, temperatures would become reasonable But the total flux from 20 plumes would be reduced to about 6 km^3 yr^{-1} Then, because the total flux of flow towards the rise axes would be many times the flux away from them, the net stress on the plates would tend to close the plates rather than move them apart Thus, as well as the necessity for a source to provide adequate motive forces for plate motions it becomes necessary to find additional stresses to overcome the closing trend That adds unnecessary complexity to the problem

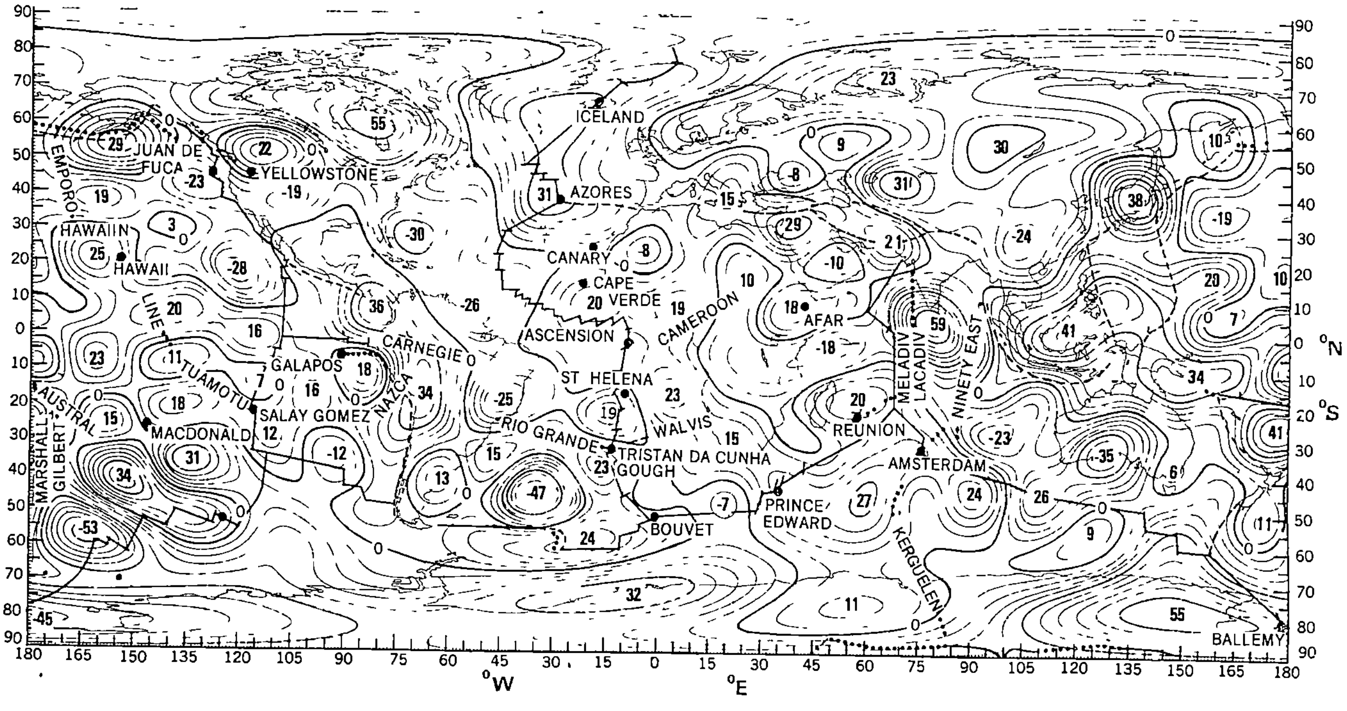

Fig 1 Relationship between proposed hotspot localities and gravity anomalies (mGal)

Table 1 Typical temperature differences and volume flux for a range of flow velocities

Flow velocity (cm yr^{-1})	Temperature difference (°C)	Volume flux per plume (km^3 yr^{-1})
200	6 75 × 10^4	18
100	1 69 × 10^4	9
10	1 69 × 10^2	9 × 10^{-1}
3	≈ 15	2 7 × 10^{-1}
1	≈ 2	9 × 10^{-2}

Therefore, either an alternative way of keeping down temperatures must be found or the idea that mantle plumes have any significant role in plate tectonics must be rejected

It may be possible to introduce variations in viscosity and conductivity, although I have assumed uniform viscosity and conductivity Both, however, are temperature dependent Therefore, the temperature, δT, generated by the flow, will be affected, but it is uncertain whether the effect would be sufficient to reduce the temperatures to a reasonable level

Thus, assuming that the results of Table 1 are correct to an order of magnitude then, if the temperatures are to be kept reasonable, some other parameter in equation (3) must be adjusted The only reasonable possibility at this stage is a reduction in the velocity of the vertical flow of the plume, perhaps accompanied by some increase in its diameter Unfortunately, that makes the mantle plume hypothesis much less attractive

It has been contended[2] that the viscous drag exerted on the bottom of the lithosphere by a typical plume, will result in the doming of lithosphere, producing a regional topographic high and a gravity excess over the area Most hotspots do indeed lie over areas of positive gravity, though very few lie directly over gravity maxima, Fig 1 shows the probable locations of the hotspots, superimposed on isostatic gravity anomalies based on gravity Model GEM 4 (Khan, M A, and Lerch, F, *et al*, unpublished) A significant number of hotspots, however, show association with negative gravity, Galapagos, Juan de Fuca, St Helena, Macdonald and Salay Gomez That contradicts the general claim that plume locations are always associated with positive gravity

Λ-type doubling in the CH molecule

Almost a year ago we set out to calculate an accurate value of the Λ-doubling in the lowest rotational level of the $X^2\Pi_{\frac{1}{2}}$ state of CH, to assist the radioastronomers, who had been searching for this species in interstellar space for some years The value we have obtained, which is reported here, represents a substantial improvement on the results of terrestrial experiments[1,2], but its significance is reduced by the astronomical observation of the species, which was reported during the course of this work[3] The result of the latter experiment indicates just how close our calculation comes to predicting the actual splitting and clearly underlines the power of the methods now available in theoretical chemistry

Van Vleck[4] has shown that the Λ-doubling of the rotational levels of a $^2\Pi$ state may be represented as a perturbation by $^2\Sigma$ states To second order, the splitting may be expressed in terms of two parameters, $(\frac{1}{2}p+q)$ and q For the lowest level of a regular $^2\Pi$ state, for which $J = \Omega = \frac{1}{2}$, the doubling is simply $2(\frac{1}{2}p+q)$, where

$$p = 4\sum\frac{\langle{}^2\Pi\,|H_{\mathrm{so}}|\,{}^2\Sigma\rangle\langle{}^2\Pi\,|B(L^+ + L^-)|\,{}^2\Sigma\rangle}{E_\Pi - E_\Sigma}$$

$$\text{and } q = 2\sum\frac{\langle{}^2\Pi\,|B(L^+ + L^-)|\,{}^2\Sigma\rangle^2}{E_\Pi - E_\Sigma}$$

where the summation extends over all vibrational levels of all $^2\Sigma$ states, the contribution from $^2\Sigma^-$ being taken as negative Matrix elements are taken over both electronic and vibrational wave functions H_{so} is the spin-orbit coupling operator, and B is the operator $h/8\pi^2\mu r^2$

An *ab initio* calculation of the parameters p and q was performed for CH by Hinkley *et al*[5] It was assumed that the electronic matrix elements were independent of internuclear distance, so that vibronic matrix elements could be factorised into electronic and vibrational integrals The Hartree-Fock orbitals calculated for the $X^2\Pi$ state by Cade and Huo[6] were used, the invarient orbital approximation was made, so that Slater's rules might be applied to the matrix elements Vibrational wavefunctions were calculated numerically from Morse curves Only the contributions of the $B^2\Sigma^-$ and $C^2\Sigma^+$ states were considered The results are shown in Table 1, they are some 20% too low

In the present work, the calculation of Hinkley *et al* was modified in several ways Herzberg and Johns[7] have shown experimentally that both $^2\Sigma$ states have maxima in their potential curves, so that the latter hardly resemble Morse curves Vibrational wave functions were therefore calculated from the extended configuration interaction potential curves of Lie *et al*[8], which represent the states rather well The functions were calculated for the hypothetical case where $J = 0$, and the effects of predissociation on excited vibrational levels were ignored The vibrational integrals obtained from these wave functions were combined with the electronic matrix elements of Hinkley *et al* to produce the result labelled (a) in Table 1

Table 1 Λ-type doubling in the $X^2\Pi_{\frac{1}{2}}$ ($v = 0$, $J = \frac{1}{2}$) state of CH

		$\frac{1}{2}p+q$ (cm^{-1})	q (cm^{-1})	Doubling (MHz)
Hinkley *et al*[5]		0 0447	0 0254	2,680
This work	(a)	0 0430	0 0245	2,576
	(b)	0 0447	0 0274	2,680
	(c)	0 0563	0 0386	3,374
	(d)	0 0552	0 0379	3,311
Terrestrial experiment[1 2]		0 0563	0 038	3,374 ± 20
Astronomical experiment[3]		0 0556	—	3,335 47 ± 0 01

The error introduced by the invariant orbital approximation was then investigated A separate set of SCF orbitals was constructed for each of the $^2\Sigma$ states from the basis set of Cade and Huo, using the ALCHEMY program[9] Electronic matrix elements were then calculated using a program written by J A Hall[10] The values now obtained for the Λ-doubling parameters (b) show that further improvements were necessary The electronic wave functions were further modified by configuration interaction, six configurations were included for the $X^2\Pi$ and $B^2\Sigma^-$ states, while eight were used for the $C^2\Sigma^+$ state Electronic matrix elements were again calculated by the Hall method, the result (c) was in close agreement with the experiment

Finally, the C I wave functions were calculated over a range of internuclear distances The electronic matrix elements were then integrated numerically over the vibrational wave functions The results (d) are within 1% of the experimental values

The Λ-doubling is predicted more accurately by this calculation than by terrestrial experimental estimates

Drag-reducing polymers and liquid-column oscillations

We report here on one of many anomalies which occur when drag-reducing polymers are dissolved in water[1–4] the damping of manometer-type oscillations

Our apparatus was made from clear PVC tubing (nominal bore 1 3 cm) mounted vertically on a wooden board The tube was partially filled with liquid, thus creating a rudimentary manometer The basic experiment consisted of giving the liquid column an initial displacement (25 cm in all cases) from equilibrium and then counting the subsequent oscillations Graphs of decaying amplitude of oscillation against time were obtained by filming the process at a speed of 18 frames per second Two pipe configurations were studied a semicircle, of radius 29 cm, and a conventional U-tube with the bend having a radius of curvature of 4 5 cm The length of the liquid column (88 cm) was the same in both cases

In each case the experiment was performed first with water and then with increasing concentrations of drag-reducing polymer in aqueous solution The additives used were polyethylene oxide (Polyox WSR 301 and WSR N3000) and polyacrylamide (Separan AP 273 and MG 200)

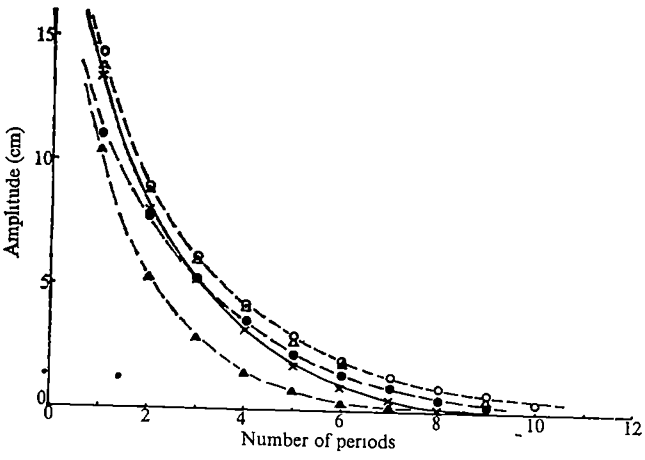

Fig. 1 Amplitude of oscillation against time for Polyox WSR 301 in a semicircular tube ×, Water, ○, 10 p p m WSR 301, △, 25 p p m WSR 301, ●, 250 p p m WSR 301, ▲, 500 p p m WSR 301 Each period=1 6 s

We found that both grades of polyethylene oxide reduced the damping (relative to water) at quite small concentrations, whereas the polyacrylamides, although effective drag-reducers in turbulent flow, gave no measurable reduction

For small additive concentrations (Polyox WSR 301), a marked reduction in damping (relative to water alone) was evident after the first few oscillations (Fig 1)

The behaviour at larger concentrations was particularly interesting For the first few oscillations the damping actually increased (presumably reflecting the increase in solution viscosity) but for the smaller amplitude motions a reduction in damping again occurred (Fig 1) These results suggest that, during the first few oscillations, the flow is controlled by the viscosity of the solution alone

The corresponding results for the U-tube were very similar, there is little apparent difference between the two flow configurations (Fig 1)

Counting the total number of oscillations does, however, reveal that the additives have surprising quantitative effects on the damping If the total number of oscillations with water is N_w and with polymer solution N_p, the percentage increase in the number of oscillations can be defined as

$$100\ (N_p - N_w)/N_w$$

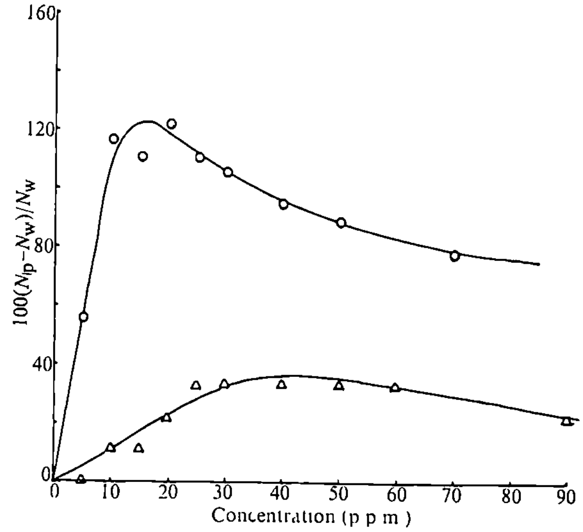

Fig. 2 Variation of damping reduction (assessed by observing the percentage increase in the total number of oscillations) with concentration of Polyox WSR 301 ○, Semicircular tube, △, U-tube

Results for the semicircular tube (Fig 2) show that the total number of oscillations is more than doubled in the concentration range 10–30 p p m On the other hand, the U-tube (Fig 2) shows a much smaller peak enhancement of about 30–40%, over the broader range of 25–65 p p m

Polyethylene oxide tends to adhere to the pipe wall In an attempt to assess the importance of this wall coating, a tube which had previously been used with solution concentrations of up to 500 p p m was rinsed out, to remove any remaining drops of polymer solution and the tests were then repeated, beginning with water It was found that, when water was added to a coated tube, there was a considerable degree of enhancement (relative to water in a clean tube) To exclude the unlikely possibility that a portion of the polymer coating had dissolved in the fresh water, the sample was decanted after a marked reduction had been observed. It was then placed in a clean PVC tube and the experiment was repeated and no significant reduction in damping was observed. It is, therefore, difficult to avoid the conclusion that observed reductions in damping occur because of an adsorbed layer of polymer additive on the tube wall, rather than because of the viscoelastic properties of the actual solution.

Our results indicate that very small amounts of polyethylene oxide can produce quite large reductions in the degree of damping of manometer-type oscillations. The failure of polyacrylamide to show any enhancement may result from the fact that it does not seem to coat the tube, or it may conceivably be a matter of time scales. Unfortunately, as the period of oscillation is proportional to the square root of the length of liquid in the tube, an investigation of much smaller time scales would have its difficulties.

The much greater reduction in the degree of damping found with the semicircular tube is presumably because the tube is entirely curved, whereas the U-tube is only partially so. This would be consistent with previous results[5] for steady flow in curved pipes, in which polymer additives resulted in marked reductions in drag.

I thank Dr M. Driels for discussion, and Mr J. Allan for assistance with the experimental work.

1/*f* noise with a low frequency white noise limit

One of us (A.A.V.), who had recently been studying channel models for electrical fluctuations caused by potassium transport through nerve membrane, noticed a possible analogy with the flow pattern of grain through an hourglass of unusual shape designed by F. Vaudan, Paris. The hourglass was filled with small grains (0.1 to 1.0 mm diameter) of coloured glass and differed from ordinary hourglasses in the length of the pore connecting the two compartments which was drawn out to about 25 cm; about 80 times the smallest inner diameter (3 mm). When the hourglass was turned, the grain did not flow steadily but exhibited slow irregular density fluctuations (Fig. 1). With a view to the analogy with potassium channels in excitable membranes, we decided to examine comparative power spectra[1-3].

In a series of experiments to measure spectral properties of the grain flow, a laser beam (Spectra-Physics model 155) was sent through the stem of the hourlgass and then through a small hole (0.2 mm diameter) placed in front of and close to a photosensitive cell and a dc amplifier.

Light-beam switching resulted in square-waves with a resolution time of about 10^{-4} seconds for the system of cell and amplifier. Another test using a white-noise modulated light source with a white band between 1 and 5,000 Hz showed that the system response was flat within the available range.

In the resulting pulse sequence, most of the pulses had comparable shapes (about triangular, or triangular with clipped peaks when the grains completely blocked the beam during part of their passage) and durations which varied from about 10^{-3} s to 10^{-2} s. After amplification, the power spectrum was calculated (Fig. 2, curve A). Its shape did not change for measurements through different levels of the stem (higher up, where the stream is dense and the light shines through occasionally, or lower down, where individual particles pass through the beam).

The mechanism responsible for the spectral shape must be the interaction between particles and wall and between the particles themselves, while a third friction coefficient is given by the counterflow of air. Clustering is known to occur in bins in the absence of a counterflow of air. The actual values of the friction coefficients (between particles and wall and between the particles themselves) are not of primary importance[4], although they may influence the detailed structure of the spectrum, such as the corner frequencies and the actual slope of the 1/*f* part.

We therefore also examined the spectrum associated with free fall flow out of an open compartment through a gradually narrowing pore (3 mm final diameter) (Fig. 2, curve B). Irregularly shaped, sharp edged steel grit (0.2 mm mean diameter) was used. In both systems the spectrum was white at low frequencies and changed to 1/*f* at higher frequencies. At still higher frequencies the spectrum shape is sensitive to several system parameters and is rather complex.

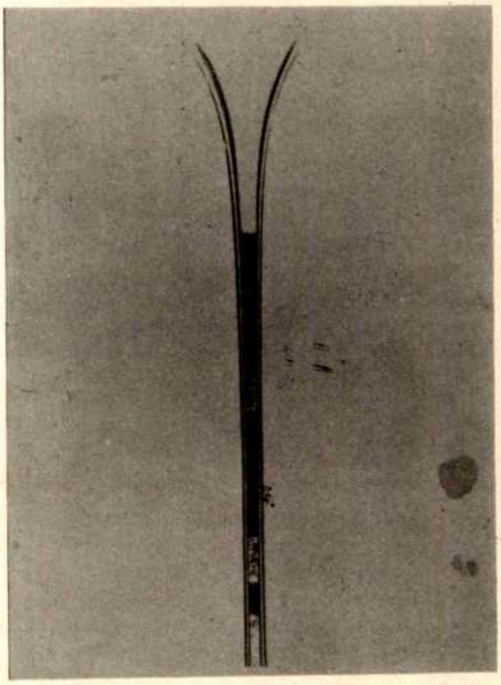

Fig. 1 Flow through hourglass exhibiting clustering (exposure time 1/1000 s).

This is to our knowledge the first report on a physical system with 1/*f* noise which changes at lower frequencies into a different and finite power spectrum. No special tricks need to be invoked, therefore, to circumvent the famous 1/*f* paradox with its explosion of power for frequencies approaching zero[5]. The mechanism at work here might, for this reason, be of general interest, since noise power spectra are investigated in a diversity of fields such as magnetism, superconductivity, semiconductors, artificial and biological membranes and synapses.

Furthermore, the transition from a 1/*f* spectral density into some other spectral density is not the kind predicted by McWhorter[6]; there one must invoke a Poisson process and a distribution of pulse time constants.

It is not very difficult to explain some of the major features of the measured spectra[7]. These include the low frequency form of the power spectrum (white) and the bandwidth over which the spectrum is essentially 1/*f*. Further, it is possible to show, in general, the conditions under which one may expect deviations from a white spectrum and from this obtain important additional insights into possible source mechanisms.

In order to demonstrate these ideas, let us[7], following Heiden[8], view a noise sequence as a sequence of unitary events (pulses) which may represent current, voltage, magnetic lines, and so on. Each individual pulse has its own time constant, τ, amplitude, h, and shape $y(t,\tau)$. In addition, characterising

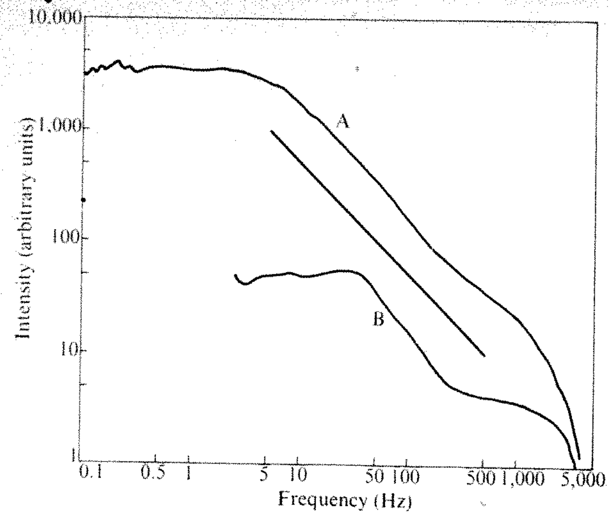

Fig. 2 Power spectra associated with particle flow through hourglass (curve A) and through a narrow pore out of an open compartment (curve B). Line between curves indicates slope of (ideal) $1/f$ noise.

each pulse is the interval φ between its beginning and the beginning of the next pulse. The simplified sequence can be drawn as in Fig. 3.

The interval distribution function $\mu(\varphi)$ may be Poisson or non-Poisson. The sequence can be written as

$$I(t) = h_1 y(t, \tau_1) + h_2 y(t - \varphi_1, \tau_2) + h_3 y(t - \varphi_1 - \varphi_2, \tau_3) + \dots$$

For those sequences in which φ, τ, and h are functionally independent of one another, the power spectrum is[7]

$$S(f) = N\langle h^2\rangle\langle|F(f,\tau)|\rangle^2\left[1 + \frac{2\langle h\rangle^2}{\langle h^2\rangle}\,\frac{|\langle F(f,\tau)\rangle|^2}{\langle|F(f,\tau)|\rangle^2}\,\mathrm{Re}\left(\frac{\psi}{1-\psi}\right)\right]$$

where $\langle\ \rangle$ indicates average value, N is the mean number of pulses per unit time, $F(f,\tau)$ is the Fourier transform of the individual pulse form $y(t,\tau)$, and

$$\psi = \int_0^{\infty} \mu(\varphi)\exp(2\pi i f\varphi)\,d\varphi.$$

For convenience, we can write $S(f) = NA(f)P(f)$ where $A(f) = \langle h^2\rangle\langle|F(f,\tau)|\rangle^2$ and $P(f)$ is the expression in the brackets.

For Poisson distributions, $\mu(\varphi) = N\exp(-N\varphi)$ and $\mathrm{Re}\,(\psi/(1-\psi))$ is zero. In these cases, then, the form of the power spectrum is determined by $F(f,\tau)$ and the distribution of pulse time constants, $\nu(\tau)$.

In general,

$$F(f,\tau) = \int_{-\infty}^{+\infty} y(t,\tau)\exp(-2\pi i f t)\,dt.$$

At low frequencies ($2\pi f\tau \ll 1$), however,

$$F(f,\tau) \cong \int_{-\infty}^{+\infty} y(t,\tau)\,dt.$$

Hence the Fourier transform is frequency independent and the low frequency portion of the spectrum is white[9].

If there is a distribution of time constants, $\nu(\tau)$, among the pulses, then, physically, there exists a maximum τ, τ_m, such that $\nu(\tau)$ is small for $\tau > \tau_m$. Now

$$\langle F(f,\tau)\rangle \simeq \int_0^{\tau_m} F(f,\tau)\,\nu(\tau)\,d\tau,$$

so at frequencies ($2\pi f\tau_m \ll 1$), $\langle F(f,\tau)\rangle$ is also frequency independent, and represents a white spectrum. This is also true for $\langle|F(f,\tau)|\rangle$. Hence, for a sequence of pulses with a distribution of time constants, $A(f)$ is white at low enough frequencies so long as there is no coupling among the parameters of a single pulse.

A similar conclusion obtains for the factor $P(f)$ which incorporates the effect on the power spectrum of deviations from a Poisson sequence.

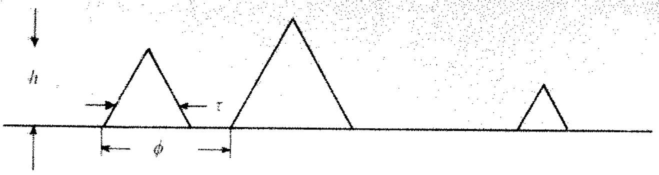

Fig. 3 Pulse sequence parameters.

We have

$$\psi = \int_0^{\infty} \mu(\varphi)\exp(2\pi i f\varphi)\,d\varphi.$$

Physically there exists a maximum φ, say φ_m, beyond which $\mu(\varphi)$ is arbitrarily small. Hence, for low enough frequencies, ($2\pi f\varphi_m \ll 1$), ψ is frequency independent and, therefore, so is $\mathrm{Re}\,(\psi/(1-\psi))$.

We therefore have a theorem which says that the power spectrum of any pulse sequence, Poisson or non-Poisson, even with a distribution of pulse time constants, is white at low enough frequencies provided that there is no coupling among the parameters of a single pulse.

There are at least two immediate and useful consequences. First, if there is not too much overlap between pulses, simple visual inspection of the sequence will permit estimates of τ_m and φ_m. This in turn allows an approximate determination of the low frequency bandwidths over which $A(f)$ and $P(f)$ respectively are white. Hence, under these conditions, visual inspection can tell us whether deviations from a white spectrum are due to $A(f)$ or $P(f)$ over a particular bandwidth. This is particularly easy to do in those cases where $\varphi_m \gg \tau_m$. Secondly, if one should find that at low frequencies ($2\pi f \ll$ the smaller of τ_m^{-1} or φ_m^{-1}) the spectrum is not white, then the implication is that coupling must exist among the parameters of a single pulse.

The first consequence permits direct comparison between the experimentally determined form of the power spectrum and the theoretical frequency range over which $A(f)$ and $P(f)$ should be white. Since one now knows over what bandwidth the form of the spectrum is due to the shape of the individual pulses, we have a direct way of determining if the sequence is non-Poisson (via $P(f)$). The second allows one to deduce that functional relations (for example, $\varphi = (\text{constant})\tau$ or $h = \text{constant}/\varphi$) exist between the pulse parameters. We note for example that $\varphi = (\text{constant})\tau$ is a kind of inhibition where the presence of a pulse with a long time constant tends to delay the appearance of a next pulse while $h = \text{constant}/\varphi$ is a kind of facilitation where a large pulse tends to encourage the appearance of the subsequent pulse. Detailed analysis of the low frequency deviations from a white spectrum will make it possible, in some cases, to select the precise form of the pulse coupling and thereby give further insight into the physical origins of the noise.

If the hourglass flow is examined at different angles with respect to the vertical, the formation of unstable vaults can easily be seen. Clearly, the formation of unstable vaults of different lifetimes generates the clustering effects (Fig. 1) in the flow. In an extensive study (published in Dutch) Peschl[4] investigated the flow of particles from bin openings. A key parameter is the ratio of the opening to the grain diameter. In an hourglass the ratio threshold, 4, is exceeded.

Only unstable vaults occur in normal use and their lifetimes have an upper limit. Hence, the distribution of the intervals between successive particles flowing through a plane must have an upper time limit. In the case of the flow of steel grit through a pore, in our experiments, for example, no intervals longer than 200 ms were found during a period of 10 min with a mean flow of 1,250 grains s^{-1} through the laser beam (0.2 mm diameter). Generally, the individual pulse time constants were considerably less than 20 ms. According to the theorem developed earlier in the paper, the low frequency spectrum should be white for frequencies below about $1/0.2 = 5$ Hz as has been found (Fig. 2). The $1/f$ portion of the spectrum is due to the non-Poisson character (clustering) of the individual particles. At higher frequencies a change from 1/*f* to some other spectrum is predicted due to pulse shape, time constant and photocell response This occurs, as expected, at frequencies ≫ 100 Hz

It is tempting to conjecture that in some systems of molecular dimensions with barriers, particles and pores analogous situations might prevail Molecular size vaults might be formed and thermal motion function as the agent for the introduction of the instabilities These systems would exhibit power spectra with strong low frequency contributions (perhaps 1/*f* in form) but, yet, at the very lowest frequencies their spectra would always turn white

Second Law of Thermodynamics

IT is widely realised that there is no single and uniquely correct statement of the Second Law of Thermodynamics but rather that there exist a number of different and mutually compatible, correct statements[1] (Everett[2] mentions "two or three dozen") each of which illuminates a different facet of what H A Bent (private communication) has called the "Second Law type of behaviour observed in nature" There is no brief statement from which " all of the thermodynamic relationships "[3] can be deduced without further knowledge In considering a particular problem one particular statement is generally more apposite than another, and for those who are concerned with the mechanisms that produce work, a statement of the Law that stresses the significance of work has distinct advantages One such statement of mine[4] has been criticised by Legon[3] Unfortunately the revised article containing the basis for some of my statements has only recently appeared[5] though it was submitted long before the other[4] This paper[5] should have forestalled many of Legon's objections For example, its first page deals with the question of "maximum work" and its equations (5) to (7) and (9) to (13) deal with equilibria and with entropy creation respectively

Legon's objections are numerous and diverse but I will try to deal systematically with them, as summarised in his last paragraph

Lack of originality. I had not seen the passage quoted from Butler[6] (page 32) when I wrote my paper[4] Legon writes of my statement "All it says is that something that is happening" (that is, that can proceed spontaneously) "can be made to do useful work" Exactly so—it is very simple Taken with its corollary, that unless a proposed change can be made to do useful work it cannot happen spontaneously, the statement specifies conditions both necessary and sufficient for predicting which changes can happen spontaneously and which cannot There is no logical necessity to add any statement about "maximum work" Readers of my two articles[4,5] can surely be in little doubt that I understand at least as well as does Legon the fundamental conclusion of Carnot[7] that to every specified change (isothermal or not) there must correspond a certain definite maximum output of work when going in one direction and an equally definite minimum input of work when going in the opposite one these transfers of work would be realised under reversible conditions, they may or may not be equal depending on the particular system under consideration

I made no claim that my statement of the Second Law sums up the whole of thermodynamics in one sentence neither for that matter does Legon's italicised quotation from Planck[8] (page 103) do so It is necessary to know more of the subject in order to comprehend either statement, and the two can then be seen as not contradictory, but complementary

To understand the 'work' view of the subject in relation to the 'entropy' view of it, one must understand the fact (explicitly stated in refs 4 and 5) that in order to obtain work from a spontaneous process a machine of appropriate design must be introduced, in imagination at least, into the situation This machine constrains the process in such a way that it can occur only if at the same time work is delivered, the machine must also contain a device (for example, a weight) for storing this work since many types of system are not, in themselves, capable of storing work All machines consist of several phases and possess geometrical features, and far from being a mere artifice, the nature of such machines and their limitations are the main topics of interest that thermodynamics has had to offer to many scientists, from the Carnots onwards As Joule[9] (who was interested in muscles as well as in galvanic cells and heat engines) wrote in 1853 "Perhaps the most important applications of dynamical theory are those which refer to the production of motive power from chemical and other actions" The matter could not be more succinctly expressed

Table 1 Range of spontaneous processes

Completely irreversible	Completely reversible
Resulting change in Universe	
Maximum entropy creation	Zero entropy creation
Zero increase in stored work	Max increase in stored work
Max inc in thermal energy	Min inc in thermal energy

Failure to apply to isolated systems. I did not in fact claim[4] that the same equation relating work to entropy creation applied to isolated systems, merely that the "argument can be easily extended" to them, by imagining a machine to be introduced into the system itself This basic idea is far from novel[10] [11] A simple example that illustrates the point well is provided by an isolated system in two parts that are initially at different temperatures Heat is allowed to flow either by ordinary conduction or through a heat engine For a given change of state it is found that the entropy created ΔS_{cr} is always a single-valued function of the work wasted If one part of the system (e) is much larger than the other the equations approach as a limit the simple form given in my paper (ref 5, equation (10))

$$\Delta S_{\mathrm{ci}} = [\text{wasted work}]/T_{\mathrm{e}}$$

Legon's preoccupation with semantics has led him to make heavy weather out of a simple situation Work can certainly be stored in an isolated system—by lifting a weight within the system or in various other ways Revealingly enough, the one form of energy that cannot be used for this purpose is the very one suggested by Legon, that is, thermal energy The fundamental distinction between thermal energy (for definition, see ref 12, page 11) and other types of energy is absolutely basic

Legon poses, as a challenge, the problem of obtaining work from the mixing of two ideal gases in an isolated system of constant total volume It is elementary that if the mixture is allowed to form by merely withdrawing a partition between the gases we have a good example of a completely irreversible process with maximal entropy creation (+11 53 J K^{-1} if we started with 1 mol of each at 300 K) and no performance or storage of work On the other hand, by introducing into the system a suitable machine, the uniform mixture could be allowed to form in such a way that a weight within the system was raised (The machine described by Planck (ref 8, page 219) may be readily adapted for this purpose) At the end of the latter mixing process the isolated system would accordingly contain more mechanical energy than it did at the beginning From the First Law it follows that the system must necessarily contain less thermal energy, that is, its temperature must have fallen In the limit, where the mixing was reversible, the maximum possible work would have been performed and transferred to the weight (2,769 J if the gases were monatomic) and the temperature would have fallen to 189 K In this reversible case the change in entropy arising from mixing (+11 53 J K^{-1}) is exactly counterbalanced by that attributable to cooling (−11 53 J K^{-1}) no entropy is created

At this point it might be objected that the change in the gases is not exactly the same as if they had mixed irreversibly, because their thermal energy and temperature have decreased This is a simple consequence of the First Law which applies equally no matter whether one is considering an isolated system, a non-isolated one or the whole Universe If a change is conducted in such a way that a weight is lifted then all the other bodies involved cannot possibly end up in the same state as if the weight had not been lifted

Failure to apply to nonisothermal systems. Legon expresses doubts about the validity of the equation for entropy creation (refs 3 and 4) save for "the trivial case for which the temperature T_e of the environment is equal to the temperature T of the system throughout the process"[3] On what grounds are these doubts based? Legon does not discuss, let alone dismiss, any of the sources quoted in my article[5] Other relevant sources which should be considered are Keenan and Hatsopoulos[13] and the classic accounts by Maxwell[10] and by Gouy[14]

Legon's quotation from Planck (ref 8, page 104) concerning "dissipated energy" deserves close consideration It seems to state that the maximum work is a definite quantity only for isothermal processes If true this would directly contradict the views of Thomson[15] (later Lord Kelvin) "On a universal tendency in Nature to the dissipation of mechanical energy" On pages 113–117 of ref 8, however, Planck discusses his own statement (ref 8, page 104) and we see that there is in fact no contradiction What Planck demonstrates is that although the change in Helmholtz free energy, $-dA = -d(U-TS)$, measures w_{max} under isothermal conditions, it cannot conveniently be used to determine w_{max} under nonisothermal conditions because the term $S\ dT$ that then appears is frequently indeterminate The same point has already been made in a footnote by Gouy (ref 15, page 506) who had also given the correct equation for determining w_{max} under nonisothermal conditions Accordingly I find no substance in Legon's objections under this heading

If it is thought that there is conflict between the 'work' view of thermodynamics and the 'entropy' view it is high time that the idea was abandoned The two views are different, but symmetrical, aspects of the same reality Spontaneous processes of all kinds fall somewhere within the pattern shown in Table 1, their position depending on the efficiency of the machinery used for the extraction of work

Information transmission under conditions of sensory shielding

WE present results of experiments suggesting the existence of one or more perceptual modalities through which individuals obtain information about their environment, although this information is not presented to any known sense The literature[1-3] and our observations lead us to conclude that such abilities can be studied under laboratory conditions

We have investigated the ability of certain people to describe graphical material or remote scenes shielded against ordinary perception In addition, we performed pilot studies to determine if electroencephalographic (EEG) recordings might indicate perception of remote happenings even in the absence of correct overt responses

We concentrated on what we consider to be our primary responsibility—to resolve under conditions as unambiguous as possible the basic issue of whether a certain class of paranormal perception phenomena exists So we conducted our experiments with sufficient control, utilising visual, acoustic and electrical shielding, to ensure that all conventional paths of sensory input were blocked At all times we took measures to prevent sensory leakage and to prevent deception, whether intentional or unintentional

Our goal is not just to catalogue interesting events, but to uncover patterns of cause–effect relationships that lend themselves to analysis and hypothesis in the forms with which we are familiar in scientific study The results presented here constitute a first step towards that goal, we have established under known conditions a data base from which departures as a function of physical and psychological variables can be studied in future work

REMOTE PERCEPTION OF GRAPHIC MATERIAL

First, we conducted experiments with Mr Uri Geller in which we examined his ability, while located in an electrically shielded room, to reproduce target pictures drawn by experimenters located at remote locations Second, we conducted double-blind experiments with Mr Pat Price, in which we measured his ability to describe remote outdoor scenes many miles from his physical location Finally, we conducted preliminary tests using EEGs, in which subjects were asked to perceive whether a remote light was flashing, and to determine whether a subject could perceive the presence of the light, even if only at a noncognitive level of awareness

In preliminary testing Geller apparently demonstrated an ability to reproduce simple pictures (line drawings) which had been drawn and placed in opaque sealed envelopes which he was not permitted to handle But since each of the targets was known to at least one experimenter in the room with Geller, it was not possible on the basis of the preliminary testing to discriminate between Geller's direct perception of envelope contents and perception through some mechanism involving the experimenters, whether paranormal or subliminal

So we examined the phenomenon under conditions designed to eliminate all conventional information channels, overt or subliminal Geller was separated from both the target material and anyone knowledgeable of the material, as in the experiments of ref 4

In the first part of the study a series of 13 separate drawing experiments were carried out over 7 days No experiments are deleted from the results presented here

At the beginning of the experiment either Geller or the experimenters entered a shielded room so that from that time forward Geller was at all times visually, acoustically and electrically shielded from personnel and material at the target location Only following Geller's isolation from the experimenters was a target chosen and drawn, a procedure designed to eliminate pre-experiment cueing Furthermore, to eliminate the possibility of pre-experiment target forcing, Geller was kept ignorant as to the identity of the person selecting the target and as to the method of target selection This was accomplished by the use of three different techniques (1) pseudo-random technique of opening a dictionary arbitrarily and choosing the first word that could be drawn (Experiments 1–4), (2) targets, blind to experimenters and subject, prepared independently by SRI scientists outside the experimental group (following Geller's isolation) and provided to the experimenters during the course of the experiment (Experiments 5–7, 11–13), and (3) arbitrary selection from a target pool decided upon in advance of daily experimentation and designed to provide data concerning information content for use in testing specific hypotheses (Experiments 8–10). Geller's task was to reproduce with pen on paper the line drawing generated at the target location Following a period of effort ranging from a few minutes to half an hour, Geller either passed (when he did not feel confident) or indicated he was ready to submit a drawing to the experimenters, in which case the drawing was collected before Geller was permitted to see the target

To prevent sensory cueing of the target information, Experiments 1 through 10 were carried out using a shielded room in SRI's facility for EEG research The acoustic and visual isolation is provided by a double-walled steel room, locked by means of an inner and outer door, each of which is secured with a refrigerator-type locking mechanism Following target selection when Geller was inside the room, a one-way audio monitor, operating only from the inside to the outside, was activated to monitor Geller during his efforts The target picture was never discussed by the experimenters after the picture was drawn and brought near the shielded room In our detailed examination of the shielded room and the protocol used in these experiments, no sensory leakage has been found

The conditions and results for the 10 experiments carried out in the shielded room are displayed in Table 1 and Fig 1 All experiments except 4 and 5, were conducted with Geller inside the shielded room In Experiments 4 and 5, the procedure was reversed For those experiments in which Geller was inside the shielded room, the target location was in an adjacent room at a distance of about 4 m, except for Experiments 3 and 8, in which the target locations were, respectively, an office at a distance of 475 m and a room at a distance of about 7 m

A response was obtained in all experiments except Numbers 5–7 In Experiment 5, the person-to-person link was eliminated by arranging for a scientist outside the usual experimental group to draw a picture, lock it in the shielded room before Geller's arrival at SRI, and leave the area Geller was then led

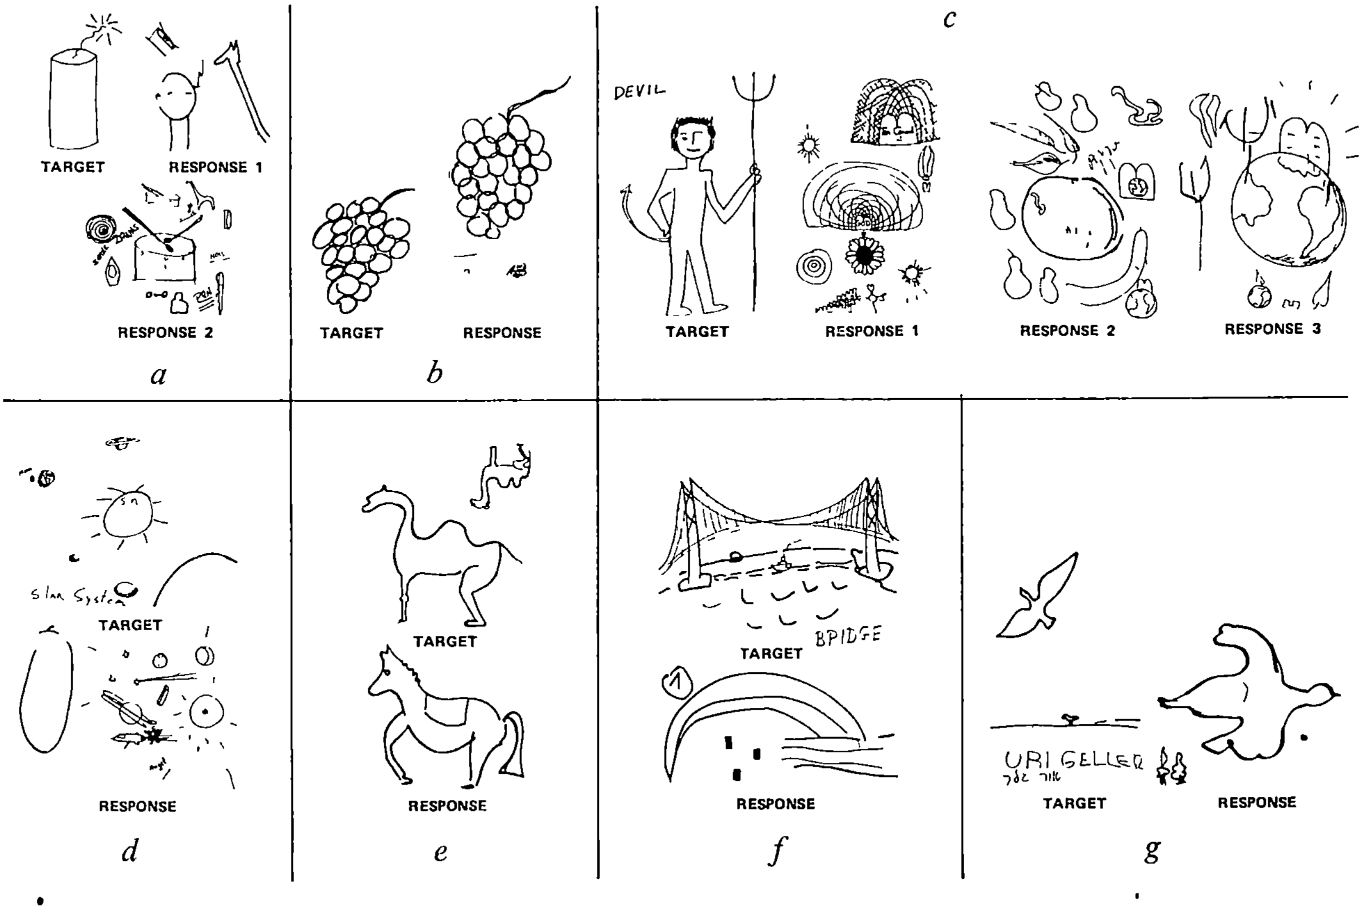

Fig. 1 Target pictures and responses drawn by Uri Geller under shielded conditions

Table 1 Remote perception of graphic material

*EEG Facility shielded room (see text)
†Perceiver–target distances measured in metres
‡SRI Radio Systems Laboratory shielded room (see text)

by the experimenters to the shielded room and asked to draw the picture located inside the room He said that he got no clear impression and therefore did not submit a drawing The elimination of the person-to-person link was examined further in the second series of experiments with this subject

Experiments 6 and 7 were carried out while we attempted to record Geller's EEG during his efforts to perceive the target pictures The target pictures were, respectively, a tree and an envelope He found it difficult to hold adequately still for good EEG records, said that he experienced difficulty in getting impressions of the targets and again submitted no drawings

Experiments 11 through 13 were carried out in SRI's Engineering Building, to make use of the computer facilities available there For these experimenters, Geller was secured in a double-walled, copper-screen Faraday cage 54 m down the hall and around the corner from the computer room The Faraday cage provides 120 dB attenuation for plane wave radio frequency radiation over a range of 15 kHz to 1 GHz For magnetic fields the attenuation is 68 dB at 15 kHz and decreases to 3 dB at 60 Hz Following Geller's isolation, the targets for these experiments were chosen by computer laboratory personnel not otherwise associated with either the experiment or Geller, and the experimenters and subject were kept blind as to the contents of the target pool

For Experiment 11, a picture of a kite was drawn on the face of a cathode ray tube display screen, driven by the computer's graphics program For Experiment 12, a picture of a church was drawn and stored in the memory of the computer In Experiment 13, the target drawing, an arrow through a heart (Fig 2*c*), was drawn on the face of the cathode ray tube and then the display intensity was turned off so that no picture was visible

To obtain an independent evaluation of the correlation between target and response data, the experimenters submitted the data for judging on a 'blind' basis by two SRI scientists who were not otherwise associated with the research For the 10 cases in which Geller provided a response, the judges were asked to match the response data with the corresponding target data (without replacement) In those cases in which Geller made more than one drawing as his response to the target, all the drawings were combined as a set for judging The two judges each matched the target data to the response data with no error For either judge such a correspondence has an *a priori* probability, under the null hypothesis of no information channel, of $P = (10!)^{-1} = 3 \times 10^{-7}$

A second series of experiments was carried out to determine whether direct perception of envelope contents was possible without some person knowing of the target picture

One hundred target pictures of everyday objects were drawn by an SRI artist and sealed by other SRI personnel in double envelopes containing black cardboard The hundred targets were divided randomly into groups of 20 for use in each of the three days' experiments

On each of the three days of these experiments, Geller passed That is, he declined to associate any envelope with a drawing that he made, expressing dissatisfaction with the existence of such a large target pool On each day he made approximately 12 recognisable drawings, which he felt were associated with the entire target pool of 100 On each of the three days, two of his drawings could reasonably be associated with two of the 20 daily targets On the third day, two of his drawings were very close replications of two of that day's target pictures The drawings resulting from this experiment do not depart significantly from what would be expected by chance

In a simpler experiment Geller was successful in obtaining information under conditions in which no persons were knowledgeable of the target A double-blind experiment was performed in which a single 3/4 inch die was placed in a 3 × 4 × 5 inch steel box The box was then vigorously shaken by one of the experimenters and placed on the table, a technique found in control runs to produce a distribution of die faces differing nonsignificantly from chance The orientation of the die within the box was unknown to the experimenters at that time Geller would then write down which die face was uppermost The target pool was known, but the targets were individually prepared in a manner blind to all persons involved in the experiment This experiment was performed ten times, with Geller passing twice and giving a response eight times In the eight times in which he gave a response, he was correct each time The distribution of responses consisted of three 2s, one 4, two 5s, and two 6s The probability of this occurring by chance is approximately one in 10^6

In certain situations significant information transmission can take place under shielded conditions Factors which appear to be important and therefore candidates for future investigation include whether the subject knows the set of targets in the target pool, the actual number of targets in the target pool at any given time, and whether the target is known by any of the experimenters

It has been widely reported that Geller has demonstrated the ability to bend metal by paranormal means Although metal bending by Geller has been observed in our laboratory, we have not been able to combine such observations with adequately controlled experiments to obtain data sufficient to support the paranormal hypothesis

REMOTE VIEWING OF NATURAL TARGETS

A study by Osis[5] led us to determine whether a subject could describe randomly chosen geographical sites located several miles from the subject's position and demarcated by some appropriate means (remote viewing) This experiment carried out with Price, a former California police commissioner and city councilman, consisted of a series of double-blind, demonstration-of-ability tests involving local targets in the San Francisco Bay area which could be documented by several independent judges We planned the experiment considering that natural geographical places or man-made sites that have existed for a long time are more potent targets for paranormal perception experiments than are artificial targets prepared in the laboratory This is based on subject opinions that the use of artificial targets involves a 'trivialisation of the ability' as compared with natural pre-existing targets

In each of nine experiments involving Price as subject and SRI experimenters as a target demarcation team, a remote location was chosen in a double-blind protocol Price, who remained at SRI, was asked to describe this remote location, as well as whatever activities might be going on there

Several descriptions yielded significantly correct data pertaining to and descriptive of the target location

In the experiments a set of twelve target locations clearly differentiated from each other and within 30 min driving time from SRI had been chosen from a target-rich environment (more than 100 targets of the type used in the experimental series) prior to the experimental series by an individual in SRI management, the director of the Information Science and Engineering Division, not otherwise associated with the experiment Both the experimenters and the subject were kept blind as to the contents of the target pool, which were used without replacement

An experimenter was closeted with Price at SRI to wait 30 min to begin the narrative description of the remote location The SRI locations from which the subject viewed the remote locations consisted of an outdoor park (Experiments 1, 2), the double-walled copper-screen Faraday cage discussed earlier (Experiments 3, 4, and 6–9), and an office (Experiment 5) A second experimenter would then obtain a target location from the Division Director from a set of travelling orders previously prepared and randomised by the Director and kept under his control The target demarcation team (two to four SRI experimenters) then proceeded directly to the target by automobile without communicating with the subject or experimenter remaining behind Since the experimenter remaining with the subject at SRI was in ignorance both as to the particular target and as to the target pool, he was free to question Price to clarify his descriptions The demarcation team then remained at the target site for 30 min after the 30 min allotted for travel During the observation period, the remote-viewing subject would describe his impressions of the target site into a tape recorder A comparison was then made when the demarcation team returned

Price's ability to describe correctly buildings, docks, roads, gardens and so on, including structural materials, colour, ambience and activity, sometimes in great detail, indicated the functioning of a remote perceptual ability But the descriptions contained inaccuracies as well as correct statements To obtain a numerical evaluation of the accuracy of the remote viewing experiment, the experimental results were subjected to independent judging on a blind basis by five SRI scientists who were

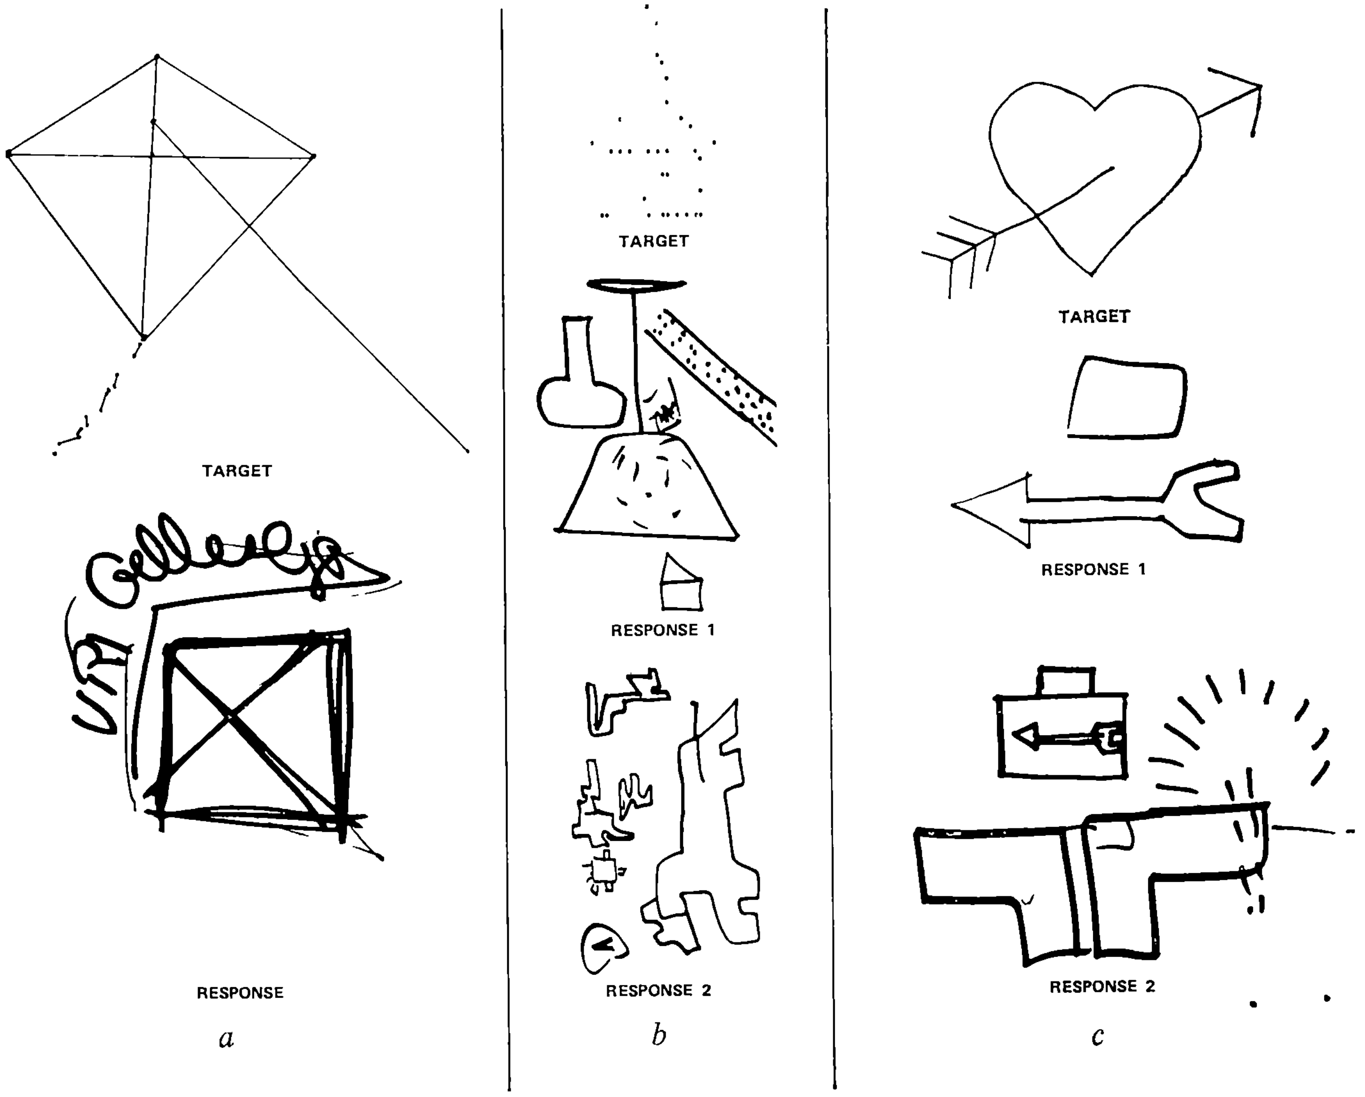

Fig 2 Computer drawings and responses drawn by Uri Geller a, Computer drawing stored on video display, b, computer drawing stored in computer memory only, c, computer drawing stored on video display with zero intensity

Table 2 Distribution of correct selections by judges A, B, C, D, and E in remote viewing experiments

Descriptions chosen by judges		Places visited by judges 1	2	3	4	5	6	7	8	9
Hoover Tower	1	ABCDE				D				
Baylands Nature Preserve	2		ABC	E				D		D
Radio Telescope	3			ACD		BE				
Redwood City Marina	4		CD		ABDE		E			
Bridge Toll Plaza	5						ABD		DCE	
Drive-In Theatre	6			B		A	C			E
Arts and Crafts Garden Plaza	7							ABCE		
Church	8				C				AB	
Rinconada Park	9		CE							AB

Of the 45 selections (5 judges, 9 choices), 24 were correct Bold type indicates the description chosen most often for each place visited Correct choices lie on the main diagonal The number of correct matches by Judges A through E is 7, 6, 5, 3, and 3, respectively The expected number of correct matches from the five judges was five, in the experiment 24 such matches were obtained The *a priori* probability of such an occurrence by chance, conservatively assuming assignment without replacement on the part of the judges, is $P = 8\ 10^{-10}$

not otherwise associated with the research. The judges were asked to match the nine locations, which they independently visited, against the typed manuscripts of the tape-recorded narratives of the remote viewer The transcripts were unlabelled and presented in random order The judges were asked to find a narrative which they would consider the best match for each of the places they visited A given narrative could be assigned to more than one target location A correct match requires that the transcript of a given date be associated with the target of that date Table 2 shows the distribution of the judges' choices

Among all possible analyses, the most conservative is a permutation analysis of the plurality vote of the judges' selections assuming assignment without replacement, an approach independent of the number of judges By plurality vote, six of the nine descriptions and locations were correctly matched Under the null hypothesis (no remote viewing and a random selection of descriptions without replacement), this outcome has an *a priori* probability of $P = 5\ 6 \times 10^{-4}$, since, among all possible permutations of the integers one through nine, the probability of six or more being in their natural position in the list has that value Therefore, although Price's descriptions contain inaccuracies, the descriptions are sufficiently accurate to permit the judges to differentiate among the various targets to the degree indicated

EEG EXPERIMENTS

An experiment was undertaken to determine whether a physiological measure such as EEG activity could be used as an indicator of information transmission between an isolated subject and a remote stimulus We hypothesised that perception could be indicated by such a measure even in the absence of verbal or other overt indicators[6,7]

It was assumed that the application of remote stimuli would result in responses similar to those obtained under conditions of direct stimulation For example, when normal subjects are stimulated with a flashing light, their EEG typically shows a decrease in the amplitude of the resting rhythm and a driving of the brain waves at the frequency of the flashes[8] We hypothesised that if we stimulated one subject in this manner (a sender), the EEG of another subject in a remote room with no flash present (a receiver), might show changes in alpha (9–11 Hz) activity, and possibly EEG driving similar to that of the sender

We informed our subject that at certain times a light was to be flashed in a sender's eyes in a distant room, and if the subject perceived that event, consciously or unconsciously, it might be evident from changes in his EEG output The receiver was seated in the visually opaque, acoustically and electrically shielded double-walled steel room previously described The sender was seated in a room about 7 m from the receiver

To find subjects who were responsive to such a remote stimulus, we initially worked with four female and two male volunteer subjects, all of whom believed that success in the experimental situation might be possible These were designated 'receivers' The senders were either other subjects or the experimenters We decided beforehand to run one or two sessions of 36 trials each with each subject in this selection procedure, and to do a more extensive study with any subject whose results were positive

A Grass PS-2 photostimulator placed about 1 m in front of the sender was used to present flash trains of 10 s duration The receiver's EEG activity from the occipital region (O_z), referenced to linked mastoids, was amplified with a Grass 5P-1 preamplifier and associated driver amplifier with a bandpass of 1–120 Hz The EEG data were recorded on magnetic tape with an Ampex SP 300 recorder

On each trial, a tone burst of fixed frequency was presented to both sender and receiver and was followed in one second by either a 10 s train of flashes or a null flash interval presented to the sender Thirty-six such trials were given in an experimental session, consisting of 12 null trials—no flashes following the tone—12 trials of flashes at 6 f p s and 12 trials of flashes at 16 f p s , all randomly intermixed, determined by entries from a table of random numbers Each of the trials generated an 11-s EEG epoch The last 4 s of the epoch was selected for analysis to minimise the desynchronising action of the warning cue This 4-s segment was subjected to Fourier analysis on a LINC 8 computer

Spectrum analyses gave no evidence of EEG driving in any receiver, although in control runs the receivers did exhibit driving when physically stimulated with the flashes But of the six subjects studied initially, one subject (H H) showed a consistent alpha blocking effect We therefore undertook further study with this subject

Data from seven sets of 36 trials each were collected from this subject on three separate days This comprises all the data collected to date with this subject under the test conditions described above The alpha band was identified from average spectra, then scores of average power and peak power were obtained from individual trials and subjected to statistical analysis

Of our six subjects, H H had by far the most monochromatic EEG spectrum Figure 3 shows an overlay of the three averaged spectra from one of this subject's 36-trial runs, displaying changes in her alpha activity for the three stimulus conditions

Mean values for the average power and peak power for each

Table 3 EEG data for H H showing average power and peak power in the 9–11 Hz band, as a function of flash frequency and sender

Flash Frequency	0	6	16	0	6	16
Sender	Average Power			Peak Power		
J L	94 8	84 1	76 8	357 7	329 2	289 6
R T	41 3	45 5	37 0	160 7	161 0	125 0

Averages	56 8	49 9	43 1	214 5	169 8	153 5
		−12%	−24%($P<0\ 04$)		−21%	−28%($P<0\ 03$)

Each entry is an average over 12 trials

of the seven experimental sets are given in Table 3 The power measures were less in the 16 f p s case than in the 0 f p s in all seven peak power measures and in six out of seven average power measures Note also the reduced effect in the case in which the subject was informed that no sender was present (Run 3) It seems that overall alpha production was reduced for this run in conjunction with the subject's expressed apprehension about conducting the experiment without a sender This is in contrast to the case (Run 7) in which the subject was not informed

Siegel's two-tailed t approximation to the nonparametric randomisation test[9] was applied to the data from all sets, which included two sessions in which the sender was removed Average power on trials associated with the occurrence of 16 f p s was significantly less than when there were no flashes ($t = 2\,09$, d f $= 118$, $P < 0\,04$) The second measure, peak power, was also significantly less in the 16 f p s conditions than in the null condition ($t = 2\,16$, d f $= 118$, $P < 0\,03$) The average response in the 6 f p s condition was in the same direction as that associated with 16 f p s , but the effect was not statistically significant

Spectrum analyses of control recordings made from saline with a 12 kΩ resistance in place of the subject with and without the addition of a 10 Hz, 50 μV test signal applied to the saline solution, revealed no indications of flash frequencies, nor perturbations of the 10 Hz signal These controls suggest that the results were not due to system artefacts Further tests also gave no evidence of radio frequency energy associated with the stimulus

Subjects were asked to indicate their conscious assessment for each trial as to which stimulus was generated They made their guesses known to the experimenter via one-way telegraphic communication An analysis of these guesses has shown them to be at chance, indicating the absence of any supraliminal cueing, so arousal as evidenced by significant alpha blocking occurred only at the noncognitive level of awareness

We hypothesise that the protocol described here may prove to be useful as a screening procedure for latent remote perceptual ability in the general population

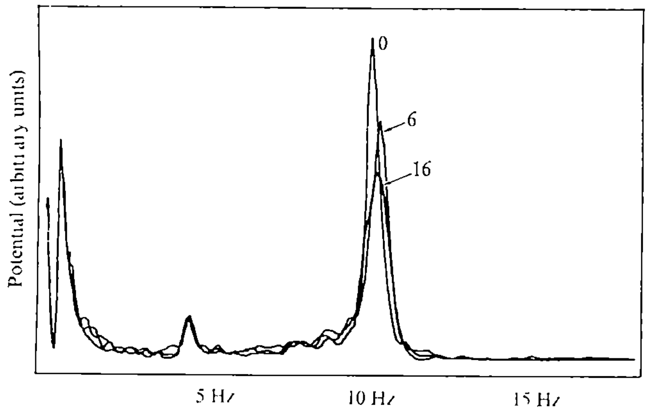

Fig 3 Occipital EEG spectra, 0–20 Hz, for one subject (H H) acting as receiver, showing amplitude changes in the 9–11 Hz band as a function of strobe frequency Three cases 0, 6, and 16 f p s (12 trial averages)

CONCLUSION

From these experiments we conclude that

- A channel exists whereby information about a remote location can be obtained by means of an as yet unidentified perceptual modality
- As with all biological systems, the information channel appears to be imperfect, containing noise along with the signal
- While a quantitative signal-to-noise ratio in the information-theoretical sense cannot as yet be determined, the results of our experiments indicate that the functioning is at the level of useful information transfer

It may be that remote perceptual ability is widely distributed in the general population, but because the perception is generally below an individual's level of awareness, it is repressed or not noticed For example, two of our subjects (H H and P P) had not considered themselves to have unusual perceptual ability before their participation in these experiments

Our observation of the phenomena leads us to conclude that experiments in the area of so-called paranormal phenomena can be scientifically conducted, and it is our hope that other laboratories will initiate additional research to attempt to replicate these findings

This research was sponsored by The Foundation for Parasensory Investigation, New York City We thank Mrs Judith Skutch, Dr Edgar D Mitchell of the Institute of Noetic Sciences—as well as our SRI associates, Mr Bonnar Cox, Mr Earle Jones and Dr Dean Brown—for support and encouragement Constructive suggestions by Mrs Jean Mayo, Dr Charles Tart, University of California, and Dr Robert Ornstein and Dr David Galin of the Langley Porter Neuropsychiatric Institute are acknowledged

The stability of a feasible random ecosystem

THE weight of the evidence, and the beliefs of most biologists, seem to support the view[1] that ecosystems tend to be more stable, the larger the number of interacting species they contain It is puzzling, therefore, that a variety of mathematical models of complex ecosystems appear to give the contrary answer that complexity makes for instability[2]

Prominent among such models is the complex system with random interactions, studied in various forms by Gardner and Ashby[3] and May[4], but their results cannot be applied as they stand to ecological systems In an ecosystem, the interacting variables are species populations (or species biomass) which cannot take on negative values Thus, for example, the equilibrium population values must be positive, and it is convenient to denote this necessary property of an ecosystem model by saying that it must be 'feasible'

The work referred to imposed no such constraint on equilibrium populations in the samples considered It is of some interest, therefore, to examine the stability of a random model capable of representing ecosystems, by imposing the restriction that the sample be feasible

I report here the results of computer calculations on such a model The interaction equations were of the well-known quasi-linear type, in which the rate of fractional increase of a species population is a linear function of the current populations in all T species That is, the number N_i in the ith species obeys

$$dN_i/dt = N_i\,(b_i + \Sigma_j\, a_{ij}\, N_j)$$

All birth rates b_i were taken as 1, and the self-regulating coefficients a_{ii} as -1 The feasibility requirement was that the

Pure Cbc [illegible] Library

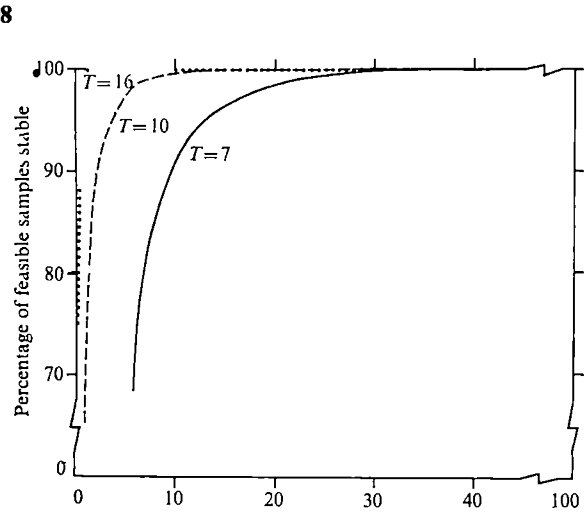

Fig 1 Stability of feasible samples

solutions for the equilibrium populations N^*_i, obtained by equating the dN_i/dt to zero, should be strictly positive. The stability matrix S is given by $S_{ij} = N^*_i\, a_{ij}$, S is unstable if it has an eigenvalue with positive real part. The interaction coefficients were chosen to have a fixed magnitude z but random sign (+ or − equally likely), with all T species uniformly self regulated. A minimum of 2,000 samples were examined for each value of T and z.

When all samples were accepted—whether feasible or not—the results for $T = 7$, 10 and 16 agreed qualitatively with the related (though not identical) models of refs 3 and 4. That is, for z small, essentially all samples were stable, but the stable fraction tended to zero as z approached $T^{-\frac{1}{2}}$.

On examining the stability of the feasible samples only, however, a significantly different behaviour emerges. We see from Fig 1 that feasible samples are generally stable, the stable percentage departing from close to 100% only when the occurrence of a feasible sample is in any case rare (that is, when z is large). Moreover, this tendency to stability increases with the number T of interacting species. (It should be noted that the curves in Fig 1 contain no extrapolated portions, but are constructed by interpolating between computed points of negligible Monte Carlo error.)

The results displayed suggest the conclusion that, for this model type, almost all feasible systems are stable when the number of interacting species increases without limit. (The curve for $T = 16$ is already barely distinguishable from such a step function.)

The results confirm previous findings (both numerical[3] and analytical[4]), in showing that both feasibility and stability are rare when $z > T^{-\frac{1}{2}}$. It is not unreal, however, to expect average interaction strength to decrease as the number of interactions increases.

It is easy to see why the general conclusions emerging differ from those of refs 3 and 4, when these are specialised to ecosystems. The latter studies worked directly on the stability matrix, and thus could not impose any feasibility requirement (this must be derived from the solutions of the original interaction equations, which do not appear in their approach). Now, unfeasible samples contain at least one species with a negative equilibrium population, this simply means, biologically, that after a time the species becomes extinct. But, if this extinction is ignored, such 'ghost species' are being implicitly retained in the stability examination and exert a profoundly destabilising effect. In the quasi-linear model above, for example, they 'live on' as an unregulated, exponentially increasing component of the system. The diagonal element of the stability matrix is $-N^*_i$, which is positive when $N^*_i < 0$. Thus the ghost species figures in it like a real species (that is, one with a positive number at equilibrium) with $a_{ii} = +1$, that is, with an eventual population increase proportional to N_i^2.

The results cited above show that, when these 'mathematical ghosts' are excluded, the model shows an actual increase of stability in the larger systems.

Objective evaluation of auditory evoked EEG responses

THE averaging of often very small responses is widely used in physiology, psychology and clinical medicine to evaluate stimulus threshold levels. It is sometimes difficult to recognise responses in the average waveform because of residual activity, so a means of improving sensitivity and objectively recognising positive responses would be useful. We have previously found[1] that the averaged responses (ERA) evoked in the electroencephalogram (EEG) of a subject by auditory stimuli were produced by imposing a phase constraint on the different Fourier harmonics of the spontaneous EEG, without necessarily influencing their amplitudes.

Merely imposing the phase-spectrum characteristic of a response to high-level stimuli on length of unstimulated spontaneous EEG from the same or another individual, creates a waveform similar to and highly correlated with a true average of responses to high-level stimuli and a similar result is produced by imposing the appropriate phase spectrum on lengths of pseudo-random white Gaussian noise instead of on spontaneous EEG. These observations provide a convenient basis for the objective detection of the existence of positive responses to given stimuli and for the determination of auditory threshold levels.

Our previous findings concerned the average, rather than the individual, evoked response but clearly must reflect phenomena in the separate lengths of EEG following individual stimuli. If so, it should be possible to demonstrate a phase-constraint operative on the various harmonic components of the individual post-stimulus lengths of EEG and such a demonstration would be useful in suggesting the basis of an objective assessment of the occurrence of response. Unfortunately, phase spectra do present difficulty of interpretation and in the present context, may be liable to some error if unnecessarily long record lengths are used. One problem is that phase values are restricted to the range −180° to +180°, and as a result of the repeated recurrence of the principal range of angles that can occur, averaging phase-spectral values for any given harmonic component, in successive sweeps, is usually unsatisfactory. We have therefore investigated instead whether the ensemble distribution of phase values for each harmonic component shows any aggregation, or if it shows the uniform distribution characteristic of uncontrolled phases as seen in unstimulated records.

Phase values have been calculated for each of the first ten Fourier harmonic components and classified into four equal-size groups covering the full 360° range of possible values. The null hypothesis leads to a uniform distribution of phase values so that for 60 sweeps, the expected number of values is 15 in each class. A χ^2 test with d f = 3 can then be applied to test the null hypothesis (that is, no phase control), for each harmonic separately The results show that for high-level stimuli, the null hypothesis must be rejected on the basis of one or more harmonics ($P<0$ 01), but for stimuli that are evidently sub-threshold according to both subjective judgment and appearance of the averaged response waveform, the null hypothesis holds Intermediate levels lead to χ^2 values that broadly decrease in significance as stimulus level decreases and the 5% level occurs near the subjective threshold For high-level stimuli which produce an evident response, most of the harmonics exhibit the phase constraint, but as the stimulus level is reduced towards threshold, significant aggregation of phase values is confined only to a few harmonics The effects reported here have been studied for increasing lengths of post stimulus record, starting with about 0 32 s and ultimately reaching the full length of our records (0 94 s post stimulus) The existence of a phase constraint is increasing evident with increasing record length, the effect often fails altogether, however, when the record length is allowed to exceed about 0 8 s This observation suggests that after about 0 75 s any phase control of spontaneous EEG activity diminishes, allowing fully spontaneous conditions to be generally restored beyond this point If the record used for analysis did include, for this reason, a segment of spontaneous activity, the appearance of the phase constraint would then be lost

These findings apply in each of the trials with different tonal or click stimuli for all the six subjects (three adults, three children) reported previously[1], and similarly to each of the records from three further subjects that we have so far examined Thus, a non-subjective and quantitative system of auditory assessment would seem to be feasible, utilising phase-spectral measurements alone This approach, however, implicitly utilises some information about the amplitude spectrum of the signal, in that low amplitude Fourier components are neglected (by restricting analysis to the first ten or fewer harmonics), and we would not rule out the possibility of utilising further amplitude spectral information to supplement the indications provided by a phase analysis

We would also remark that the characterisation of these signals in phase-spectral terms is an abstraction to describe a mechanism that is perhaps more realistically envisaged as a synchronisation process in the time domain, rather than as a phase-constraint in the frequency domain

Imprinting and exploration of slight novelty in chicks

Shortly after hatching, domestic chicks will respond socially to a wide range of moving or conspicuous objects As a result of 'imprinting', their social behaviour is increasingly limited to objects with which they have had visual experience In general, the longer that chicks have been exposed to an object, the more strongly they prefer it when given a choice between it and something else[1-5] Some evidence, however, suggests that in the early stages of imprinting, the trend towards a highly restricted preference is temporarily reversed and some birds may even prefer the unfamiliar object[6,7]

Here we report that day-old chicks will even work to expose themselves to novel stimulation at an early stage in imprinting At that stage, by changing the characteristics of a visual stimulus when a chick stepped onto a pedal, it was possible to increase the likelihood that it would step on to the pedal again

Bateson and Reese[8] found that day-old chicks hatched and reared in the dark would rapidly learn to press a pedal which turned on a flashing rotating light We have used a similar technique in this study but with two important differences first, the chicks had been exposed to a flashing, rotating light for varying amounts of time before the experiment, second, the familiar stimulus was turned on when a bird was not on the pedal As soon as the chick stepped on the pedal the colour of the stimulus was changed In other words, the bird was exposed to a novel stimulus for as long as it stood on the pedal

The apparatus consisted of a chamber measuring 37 5 by 34 5 by 33 cm Two of the walls were made of hardboard and the front and back walls of 1 27-cm wire mesh Two pedals were set into the floor, each measured 4 8 cm square and was placed 2 0 cm from the wire mesh front and 2 6 cm from one of the sides All the apparatus was painted matt black except for the pedals which were matt white The temperature 5 cm above the floor of the apparatus was 23 5–26 5° C The stimulus was placed 60 cm in front of the wire mesh and midway between the two pedals It

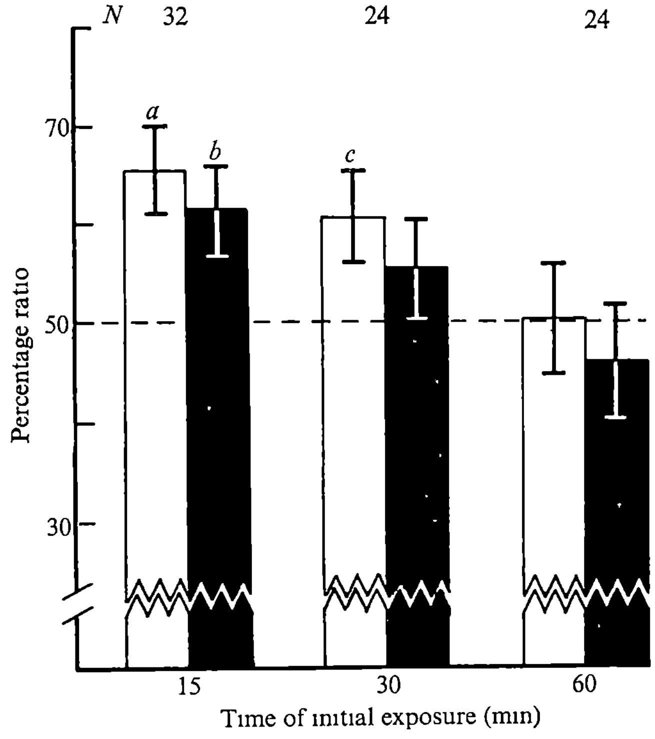

Fig 1 Means and s e for the total presses by day-old chicks of a pedal altering a flashing light from a familiar to unfamiliar colour The pedal presses are expressed as percentages of the total presses of that pedal and another symetrically placed pedal having no effect on the light Open bars are percentage durations of pressing and solid bars are percentage frequencies of pressing The chicks were previously exposed to the familiar light for 15, 30 or 60 min Departures from the chance level of 50% are indicated as follows a, $t=3$ 29, $P<0$ 01, b, $t=2$ 56, $P<0$ 02, c, $t=2$ 14, $P<0$ 05

consisted of a translucent cylinder 15 3 cm in diameter and 16 cm in length rotating at 45 r p m on a horizontal axis The cylinder was covered with a chequerboard pattern (2-cm squares) A primary red and primary yellow filter were fitted inside the cylinder, each over a 45 W bulb The bulbs could be individually lit to make the whole cylinder appear as either red or yellow checks, the background was matt black When one pedal was pressed the colour of the cylinder changed, the other pedal had no effect on the stimulus and was used to measure any general changes in activity

Eighty Ross 'Chunky' chicks were hatched in the laboratory and individually exposed to constant white light for 50 min When they were 14–22 h old, half were individually exposed in activity wheels[9] to a flashing rotating light like the red stimulus in the operant conditioning situation and half were exposed to one like the yellow stimulus The chicks were exposed for 15, 30 or 60 min and 3 min later were separately placed in the operant conditioning box The experimental design was balanced so that for half the chicks the pedal changing the colour of the stimulus was on the right hand side and for the other half it was on the left hand side Each chick was left in the apparatus for 50 min

The results are shown in Fig 1 The presses of the pedal changing the colour of the light are expressed as a percentage of the total presses of both pedals, if they were responding at the chance level the ratio would have been 50% The absolute measures of pedal pressing were the same for all groups In Fig 1 percentages are given for both the number of presses in the 50-min tests and the total time spent pressing the pedals It can be seen that after 15 min previous experience with the familiar stimulus the chicks pressed the pedal which changed the colour of the light more frequently and for longer than they did the other pedal The red-trained birds did not differ from the yellow-trained birds in the extent to which they worked for change In the red-trained chicks exposed for 30 min, the effect was much less clearly marked and by 60 min the birds in both groups were responding at the chance level The overall decline in the ratios is statistically significant for both measures (for response number Pearson $r=-0\ 242$, $P<0\ 05$, for response duration, $r=-0\ 240$, $P<0\ 05$)

Differential pressing of the two pedals cannot be attributed to an initial preference for one stimulus over the other regardless of previous experience because the experimental design was balanced and the subgroups did not differ Similarly their behaviour cannot be explained in terms of a preference for the position of one pedal over the other We believe that the results unequivocally support earlier suggestions that chicks prefer novel objects at an early stage in imprinting[6] Moreover, they show that the birds will actively work to expose themselves to slightly novel stimulation The biological advantages of such behaviour may lie in the very complexity of what the young bird has to learn under natural conditions The ability to recognise a parent from all likely angles almost certainly requires more information than could possibly be acquired as the result of learning the characteristics of a single view of that parent The transformation from front view to side view and from side view to back view could not easily be accomplished by mechanisms ordinarily understood as being involved in perceptual constancy[7] Therefore, if a young bird must recognise its parent from a variety of angles it must have first seen its parent from all those angles This would in part be accomplished by rotations of the parent as it went about its business, but the process of attachment would be accelerated if, in addition, the young moved round the parent after familiarising themselves with one view Such a process of working for slight novelty balanced against a growing restriction of preference for what is familiar would not only make good biological sense, it would account for the birds preferring the unfamiliar object only in the early stages of imprinting[10]

Microbial activation of prophenoloxidase from immune insect larvae

INTEREST in the infection of insects by parasites has been generated by the pathogenic potential of the parasite to the insect itself, or to a vertebrate host to which the parasite may be transmitted For example, because of the effects of malaria on man, the relationships between *Plasmodia* and various mosquito species have received much attention[1,2] An important part of the host-parasite relationship is the defence system of the host In insects, phenoloxidase (*o*-diphenol O_2 oxidoreductase, EC 1 10 3 1) has been suggested to be at least partially responsible for insect immunity and parasite resistance[3–5]

The enzyme produces quinones which can react with proteins[6] and with the thiol and amino groups of other compounds[6–8] Quinones can be bactericidal[9] When quinones are present in excess, the black pigment melanin is formed[6] A layer of melanin is frequently observed deposited on parasites by insects as part of their resistance The exact reactions of quinones with parasite tissues have not been determined, but by blocking quinone formation with phenylthiourea an insect's parasite resistance can be suppressed[5] Melanin deposition is often associated with insects' cellular response[5], but can also be a strictly humoral response[10] In some cases of unsuccessful malaria transmission by mosquitoes there is an apparent melanisation manifest in Ross black spores and degenerate oocysts[1,2] For quinones to be involved in resistance to an insect parasite, however, control of phenoloxidase activity would be essential Quinones randomly reacting with the insect host would be ineffective as antiparasitic agents Furthermore, large amounts of active phenoloxidase can kill insects[11] As a contribution to this problem, I describe here the activation of prophenoloxidase in the plasma of immune[12,13] *Galleria mellonella* larvae by microbial products

For immunisation, larvae (each larger than 200 mg) were injected with 1 0-μg doses of *Shigella flexneri* lipopolysaccharide B (Difco)[13] and incubated at 23° C Control larvae were uninjected Haemolymph was collected 18–24 h after immunisation and pooled in a CO_2 environment, at

least 20 larvae were used for each pool Care was taken to avoid gross contamination of haemolymph with fat body tissue To quantitate properly phenoloxidase activity per amount of haemolymph and to facilitate handling, pooled haemolymph was quick frozen with acetone-dry ice, lyophilised and stored at −20° C Haemolymph from control larvae was collected and stored in an identical manner

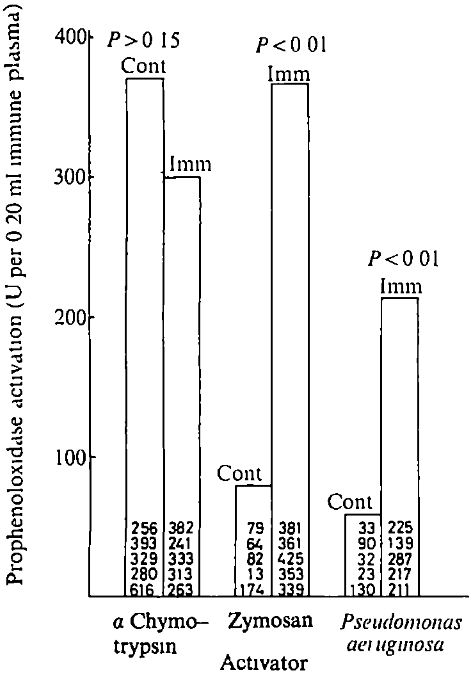

Fig. 1 Activation of prophenoloxidase in control (Cont) and immune (Imm) plasmas by various materials The values indicated by the bars are the average amounts of prophenoloxidase found in five different determinations A determination used 0 20 ml of plasma from a different pool of control or immune haemolymph mixed with 0 01 ml of activator solution or suspension, incubated for 5 min at 30° C, then assayed for phenoloxidase (See text for assay technique) Results for individual determinations are listed within each bar With no activator materials present—water controls—the phenoloxidase activities of plasmas ranged from zero to two units, these values have been subtracted Statistical comparisons are between control and immune plasmas α-Chymotrypsin (Nutritional Biochemicals Corp , three times crystalline) 6 mg ml^{-1} water Zymosan[16] (General Biochemicals) 1 mg ml^{-1} water *Pseudomonas aeruginosa* P11-1[12] was grown in nutrient broth +1% glucose and collected at 24 h by centrifugation, 8,000*g* for 15 min Cells were washed with 0 85% NaCl, then brought to $A_{530}=1$ 1, a concentration of about 5×10^9 bacteria per ml and frozen The cell suspension was thawed, resuspended in water and refrozen It was rethawed and heated at 100° C for 30 min After cooling, 0 10 ml aliquots were used to activate prophenoloxidase None of these activator materials had inherent phenoloxidase activity

My preliminary experiments and those of Evans[14] have shown that haemolymph phenoloxidase occurs as the proenzyme in plasma and can be activated by material from haemocytes To test for other types of activation, lyophilised haemolymph was reconstituted with distilled water to a concentration of 10 mg solids per ml This was 1/17 to 1/18 the usual concentration of solids in fresh haemolymph, and its purpose was to slow spontaneous activation of prophenoloxidase by haemocytes, so that plasma could be collected before activation The plasma and cellular fractions were separated by centrifuging whole reconstituted haemolymphs at 650*g* for 15 min at 4° C The supernatant fluids—the plasmas—were removed and used immediately When water was added to the haemocytes in the lyophilised material no lysis was observed microscopically Also, haemocyte concentrations were calculated, with correction factors for dilutions, to be 18,590 mm^{-3} for immune and 40,040 mm^{-3} for control reconstituted haemolymph, slightly higher than those reported by Stephens[15] for immune and control fresh haemolymph These observations tend to preclude massive haemolysis during handling although the release of some haemocyte materials into the plasmas was possible

Phenoloxidase activity was measured by spectrophotometric determinations of initial reaction rates with a Gilford recording spectrophotometer For a standard assay, 0 30 ml of test material was mixed with 4 7 ml of 0 1 M KPO_4^{2-}, *p*H 6 4, containing 20 μmol of 4-methylcatechol and 40 μmol of 4-hydroxyproline ethyl ester 4-Methylcatechol was enzymatically oxidised to its quinone The quinone reacted nonenzymatically with 4-hydroxyproline ethyl ester to form a stable product, 4-(4′-hydroxy-2′-carbethoxy-1′-pyrrolidyl)-5-methyl-*o*-benzoquinone, with a λ_{max} at 520 nm (ref 7) In the system used, with excess substrates, ΔA_{520} was directly proportional to enzymatic activity One phenoloxidase unit was defined as $\Delta A_{520}=+0$ 001 per min at 30° C, the maximum rate observed during the first 2 min after the initiation of the reaction was used By measuring the phenoloxidase activity of plasmas incubated with and without activator materials, prophenoloxidase activation was quantitated

Immune plasmas showed significantly more prophenoloxidase activation than control plasmas when both were incubated with either zymosan (a yeast polysaccharide)[16] or a preparation of damaged *Pseudomonas aeruginosa* (Fig 1) After treatment with α chymotrypsin (EC 3 4 4 5) both control and immune plasmas showed a high degree of prophenoloxidase activation, similar to that in immune plasmas treated with the microbial products

The activator(s) associated with zymosan and *P aeruginosa* did not have esterase activity towards benzoyl-L-tyrosine ethyl ester when tested at *p*H 6 0 (the *p*H of the plasmas) or at *p*H 7 8 The activator(s) in zymosan suspensions was associated not only with particles, but also with the particle-free solution It (they) passed through a 0 22-μm filter, but not through a dialysis membrane The zymosan activator(s) was stable at 100° C for 3 h, but after 3 h in 0 2 M H_2SO_4 at 100° C and then neutralisation with $Ba(OH)_2$ it was not found when assayed Activation associated with *P aeruginosa* was not manifest unless the cells were damaged by physical means or by pretreatment with egg white lysozyme (EC 3 2 1 17) (Fig 2) Egg white lysozyme does not lyse or kill *P aeruginosa*, but alters its cell wall[17]

Immune plasma was fractionated with $(NH_4)_2SO_4$ (Table 1) The material precipitated with 40% saturation (fraction *A*) contained most of the prophenoloxidase The material still in solution after 60% saturation (fraction *B*) had most of the lysozyme activity Prophenoloxidase in fraction *A* was activated by α chymotrypsin, but not by zymosan alone, however, the prophenoloxidase in fraction *A* could be activated by zymosan if fraction *B* was also added If egg white lysozyme was substituted for fraction *B*, activation did not occur The K_ms of phenoloxidase activated by zymosan and α chymotrypsin for 4-methylcatechol were similar, 1 20 and 1 07 mM respectively Figure 3 shows that when prophenoloxidase was diluted before activation by zymosan there was an exponential relationship between proenzyme concentration and activity, while dilution of the enzyme after activation gave an almost linear relationship

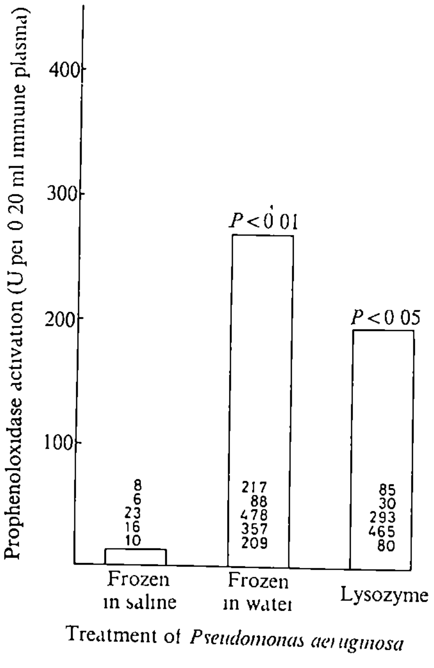

Fig 2 Manifestation of prophenoloxidase activator(s) in *Pseudomonas aeruginosa* after various treatments The activator(s) was determined by the activation of prophenoloxidase in immune plasmas The assay procedures were the same as for Fig 1 *P aeruginosa* cells frozen in 0 85% NaCl saline (see Fig 1), resuspended in water, but not refrozen or heated, served as controls Statistical comparisons are between these cells and those submitted to other treatments The cell suspension frozen in water was the *P aeruginosa* preparation used for Fig 1 Cells treated with lysozyme were frozen in saline, resuspended in 0 1 M KPO_4^{2-}, *p*H 7 0, with 10 mg lysozyme (Sigma, from egg white, three times crystallised) ml^{-1}, incubated 20 min at 30° C, and then resuspended in water Bacterial concentrations were the same for all three suspensions

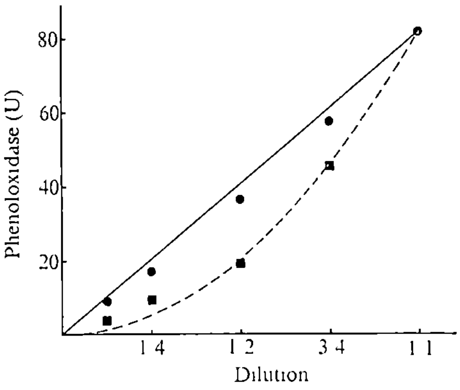

Fig 3 Effect of prophenoloxidase concentration in the zymosan activation mixture on the resulting phenoloxidase activity ■, Prophenoloxidase diluted before activation ($y=81x^2$) fraction *A* was brought to various dilutions with 0 01 M KPO_4^{2-}, *p*H 6 0 0 10 ml of a dilution was mixed with 0 10 ml of fraction *B*, and 0 10 ml of zymosan suspension, 1 mg ml^{-1} water Each of these mixtures was incubated for 5 min at 30° C, then assayed for phenoloxidase ●, Phenoloxidase diluted after activation ($y=81x$) fraction *A*, fraction *B*, and zymosan suspension were mixed 1 1 1 (v v v), then incubated at 30° C After 5 min, various dilutions of this mixture were made using a mixture of 0 01 M KPO_4^{2-}, *p*H 6 0, and zymosan suspension, 2 1 (v v) Immediately after all dilutions had been prepared, 0 30 ml aliquots were assayed for phenoloxidase activity These assays were completed within 15 min

Activation of prophenoloxidases is associated with the aggregation of enzyme subunits[18,21] An aggregation mechanism is consistent with the concentration effect shown in Fig 3 Haemolymph lysozyme in fraction *B* may partially digest zymosan material which then acts as a site for the adsorption, aggregation and activation of prophenoloxidase subunits This would explain the differences observed between control and immune plasmas in Fig 1, since immune haemolymph contains larger concentrations of lysozyme[22] Another hypothesis is that zymosan activates a proteolytic enzyme in fraction *B*, as it does in complement[23] The proteolytic enzyme would in turn activate the prophenoloxidase

I thank Dr J D Briggs for help and Dr V Raghavan for the use of a spectrophotometer I thank Dr H G Boman for useful discussions and for help in manuscript preparation Financial support for these investigations came in part from the World Health Organization International Reference Centre for Diseased Vectors

Elevation of total serum IgE in rats following helminth parasite infection

HELMINTH parasites provide the most potent stimulus known for the biosynthesis of IgE In every species which has been studied, infections with parasitic worms lead to the production of high levels of reaginic or IgE antibodies against parasite antigens[1,2] and, in man, greatly elevated levels of total IgE occur in most individuals infected with any one of a variety of helminths including *Ascaris lumbricoides*[3], *Capillaria philipinensis*[4] and ancylostomes[5]

Experiments in the rat have indicated how the IgE stimulating effect of helminth parasites may operate In this species, infections with *Nippostrongylus brasiliensis* or *Fasciola hepatica,* as well as stimulating parasite specific IgE antibodies, cause nonspecific potentiation of unrelated IgE responses to such antigens as egg albumen, keyhole limpet haemocyanin, and house dust[6–8] Present evidence indicates that live worms produce a factor which, acting via T cells[9], has the capacity to stimulate those B cells which have been programmed for IgE production by previous immunisation In so far as IgE responses against different antigens may be simultaneously potentiated[8] it seems likely that all the existing IgE responses of the animal are affected

Here we now present evidence which supports this We have compared the level of total serum IgE in rats following conventional immunisation with that of rats whose response has been potentiated by subsequent infection with helminth parasites In the latter, the amount of total serum IgE is much greater, and far more than can be ascribed to IgE antibodies specific for the immunising antigen or the parasite

Until recently it has not been possible to estimate total serum IgE in the rat, or indeed in any other species but man, for lack of specific antiserum to this immunoglobulin The recent discovery of a strain of rats bearing IgE immunocytomas[10, 11] has overcome this difficulty since they provide a source of myeloma protein from which purified IgE can be isolated in relatively large amounts Such a purified IgE preparation has been used to induce specific antiserum to rat IgE and also as a reference preparation in an assay for rat total serum IgE using the radioactive single-radial-diffusion technique of Rowe[12]

The specific immunological reagents were prepared as follows The purification of rat IgE from the serum or rats bearing IgE secreting immunocytomas was as previously described[10] with the following modifications Ammonium sulphate precipitation was performed at 50% final concentration, and as a supplementary step preparative agarose electrophoresis was done in 1% agarose equilibriated with 63 mM sodium barbiturate, 15 mM Barbital, 1 8 mM calcium lactate buffer, adjusted to pH 8 6 with HCl The electrophoresis was carried out for 1 h at 20 V cm^{-1} After electrophoresis, the position of the monoclonal IgE was located by comparison with a fixed and stained agarose gel electrophoretic pattern of the same IgE preparation The agarose-containing myeloma IgE was cut out and removed from the slide and the proteins were extracted from the gel by pressure Goat antiserum to rat IgE was obtained by immunisation with purified antigen (IR2 monoclonal protein) emulsified in complete Freunds adjuvant Antisera were absorbed with a solid immunoabsorbant[13] made of serum from germ-free rats Antiserum to goat IgG was prepared by immunisation of rabbits with goat IgG (prepared by the caprylic acid method)[14] in complete Freunds adjuvant The antiserum was also purified by the caprylic acid technique and the resultant IgG fraction was labelled with ^{125}I by the method of McConahey and Dixon[15]

Dilutions of anti-rat IgE in the agar from 1 100 to 1·4,000 could be used The last dilution gave the greatest sensitivity enabling estimation in the range of 0 35-22 24 μg IgE ml^{-1} The reference preparation (IR162 Temoin) contained 5 7 mg ml^{-1} of rat IgE

Outbred female Hooded Lister rats weighing 150–200 g were used in the experiments described here Twenty normal rats (Group 1) were bled before treatment and were then

Table 1 Reaginic antibody titre and total serum IgE (mean ± s e) in serum from normal, immunised infected and potentiated rats

Group	Treatment of rats	Passive cutaneous anaphylaxis* titre		Total serum IgE (μg ml^{-1})
		Egg albumen	*N brasiliensis*	
1	Normal rats no treatment	—	—	most rats <0 35
2	Primary response to 1 μg EA†	92 ± 36	—	1 33 ± 0 25
3	Secondary response to 10 ng EA	1,228 ± 231	—	1 80 ± 0 39
4a	Potentiated reagin response to EA 12 d after *N brasiliensis*‡	1,316 ± 270	—	288 ± 47
4b	Not potentiated reagin response to EA 12 d after *N brasiliensis* (pool of 12 sera)	4,096	—	493
5	Unimmunised rats 12 d after *N brasiliensis* infection	—	—	247 ± 42
6	Unimmunised rats 18 d after *N brasiliensis* infection	—	640 ± 109	104 ± 8

*To estimate specific reaginic antibodies by the passive cutaneous anaphylaxis technique[17], 0 1 ml quantities of saline dilutions of the test sera were injected intradermally in Hooded Lister recipient rats each injection being duplicated on a different animal 48–72 h later, the animals were injected intravenously with 2 5 mg of EA or 0 5 ml *N brasiliensis* antigen (saline extract of 500 homogenised worms) together with 0 5 ml of 1% Evans blue which acts as an indicator of vasodilation The skin reactions were examined after 20 min and the titres recorded above are the greatest dilutions of serum which gave reactions larger than 5 mm in diameter

†Egg albumen

‡The method of culture of *N brasiliensis* and preparation of the infective dose have been previously described[18,19]

immunised with 1 μg egg albumen (Sigma grade V) injected intraperitoneally together with 10^{10} *B pertussis* organisms (Wellcome Biological Reagents) They were bled again 20 d after immunisation (Group 2) and were then divided into two groups and treated as follows Group 3 rats received a booster injection of 1 μg egg albumen and were bled 4 d later, while Group 4a rats were infected by subcutaneous inoculation of 4,000 *N brasiliensis* larvae and were bled 12 d later These times of bleeding were determined by previous observations of the timing of peak secondary and potentiated reagin responses respectively[6,16]

Table 1 shows the specific reaginic antibody levels and total serum IgE in the serum of these animals It is evident that the second injection of egg albumen although resulting in a good secondary antigen-specific IgE response (Group 3) did not have a marked effect on total serum IgE Infection with *N brasiliensis* on the other hand (Group 4a), as well as causing a similar elevation of egg-albumen specific IgE resulted in a most dramatic elevation of total serum IgE from 1 33–288 μg ml^{-1} This level is well in excess of that which, by comparison of the egg-albumen reagin titres of the two groups, can be accounted for by egg-albumen reagins alone Equally the parasite-specific response cannot be implicated at this time after infection since anti-*N brasiliensis* reagins do not normally appear until later in the infection and no parasite specific reagins could be detected in these areas A pool of serum from another group of rats with a very marked potentiated reagin response to egg albumen (Group 4b) showed even greater levels of total serum IgE

The remaining two groups shown in Table 1 were 10 normal animals infected with *N brasiliensis* without previous immunisation Group 5 were bled 12 d after infection with 4,000 larvae at which time no parasite specific reagins were present Greatly elevated levels of total serum IgE occurred in this group in the absence of IgE antibody responses to any known antigens Group 6 were bled 18 d after infection when parasite specific IgE was present, but when the level of total serum IgE had actually declined

The results following infection with the parasite *Fasciola hepatica* have been essentially similar to those we report here

We have also estimated total serum IgE in Wistar rats and find that animals of this strain do not produce levels as high as those of the Hooded Lister strain For instance, 12 d after *N brasiliensis* infection the IgE level in Wistar serum (five rats) was 25 3±5 6 μg ml^{-1} It has been reported that Hooded Lister rats have an exceptional ability to produce IgE antibodies, in that prolonged responses are induced by immunisation with small doses of conventional antigen and that marked secondary responses can occur[16] It is interesting that this facility is also reflected in very high levels of total serum IgE (up to 493 μg ml^{-1}) following helminth infection in rats of this strain

The main points which emerge from these results are that infection of the rat with helminth parasites leads to a great elevation of total serum IgE and that the bulk of this IgE is surplus to levels of IgE antibody against known antigens It would seem reasonable to assume that this IgE consists at least in part of a number of potentiated reagin responses to miscellaneous unknown antigens to which the animal has previously become sensitised By analogy it is of course tempting to suppose that the high levels of total serum IgE seen in parasite infected human beings consist not exclusively of antiparasite IgE responses to unrelated antigens

Alternative route for nitrogen assimilation in higher plants

IT is generally considered that glutamate dehydrogenase (EC 1 4 1 3) is the enzyme that is chiefly responsible for the incorporation of nitrogen into the α-amino group of amino acids

$$\alpha\text{-oxoglutarate}+NH_4+NAD(P)H+H^+$$
$$=\text{L-glutamate}+H_2O+NAD(P)^+ \qquad (1)$$

We suggest that this is not the case in the leaves of higher plants

There is considerable evidence that chloroplasts are a major site of α-amino nitrogen production[1–5] but, although the chloroplast contains glutamate dehydrogenase, the level of activity is low and the enzyme has a high K_m for ammonia[5], greater in fact than the concentration of ammonia required to uncouple chloroplasts Chloroplasts also contain glutamine synthetase which has a much lower K_m for ammonia and a much higher activity[4 6,7] If glutamine synthetase is the route of entry for ammonia, how-

Table 1 Glutamate formation by intact chloroplasts in the presence of various amino donors in the light

Nitrogen donor	Acceptor	Glutamate formed (μmol per mg chlorophyll h^{-1})	Glutamine lost (μmol per mg chlorophyll h^{-1})
None	α-oxoglutarate	0 4	—
Glutamine	α-oxoglutarate	6 9	3 6
NH_4Cl	α-oxoglutarate	0 5	—
Asparagine	α-oxoglutarate	3 5	—
Aspartate	α-oxoglutarate	4 8	—
Glutamine	None	0 7	0

The reaction mixture consisted of intact chloroplasts containing about 100 μg chlorophyll, 0 5 μmol α-oxoglutarate and 0 5 μmol of amino donor except asparagine which was 1 25 μmol, in a final volume of 0 3 ml of 0 33 M Sorbitol, 5 mM potassium chloride and 10 mM sodium pyrophosphate, *p*H 7 5

ever, some way must exist to transfer the amide group of glutamine to the amino group of glutamate Such an enzyme, glutamate synthase (EC 2 6 1 53), also known as GOGAT, L-glutamine α-oxoglutarate aminotransferase (NADPH-oxidising) (equation (2)), has been shown to be present in bacteria[8] and yeasts[9], particularly when grown under limiting concentrations of ammonia, and in nitrogen-fixing bacteria and the bacteroids of nodulated higher plants[10,11]

$$\text{L-glutamate} + \alpha\text{-oxoglutarate} + \text{NADPH} + \text{H}^+ = 2\ \text{L-glutamate} + \text{NADP}^+ \qquad (2)$$

This pyridine nucleotide-linked enzyme has not been reported in the tissues of higher plants in spite of attempts by ourselves and others[7,11] to find it Here we present evidence to show that chloroplasts can perform a light-dependent synthesis of glutamate from α-oxoglutarate and glutamine and that extracts of chloroplasts contain a ferredoxin-dependent glutamate synthase

Chloroplasts from 10–15-d-old *Pisum sativum* (var Meteor) plants were extracted by a method based on that of Walker[12] in a medium containing 0 33 M sorbitol, 1 mM $MgCl_2$, 2 mM EDTA, 1 mM mercaptoethanol, 10 mM sodium pyrophosphate, *p*H 7 0 The chloroplast pellet was washed in 0 33 M Sorbitol, 5 mM KCl, 10 mM sodium pyrophosphate, *p*H 7 5 and then resuspended in the same medium Aliquots containing 100–150 *μ*g chlorophyll were incubated with substrates for 20 min at 30° C The reaction was stopped by the addition of ethanol Amino acids were separated by paper chromatography in 75% (w/w) phenol, in the presence of ammonia vapour, and quantified by the method of Atfield and Morris[13]

The results (Table 1) show that chloroplasts are capable of converting α-oxoglutarate to glutamate in the light, confirming the findings of earlier workers[14] They also confirm that this reaction is not stimulated by ammonia—the substrate for glutamate dehydrogenase When glutamine is supplied, however, there is a seventeenfold stimulation in the rate of glutamate formation and the reaction is absolutely light dependent The only reaction shown in Table 1 that occurred in the dark was between aspartate and α-oxoglutarate, which was at the same rate as determined in the light Asparagine also markedly stimulates the conversion of α-oxoglutarate to glutamine The light dependence of the reaction, compared with the light independence of transaminase activity, and the inability of ammonia to act as an amino group donor would suggest that asparagine is not being cleaved by asparaginase to give aspartate and ammonia which could be subsequently incorporated

The results with glutamine are best explained by the presence of glutamate synthase To test this, chloroplasts prepared and washed as described above were resuspended in 0 1 M tricine, *p*H 7 5 After standing for 30 min the ruptured chloroplast debris was centrifuged off and the supernatant passed over a Sephadex G-75 column pre-equilibrated with 0 1 M tricine pH 7 5 The chloroplast extract was eluted with the same buffer Aliquots of the extract were incubated with various substrates for 20 min at 30° C The reaction was stopped and the amino acids separated and determined as described above

Preliminary studies with a spectrophotometric assay confirmed that these extracts had no NADPH dependent glutamate synthase and only a trace of glutamate dehydrogenase activity But experiments using methyl viologen and dithionite as an electron donating system showed the presence of a glutamine and α-oxoglutarate dependent synthesis of glutamate (Table 2) Subsequent studies showed that ferredoxin is an extremely effective donor, none of the other donors tried was capable of supporting the reaction The stoichiometry of the reaction is two molecules of glutamate formed for each glutamine utilised, as predicted by equation (2) The rates of glutamate synthesis expressed on a chlorophyll basis are of the same order of magnitude as those in the intact chloroplasts and are also similar to those of nitrite reduction and α-amino nitrogen production measured in other studies[2,4]

The demonstration of a ferredoxin-dependent glutamate synthase in the chloroplasts completes a chain of reactions for the incorporation of nitrate into α-amino nitrogen (Fig 1) Several considerations suggest this is the major

Table 2 Glutamate formation by chloroplast extracts under various conditions

The reaction mixture consisted of 70 μmol tricine, *p*H 7 5, chloroplast extract equivalent to approximately 100 μg chlorophyll, 3 5 μmol α-oxoglutarate and the electron donors and nitrogen donors as indicated The final volume of the reaction mixture was 0 7 ml The amounts of electron donors in the reaction mixture was as follows ferredoxin (Fd) 0 1 mg, sodium dithionite + $NaHCO_3$ (DIT) 1 6 mg each, FMN 0 2 mg, methyl viologen (MV) 0 1 mg, NAD(P)H 0 4 mg Amino donors were present at 2 mM concentration except asparagine which was at 5 mM Ferredoxin was derived from *Spirulina maxima*

*No visible glutamate spot on the chromatogram

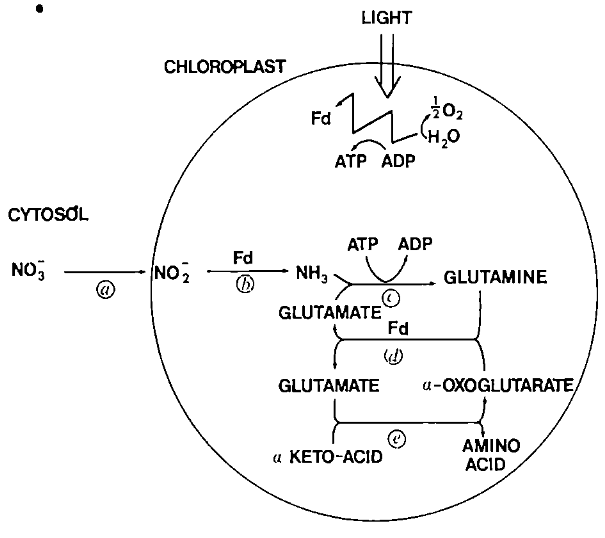

Fig 1 The proposed route of entry of nitrate into amino acids in leaves The enzymes are, *a*, nitrate reductase, *b*, nitrite reductase, *c*, glutamine synthetase, *d*, glutamate synthase and *e*, transaminase

route of entry of nitrogen into the organic form in the leaves of higher plants The leaf normally receives its inorganic nitrogen in the form of nitrate This nitrate is metabolised through nitrate and nitrite reductases to ammonia Both of these reactions are strongly light stimulated[2,3] as is the incorporation of $^{15}NO_3$, $^{15}NO_2$, and $^{15}NH_3$ into α-amino nitrogen[15] Nitrite reductase is located in the chloroplasts and the presence of glutamine synthetase with a low K_m for ammonia ensures that the ammonia formed can be incorporated without building up to levels which would uncouple the chloroplasts The presence of glutamate synthase does not preclude a role for glutamate dehydrogenase in ammonia assimilation, particularly under conditions of high ammonia availability These are most likely to occur in roots Since ammonia is not normally a major nitrogen constituent of the xylem sap[16] it is unlikely that it occurs in any concentration in the leaves unless it is produced by deamination of transported amines and amino acids

The operation of the route in Fig 1 would result in the same pattern of incorporation of the nitrogen of NO_3, glutamate and the amide group of glutamine into all the amino acids The results of Lewis and Pate[17] with ^{15}N feeding studies confirm that this occurs in leaves This is distinct from the traditional idea of incorporation of glutamine into relatively few amino acids, as suggested for yeast by Sims and Folkes[18] The ^{15}N studies of Baker and Thompson[19] with *Chlorella* are also consistent with Fig 1

The results we present suggest that asparagine is metabolised by chloroplasts although not by the same enzyme as glutamine It is probable that the amide is transferred to another acceptor molecule (such as, pyruvate, phosphoenol pyruvate or oxoaloacetate) in the presence of a reductant or to glutamate to form glutamine and pass into the chain The strong light dependence of glutamate synthesis from asparagine is consistent with the rapid disappearance of asparagine from leaves in the light

We suggest that the leaves of higher plants contain a glutamate synthase which plays a crucial role in nitrogen assimilation This enzyme differs from those previously described in being ferredoxin dependent Its presence helps to explain a major anomaly of intermediary nitrogen metabolism in higher plants, namely the unsuitability of glutamate dehydrogenase as a major point of entry of nitrogen into organic combinations in chloroplasts

We thank Mrs Shirley Burgess for technical assistance and Dr D O Hall of Kings College, London for a gift of ferredoxin P J L was supported by a Pickering Research Fellowship

Note added in proof Since this paper was submitted we have become aware of a report[20] on NAD(P)H-dependent glutamate synthase type activity in extracts of carrot cell cultures

Evolution of cell senescence, atherosclerosis and benign tumours

IT has been proposed that cell senescence is the cause of organismic senescence[1–3] and that senescence is under evolutionary control[4] Orgel[5] has argued that cell senescence could not be under evolutionary control because it is difficult to imagine how senescence of the organism has a positive evolutionary advantage

I propose that cell senescence itself, rather than senescence of the organism, is the genetically controlled and programmed event selected by evolution and that any effects on somatic senescence is a pleiotropic effect of this function The advantage of programmed cell senescence to the organism is that it stops cells which have escaped from normal control from dividing indefinitely If a cell with potential for further division gets out of place in the body, it is possible for it to settle in a new location where the normal environmental signal inhibiting division is lacking Were these now uninhibited cells capable of unlimited growth, they would divide to fill the entire space available A limited number of cell divisions, however, would limit the size of the growth, thus saving the organism

In vitro normal human fibroblasts are limited in the number of divisions[1,2]. The life of a culture of cells from a tissue explant can be divided into three phases[1]. Phase I ends with the formation of the first monolayer; phase II refers to a period when rapid growth occurs in proper culture conditions, while phase III refers to the period of senescence of the culture. Not only is the percentage of non-dividing cells higher in phase III cells than phase II cells[6], but the growth rate of dividing cells is is reduced[7]: so all cells of the culture are affected by senescence. Phase II cells, however, are unaffected by being mixed with phase III cells[2].

Phase II cells can be held for long periods in a non-dividing state without affecting the number of divisions the cells undergo before senescence[8]. Thus, the metabolic age of a culture can be separated from the doubling age. The onset of senescence is shown to be dependent on the doubling age and the doubling age of a culture can be estimated[9].

Growth of a clone which arose from a single cell is restricted to the edge. The cells in the centre are inhibited by contact inhibition. Thus, the cells in the centre are at a younger divisional age than the cells near the edge[10]. As the cells go out from the centre, they become progressively older and growth stops at the outer edge of the colony when the cells there have divided the maximum number of times and senesce.

The evidence also indicates that cells senesce *in vivo*. With increasing age of the human donor there is a reduction in the number of cell doublings before senescence in culture[11]. Serial transplants of normal tissue into young inbred animals die out[12–14] and the death of the tissue is related to number of cell divisions rather than to its metabolic age[15]. In contrast, transformed cells (malignant cells) which do not show contact inhibition and do not senesce in tissue culture, can be transferred *in vivo* indefinitely[12].

Hayflick postulated that organisms age because their cells age[2,3] and this relationship has been supported by studies on Werner's syndrome, a genetic disease characterised by the development in early adulthood of a wide variety of degenerative features similar to those found in old age. Cells from sufferers of this syndrome are already senescent, doubling less than ten times in tissue culture[11], while cells of normal people of similar age double 35 times. Cell senescence is not necessarily the only cause of organismic senescence since humans aged 70–90 yr are senescent; but fibroblast cultures from them are not senescent, doubling at least twenty times in tissue culture[11], which is over 40% of the doublings found in human embryo cultures.

Atherosclerotic lesions consist of 'plaques' of fibroblasts lining the interior of the great arteries. Limitation in the size of these plaques provides a strong selection for cell senescence.

Benditt and Benditt[16] present the following evidence that a single plaque is monoclonal; that is, all of the cells of a plaque are derived from a single dividing precursor cell. They looked at plaques from the three females who were heterozygous for two electrophoretic variants of the X-linked glucose-6-phosphate dehydrogenase. There is random inactivation of one or the other of the X chromosomes at about the 1,000 cell stage of embryo development, consequently each heterozygous female has a mixture of cells with one or the other X chromosome inactivated[17]. When small pieces (0.1 mm^3) were taken from the aorta wall, both enzyme types were present. But when larger pieces from plaques (0.5 mm^3 to 20–30 mm^3) were taken, most of them had only one isozyme present. It is unlikely that these plaques are scars[18] formed where the artery had been injured, since hypertrophic scar tissue is polyclonal[16].

Cells escaping into the blood stream from points where there is injury to the vascular system would be carried away from the wound by blood flow and could settle on the inner wall of arteries. Possibly they have trouble settling or dividing except where there are fatty streaks, thus giving the correlation between fats and atherosclerosis. The fibroblasts, now living in a new place in the body, exposed to a high velocity flow of nutrient rich blood, would no longer be contact inhibited[19] and would start dividing. As the single cell forms a clone, the cells in the centre away from the flow of blood, will cease dividing, while the cells on the edge will continue to divide. If these cells were able to continue dividing they would form quite a large growth and constrict the artery. Since they are limited to a certain number of divisions, however, the size of the plaque is limited in the same way as the size of a colony arising from a single cell in tissue culture[10].

I am postulating that atherosclerotic plaques arise from cells which escape into the arteries, settle and start growing. To keep these plaques at a minimum size, evolution has selected for a 'clock' which limits the number of cell divisions. This number is set by the conflicting demands of the large number of divisions required for wound repair and cell replacement and the restriction in the number of cell divisions needed to control atherosclerotic plaques and other abnormal growths.

The theory does make several predictions which can be tested. The first is that plaques will grow quickly and then stop when the cells on the outer surface senesce. Second, with fully grown but relatively young plaques, the cells at the centre of the plaque should be able to divide in tissue culture and the ones at the edge should not. Third, the number of divisions the cells from the centre of a plaque can go through should be correlated with the size of the plaque, given that the plaque started from a single cell; and last, the median final size of a plaque should be correlated with the age of the person at the time the cells were released into the blood stream.

Limitation in the size of some benign tumours could also provide strong selection for cell senescence. It has been shown that leiomyomas are monoclonal[20]. Many leiomyomas seem to originate near arteries[21] and thus may have arisen from cells from arterial walls which have escaped into the lyometrium of the uterus. Similar predictions as those made for atherosclerotic plaques apply to such benign tumours. Other benign tumours particularly the large ones, could originate from other causes, such as by a mutation which destroys the system providing contact inhibition. In this case, all the cells, not just the ones on the edge, would go through the maximum number of divisions.

So far no mechanism has been proposed as to how cell senescence takes place. The theory presented above explains how natural selection can select for cell senescence and implies that cell senescence is under genetic control. Views on cell senescence may be divided into two groups: one favours an evolutionary-genetic basis, as in this paper, and the other believes that senescence is caused by random events which create disturbances within the cell which are not fully correctable and that this accumulation of errors eventually leads to death. Any random error theory, such as the 'error catastrophe theory'[15], must be able to explain why cultures of transformed cells are not severely enough affected by the errors to senesce and why normal cells can not evolve the state of perfection enjoyed by transformed cells. Moreover, any random error theory needs to explain why germ line cells are less affected by the errors than the somatic cells. The simplest explanation to these problems is that senescence is under genetic control and that induction of senescence takes place during differentiation leaving the germ line unaffected.

Any mechanism, such as that proposed by the 'error catastrophe theory', could be used by evolution as the means to induce senescence. But a special compound could be produced whose sole function is to induce senescence.

Milo[22] has presented evidence that a glycoprotein extracted from the cell wall of senescent phase III cells causes almost immediate senescence when put on phase II cells.

I thank Dr P. Morrow, Dr B. Richardson, Dr J. Campbell and Professor W. Hayes for helpful criticism.

Insulin stimulates myogenesis in a rat myoblast line

THE clonal rat myoblast cell line L_6 isolated by Yaffe[1] undergoes myogenesis when the mononucleated myoblasts become confluent and fuse into multinucleated myotubes. This morphological differentiation is correlated with the synthesis of characteristic muscle proteins such as myosin and creatine kinase[2]. When L_6 myoblasts fuse the specific activity of adenylate cyclase[3] decreases and cyclic AMP, dibutyryl cyclic AMP and theophylline reversibly inhibit the differentiation process[4]. In primary cultures of rat muscle cells, a decrease in cyclic AMP has been reported at the time of fusion[5]. These facts support the hypothesis that low levels of cyclic AMP correlate with myoblast differentiation, while high levels inhibit fusion. In view of the relationship between the action of insulin and the biosynthesis of cyclic nucleotides[6] and the effects of the hormone on muscle metabolism[7], we have examined the influence of insulin on myogenesis of cultured L_6 myoblasts. The hormone replaces partially the serum requirement for morphological differentiation of primary cultures of chick embryo myoblasts[8,9], and now we have found that it stimulates fusion and the specific activity of creatine kinase in L_6 myoblasts in the presence or absence of serum.

In an attempt to separate the effects of insulin on myogenesis from those on metabolism, we examined the effect of the hormone on myoblast fusion in the presence of different concentrations of serum (Fig. 1). In serum-free medium almost no myotubes were observed in the absence of insulin and many cells died (Fig. 1*a*). In 1% serum, myotubes formed after 2 d and in 10% serum they appeared after 4 d (Fig. 1*c* and *e*). Addition of insulin (1 μg ml^{-1}) to the medium stimulated both the rate and extent of fusion at all serum concentrations tested (Fig. 1*b*, *d* and *f*), most of the nuclei being incorporated into myotubes within 24 h of the onset of fusion. Myotubes formed in the presence of insulin were much larger than those formed in its absence,

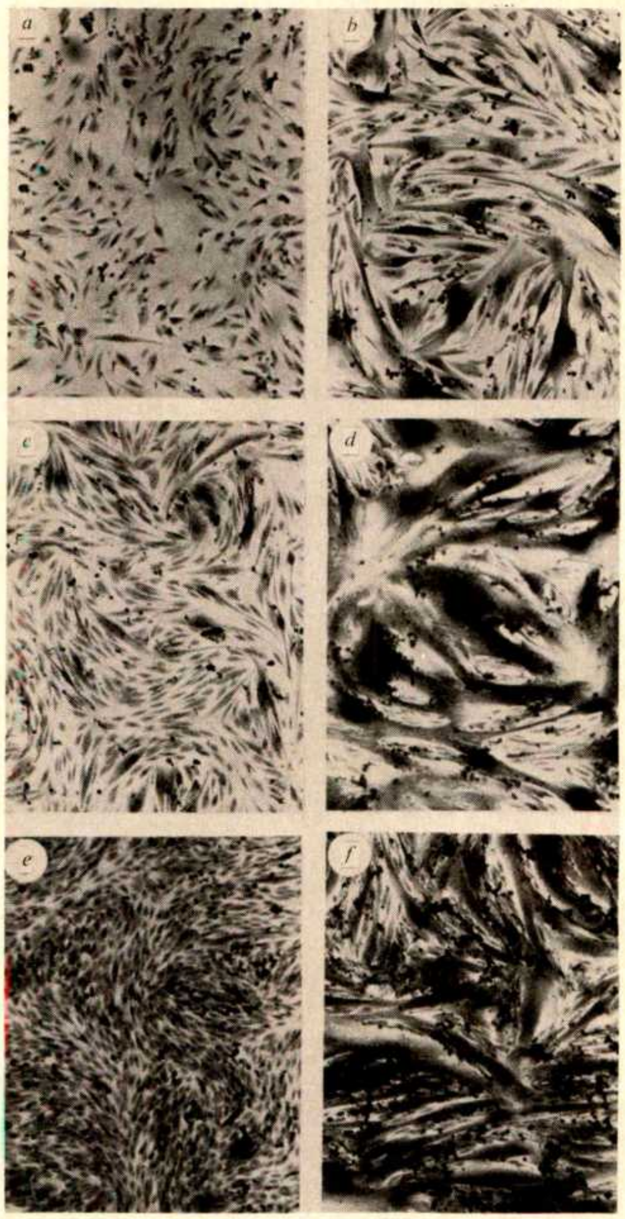

Fig. 1 Effect of insulin and serum on myoblast fusion. Rat myoblast L_6 cells (from Dr S. Heinemann, Salk Institute) were grown at 37° C in a humidified incubator under a 5% CO_2 95% air atmosphere in complete medium (Dulbecco's modified Eagle's medium supplemented with 10% foetal calf serum, Grand Island Biological Co.). To study fusion, cells were plated in complete medium at 8×10^3 cell cm^{-2} in 35 mm dishes. This medium was removed 24 h later, the dishes were rinsed with phosphate-buffered saline, and re-incubated under the following conditions. *a* and *b*, Serum-free medium containing 1.5 mg ml^{-1} bovine serum albumin (BSA); *c* and *d*, medium containing 1% foetal calf serum; *e* and *f*, complete medium (10% foetal calf serum). Insulin (1 μg ml^{-1}, zinc-free, from Dr C. Yip, University of Toronto) was added when the medium was changed for *b*, *d*, and *f* and the dishes were stained with methylene blue 3 d later.

with nuclei located more centrally. They also tended to degenerate more rapidly[8].

We then found that in the presence of insulin the specific activity of creatine kinase increased markedly at three serum concentrations (Fig. 2). The increase coincided with the onset of fusion (data not shown). The highest specific activity was reached in cultures grown in 1% serum in the presence of insulin, and under these conditions the maximum was reached in only 48 h (Fig. 2*b*). The increase in creatine kinase activity (as well as in morphological fusion) was delayed by about 24 h in cultures containing 10% serum (Fig. 2*c*). By changing the insulin-containing medium at 4 d, we obtained a further stimulation of creatine kinase levels in the presence of 10% serum, but not 1% serum (dashed lines, Fig. 2*b* and *c*). In other experiments the glycogen phosphorylase content of myotubes, detected histochemically[2], also increased after addition of insulin. It is interesting that de la Haba *et al.* found no accumulation of the characteristic muscle enzyme glycogen synthetase in primary cultures of myoblasts fused in the presence of insulin in serum-free medium[9]. Since under similar conditions with the L_6 myoblast line we observed a marked stimulation of creatine kinase activity by insulin, either there are differences in the response to insulin of primary cultures and L_6 cells, or glycogen synthetase and creatine kinase levels are controlled independently during myogenesis.

All the above experiments were carried out using 1 μg ml^{-1} of insulin. When we used 10^{-2} μg ml^{-1} insulin (Fig. 3*a*) we observed a significant stimulation of morphological fusion and creatine kinase activity: this concentration is about one order of magnitude higher than that found *in vivo*. When the concentration of serum was low, the maximum stimulation was obtained with 1 μg ml^{-1} insulin, while in 10% serum no plateau was apparent even with 5 μg ml^{-1} insulin. The requirement for high concentrations of insulin for maximum stimulation of creatine kinase may be due in part to inactivation of the insulin, especially in 10% serum (compare Fig. 2*c*). It may also indicate that a continuous and prolonged exposure to insulin is needed for the increase in fusion and creatine kinase activity. This possibility was tested by exposing cultures to insulin for various times, up to 4 d, removing the hormone, then measuring creatine kinase activity at 4 d. Figure 3*b* shows that insulin had to be present for more than 24 h to stimulate significantly creatine kinase specific activity, and longer exposure resulted in greater enzyme activity.

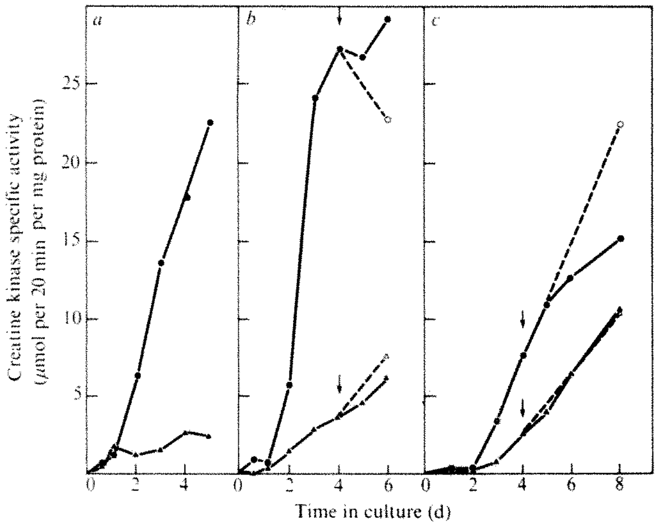

Fig. 2 Effect of insulin and serum on specific activity of creatine kinase. Cells were plated as described in the legend to Fig. 1, and the medium was replaced by medium containing various concentrations of serum in the presence or absence of insulin (1 μg ml^{-1}). At the indicated times after the medium change, the medium was removed, the cells were rinsed quickly with buffer *A* (100 mM Tris-acetate, *p*H 6.8 (22° C), 25 mM magnesium acetate, 10%, v/v, glycerol), drained, and kept frozen at −35° C. After thawing, cells were scraped into 0.35 ml buffer *A* supplemented with 0.2%, v/v, Nonidet P-40, and 0.1 mM phenymethylsulphonylfluoride (Sigma) and subjected to two cycles of freezing and thawing. Aliquots from duplicate plates were assayed for creatine kinase[10] and protein[11]. Variations in specific activity were usually less than 15% for values greater than 1 μmol per 20 min per mg protein. *a*, Serum-free medium containing 1.5 mg ml^{-1} BSA; *b*, medium containing 1% foetal calf serum; *c*, complete medium (10% foetal calf serum). ▲, Minus insulin; ●, 1 μg ml^{-1} insulin. The open symbols indicate values obtained after replacing the medium on day 4 (arrows) with fresh medium with (○), or without insulin (△).

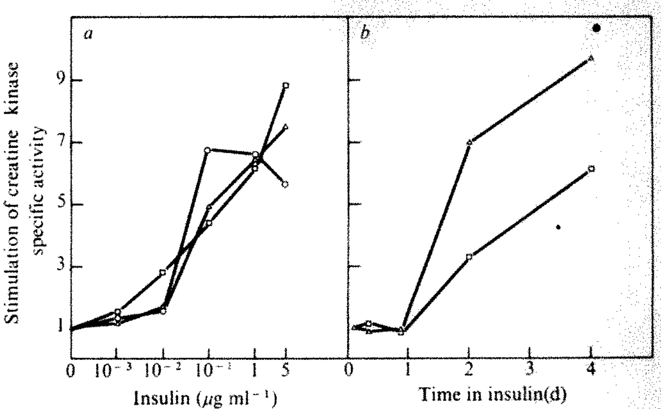

Fig. 3 Characteristics of the stimulation of creatine kinase by insulin. Cells were handled as described in the legend to Fig. 1, insulin was added at the time of the medium change, and cells were frozen 4 d later for determination of specific activities as described in the legend to Fig. 2. Results are expressed as relative stimulation over the control incubated without insulin. *a*, Insulin concentration dependence. Control specific activities were 1.0, 1.0 and 0.6 μmol per 20 min per mg protein in 0, 1% and 10% serum respectively. *b*, Dependence on time of exposure to insulin. Insulin (1 μg ml^{-1}) was added at time 0 for various times after which the medium was removed and replaced by medium at the same serum concentrations but lacking insulin. Initial specific activities without insulin were 1.3 and 0.6 μmol per 20 min per mg protein in 1% and 10% serum respectively. ○, No serum; △, 1% serum; □, 10% serum.

Insulin stimulates many cellular activities, especially in muscle cells[7], and its observed effect on myogenesis in both L_6 cells and primary cultures[8] may not be a specific effect on differentiation, but an indirect result of a general stimulation of cellular metabolism, especially in serum-free medium. For example, in fibroblasts serum starvation results in a reduction in RNA and protein synthesis, and these activities can be restored by the addition of insulin[12]. In the case of L_6 myoblasts, however, cell density and protein synthesis are higher in 10% serum minus insulin than in serum-free medium plus insulin, yet myogenesis is increased in the latter case. (We have also found that insulin does not increase RNA or protein synthesis in the first 30 h after its addition to cells grown in 10% serum; a twofold stimulation was obtained later at 48 h during an 8 h label period.) Thus, although further experiments are needed, we believe it unlikely that the stimulation of the specific activity of creatine kinase and the morphological changes caused by insulin are due to nonspecific stimulation of protein synthesis.

Alternatively, the insulin stimulation of myogenesis may be a consequence of alterations in cyclic nucleotide metabolism, since insulin is known to affect cyclic AMP synthesis[13] and degradation[14] and cyclic GMP levels[6] in different cell types. Therefore it is attractive to suppose that such effects account for the stimulation of myogenesis in L_6 myoblasts reported here, and perhaps for the insulin-promoted differentiation of mammary gland in organ culture[15], and of primary cultures of lens epithelium[16]. In the case of L_6 myoblasts, it is worth noting that insulin improves both the reproducibility and synchrony of fusion, and allows myogenesis to be studied in a defined serum-free medium.

Sickle cell resistance to *in vivo* hypoxia

THE rapid disappearance from circulation of human erythrocytes transfused to rats can be prevented if the animals are pretreated with ethyl palmitate (EP) and a cobra venom factor (CVF)[1]. The improvement in human erythrocyte survival in these animals is due to EP-induced impairment of reticuloendothelial function[2] and to suppression of intravascular haemolysis through CVF inhibition of the third component of complement[3]. The halflife of normal human erythrocytes in the blood of untreated rats is less than 15 min, but is about 30 h in the EP and CVF treated rats[4].

Application of this animal system to the study of human sickle cell anaemia erythroctyes (sickle cells) has verified many of their known survival characteristics in man[5-7]. These include a short intravascular survival, an improved survival with *in vivo* hyperoxygenation and an improved survival following *in vitro* cyanate treatment[8,9]. Human sickle cells transfused into rats exposed to widely divergent concentrations of oxygen seem to consist of two populations with regard to their *in vivo* sensitivity to oxygen changes. The circulation of a minor population of sickle cells is dependent on the concentration of oxygen the rats breathe, as shown by rapid increases and decreases in circulating cells with increases and decreases in the amount of oxygen administered to the rats (O_2-sensitive cells)[8,10]. In contrast, the majority of sickle cells seems to be relatively insensitive to the levels of hypoxia attainable *in vivo*. They continue to circulate after the initial rapid removal of the oxygen-sensitive cells in spite of exposure to hypoxic atmospheres barely compatible with life. The proportion of sickle cells which is oxygen sensitive is not influenced by the total number of sickle cells transfused (O.C., S.C.F., and G.O., unpublished). Oxygen-sensitive sickle cells are most readily demonstrated when the animals breathe 100% O_2 followed by 7–8% O_2 in short alternating periods. In these conditions the ^{51}Cr survival curve of the transfused sickle cells assumes a characteristic 'saw tooth' pattern with peaks during hyperoxia and valleys during hypoxia[10].

Here we report that separation of hypoxia-resistant sickle cells is possible if blood from a rat previously transfused with sickle cells is removed during hypoxia and then retransfused into another rat. Presumably all of the human sickle cells in circulation in the blood of donor animals during hypoxia are insensitive to a low pO_2 after the sensitive population has been sequestered. Figure 1 shows that in the recipient animals the

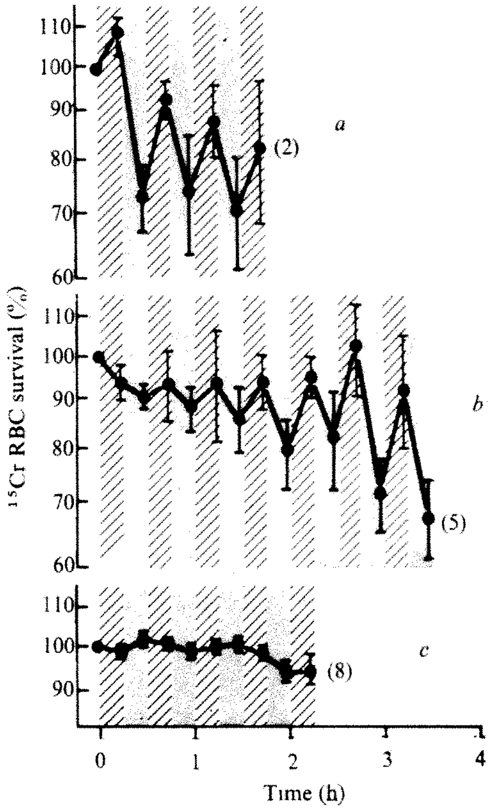

Fig. 1 Human sickle cell resistance to O_2-dependent circulatory changes after their removal from hypoxic rats and retransfusion into separate animals. Each rat was injected with 0.5 g kg^{-1} of EP and with 10 units of CVF 2 h before transfusion. Three donor animals then were transfused with 4 ml of a 50% saline suspension of ^{51}Cr-labelled erythrocytes (RBCs) from one of three patients with sickle cell anaemia. After a 20–60 min exposure of the donor animals to 7.5% O_2 in N_2 5 ml of rat blood—containing transfused ^{51}Cr human sickle cells—were removed by cardiac puncture. The RBCs were washed with physiological saline, adjusted to a 50% suspension in saline and then 1–3 ml were retransfused into recipient animals. Following this, all rats were exposed to a minimum of three hyperoxia–hypoxia cycles each consisting of 15 min of 100% O_2 followed by 15 min of 7.5% O_2 in N_2. The ordinate measures ^{51}Cr RBC survival expressed as % activity found in the rats' blood immediately before exposure to the hyperoxia–hypoxia cycles. The abscissa measures time (h) after start of the first hyperoxia–hypoxia cycle. Points in the graph represent means and bars ± 1 s.d. of the values for each patient study. The number of rats used in each group is shown in parentheses. *a*, Transfused sickle cells showing that the sickle cells remaining in the two donor animals that survived cardiac puncture exhibited characteristic O_2-dependent circulation during each hyperoxia–hypoxia exposure. *b*, Retransfused sickle cells (previously obtained from hypoxic donor animals) did not show this behaviour initially. After the third cycle, an O_2-sensitive population developed in the retransfused sickle cells. *c*, The survival in the rats' blood of ^{51}Cr-labelled control human RBCs obtained from two individuals without haematological abnormalities was not influenced by oxygen changes. Stippled areas, hypoxia; cross-hatched areas; hyperoxia.

survival curves of retransfused sickle cells obtained from hypoxic donor animals do not exhibit the saw tooth pattern during the initial alternating periods of hyperoxia and hypoxia. The sickle cells remaining in the donor animal (transfused sickle cells) continue to show this response. Sickle cells removed from donor animals while they breathe 100% O_2 and retransfused into recipient animals (not shown in the figure) retain an O_2 sensitive population. Continuation of the hyperoxia–hypoxia cycles in the recipient rats with O_2 insensitive retransfused sickle cells eventually results in a survival pattern consistent with the development of a population of sickle cells which is oxygen sensitive (Fig. 1). The proportion of O_2-sensitive sickle cells to total sickle cells is similar to that in the original population. Wide changes in O_2 tension seem to be necessary for the appearance of an O_2-sensitive population of sickle cells in the recipient animals. This statement is based on the observation (O.C., S.C.F., and G.O., unpublished) that the O_2-insensitive retransfused sickle cells in rats maintained on room air will remain resistant to O_2 changes until they have been subjected to several hyperoxia–hypoxia cycles.

The physical separation of hypoxia resistant sickle cells from the total population confirms the heterogeneity of human sickle cells with regard to their oxygen dependent circulation in this animal model. The temporary loss of O_2-sensitive sickle cells from the animals' circulation during exposure to low O_2 tension is best explained by *in vivo* sickling and trapping of sickled erythrocytes in the animals' microvasculature. This explanation is supported by our finding in this animal model of hypoxia sensitive erythrocytes not only from patients with sickle cell anaemia but also from patients with sickle-thalassaemia and with sickle-Hb C disease[4]. In contrast, none of eight individuals with sickle trait studied thus far has shown this type of response[11].

The observations reported here demonstrate that a proportion of O_2-insensitive sickle cells can be transformed into an oxygen sensitive population when challenged with repeated hyperoxia–hypoxia cycles. Our findings suggest that repeated sickling may be an important factor in the production of cells that do not circulate during hypoxia. Direct extrapolation of animal data to the human situation must be viewed with caution. Nevertheless, it is possible that vaso-occlusive episodes in patients with sickle cell anaemia may be a function of the relative number of sickle cells that are oxygen sensitive with regard to their capacity to circulate. The isolation and study of any oxygen resistant population may help to determine those factors that protect sickle cells from sequestration during *in vivo* hypoxia.

Expression of the dystrophia muscularis (*dy*) recessive gene in mice

STUDIES *in vitro* of mutant gene expression in murine muscular dystrophy now seem to have reached an impasse. For 15 years there was only one species of dystrophic mouse[1], the Bar Harbor 129 ReJ strain (denoted *dy*/*dy*). Then in 1970, a second strain BH WK ReJ (denoted dy^{2J}/dy^{2J}) was reported[2] which was described as being similar in all histopathological respects to the allelic *dy*/*dy* mutant except that it showed a slower progression of muscle necrosis. The new mutant gene was transferred to another mouse strain C57Bl/6J for commercial retail. The new strain, offering many advantages over the original strain, has been readily adopted for study by research workers; certain findings obtained with this strain have added confusion to a difficult problem simply because it is not the same as the original strain.

Over the past four years I have been growing dystrophic (*dy*/*dy*) muscle *in vitro*, and have noticed that muscle explants from crush lesions in dystrophic (*dy*/*dy*) muscle did not form multinucleate myotubes, whereas muscle explants from crush lesions in normal muscle readily did so. I report here some brief details of this work (previously described in refs 3 and 4), and include the results of some preliminary experiments using dystrophic (dy^{2J}/dy^{J2}) mice which suggest that allelic mutant genes do not have the same phenotypic expression.

Crush lesions were made in the triceps and quadriceps muscles of normal Bar Harbor 129 ReJ+/+, dystrophic 129 ReJ *dy*/*dy*, and dystrophic C57Bl/6J dy^{2J}/dy^{2J} mice under pentobarbital anaesthesia. Four days after the lesion was inflicted the mouse was killed by cervical dislocation and the lesion zone was removed under sterile conditions for tissue culture. The excised regions were dealt with separately. The tissue was chopped and the explants set up in coded Pulvertaft[5] chambers or 50-mm Petri dishes. The culture medium was 10% EE50, 10% horse serum and 80% Eagle's MEM with streptomycin and penicillin.

Each day, over a period of 8 d, all the coded cultures were assessed microscopically using differential interference optics. The assessment was carried out blind and the results are therefore unbiased. The total number of cultures was in excess of 100 for normal and *dy*/*dy*, and 40 for dy^{2J}/dy^{2J} mice.

Days 1, 2 and 3 showed essentially the same pattern of growth in all cultures. Proliferation and explant spreading were similar, and occasional cells with up to five nuclei were found. From day 4 to day 8 proliferation continued until the cultures became overgrown and degenerated. During this second period all normal cultures (Fig. 1*a*) and all dystrophic dy^{2J}/dy^{2J} cultures (Fig. 1*b*, *d*) developed multinucleate myotubes of considerable size. There was an indication, which could not be quantified, that explants of dy^{2J}/dy^{2J} quadriceps showed less multinucleation than triceps cultures from the same animal. All dystophic *dy*/*dy* cultures (Fig. 1*c*) showed associations of cells which have been named pseudostraps[4]. These are muscle strap-like or myotube-like aggregates of myoblasts which do not fuse. There were no multinucleate structures of any kind to be found. I believe that these results clearly demonstrate an abnormality of early myogenesis caused by the expression of the *dy*/*dy* gene, but no indication of any abnormality caused by the expression of the dy^{2J}/dy^{2J} gene.

The results clarify some of the conflicting evidence already produced. Three groups[6–8] have used organotypic methods of tissue culture combining foetal spinal cord sections with adult muscle. Paul *et al.*[7] were very careful not to draw any far-reaching conclusions from their work, recognising the genetic background on which it was based. But they did state that adult myogenic cells were in some way affected by the dystrophy (*dy*/*dy*) and were incapable of

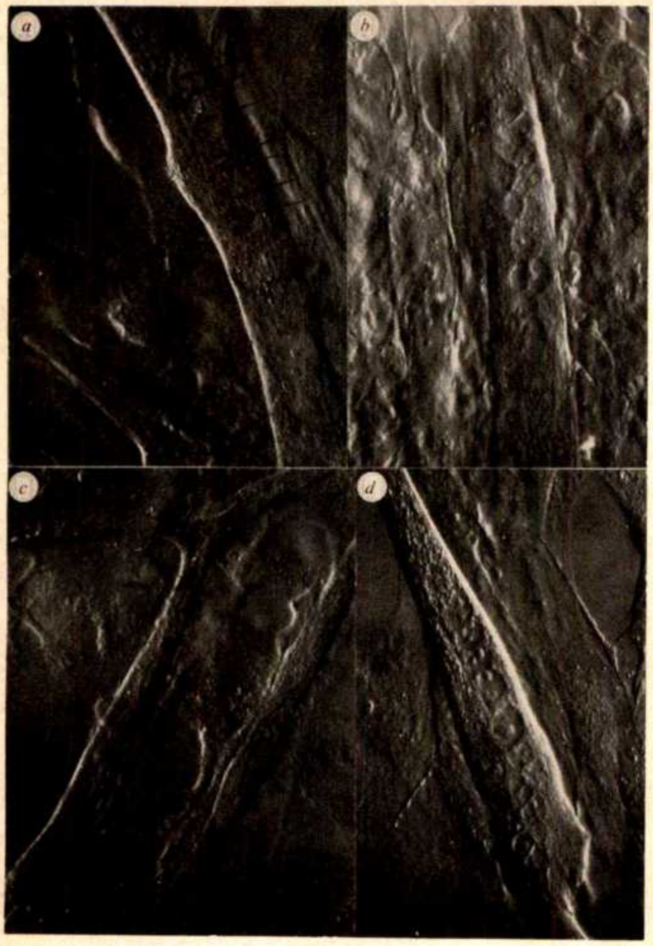

Fig. 1 Unstained, living cultures seen using differential interference optics (Reichert). They are representative of muscle formation *in vitro* from crush lesion explants. *a*, Part of a large multinucleate myotube showing a chain of central nuclei (arrows), normal +/+. *b*, Part of a myotube from dystrophic dy^{2J}/dy^{2J} quadriceps. c, Pseudostraps from dystrophic dy/dy muscle. All photographs were taken at 7 d *in vitro*, under identical conditions.

regeneration. Hamburgh *et al.*[8] came to the conclusion that muscle from dystrophic (dy^{2J}/dy^{2J}) mice exhibited a capacity to regenerate similar to normal muscle. Gallup *et al.*[6], using both strains of mice, concluded that the regeneration of normal and dystrophic muscle is dependent on the genotype of the cord section with which it is coupled. Peterson[9], using mouse chimeras (SWV+C57Bl/6J dy^{2J}/dy^{2J}), was led to suggest that the presence of dystrophic nuclei did not affect myogenesis in any way. My results are essentially similar to those of Paul *et al.*[7] and Hamburgh *et al.*[8] I cannot, however, agree with any of the findings or conclusions of Gallup *et al.*[6]. Finally, I am in agreement with Peterson[9] that dy^{2J}/dy^{2J} muscle behaves in the same way as normal muscle with regard to myogenesis.

Therefore I would submit that the recent study of murine dystrophy has been based on the false assumption that allelic mutant genes have the same phenotypic expression. Consequently, if researchers into muscular dystrophy are to continue to use the mouse as an experimental animal they must take care to specify the strain of animal used before drawing up conclusions relating to the pathogenesis. These findings suggest that the causal lesion of the dy/dy dystrophic mutant lies in the muscle cell; this seems unlikely to be the case in the so-called (dy^{2J}/dy^{2J}) dystrophic strain.

I thank Professor J. N. Walton and Dr J. B. Harris for discussion and criticism of the manuscript. The work was supported by The Medical Research Council, The Muscular Dystrophy Group of Great Britain, and The Muscular Dystrophy Associations of America.

Growth of human muscle spindles *in vitro*

STRIKING histological, histochemical and physiological differences between intrafusal and extrafusal muscle have been observed in a large number of species. Enzyme profiles, for instance, of intrafusal muscle not only fail to reflect the extrafusal pattern but show considerable interspecies variation[1,2].

The precise relationship of genetic, neural and environmental influences and their role in determining the peculiar properties of intrafusal muscle, is uncertain. There is strong evidence that innervation is essential for the normal ontogenetic development of spindles[3] and neural control of the histochemical properties of fully differentiated extrafusal muscle has been shown to be considerable[4]. Spindles denervated at maturity, however, are remarkably resistant to change.

We considered that an investigation of the growth and differentiation of intrafusal muscle *in vitro*, thus isolated from its normal neural and environmental influences, might elucidate the role of genetic factors in determining its characteristics *in vivo*. It was of particular interest to examine the behaviour of human tissue in this context in view of the large number of genetically determined muscle disorders and the relative lack of information concerning the pathological role of the spindle.

The regenerative capacity of skeletal muscle following injury, disease, or experimentally-induced trauma is considerable[5-8] and is, to some extent, reflected by the growth and differentiation of muscle explants in culture. Normal and diseased adult human muscle has been successfully grown *in vitro* by several workers[7-9], but none has specifically investigated the growth of intrafusal muscle. Whether spindles possess a similar regenerative potential and to what extent intrafusal muscle retains its identity in the simplified conditions of tissue culture is as yet unknown.

The varied findings of other workers in the field indicate that the culture employed may itself influence results and, for valid comparisons to be made between the behaviour of different tissues *in vitro*, must be a controlled factor. For this reason, in our study, explants of both extrafusal and intrafusal muscle from each specimen were cultured in identical conditions.

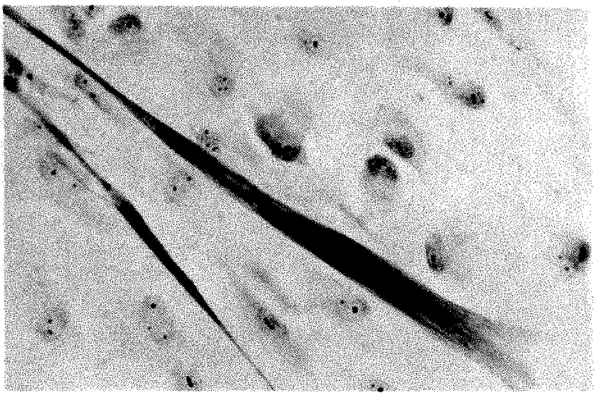

Fig. 1 A multinucleate myoblast from a culture of intrafusal muscle after 36 d *in vitro* (×280.80).

Muscle specimens (commonly of palmaris longus) were obtained from patients undergoing diagnostic, motor-point muscle biopsy. Adjacent specimens in each case were examined by routine histological and histochemical procedures and cases in which the results of these investigations were found to be within normal limits were used in this study.

The specimen, approximately 2 cm×0.5 cm was placed in a Petri dish containing Eagles minimum essential medium (MEM) with 100 U ml^{-1} penicillin and streptomycin. Any spindles present were dissected out from the surrounding tissue under a microscope, care being taken to isolate the spindle completely from the extrafusal fibres. The outer layers of the spindle capsule were removed and the spindle cut transversally to form explants approximately 1 mm long. The explants were placed on coverslips coated with reconstituted rat tail collagen and covered with a thin clot of chicken plasma. They were then placed in test tubes with 3 ml of a nutrient medium consisting of 80% MEM, 10% horse serum and 10% chick embryo extract. Each tube was sealed with a silicone rubber bung, placed on a tube roller and incubated at 37° C. Small pieces of extrafusal muscle (approximately 1 mm cube) were set up in a similar manner. The medium was changed once a week and living cultures were examined from time to time using the Maximow slide system and phase contrast microscopy. All the above procedures were carried out aseptically. At intervals between 20 and 70 d after setting up, suitable cultures were fixed and stained with PTAH.

Fifteen stained cultures of normal intrafusal muscle have so far been obtained, these being derived from nine different patients and representing less than half the number of normal intrafusal cultures initially set up, the remainder have failed to grow. In all cases parallel extrafusal cultures were also obtained.

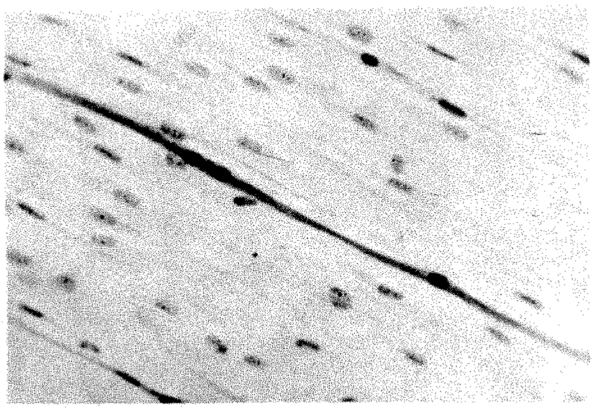

Fig. 2 A myotube from a culture of intrafusal muscle after 55 d *in vitro* (×176.80).

The first growth of intrafusal muscle is observed between 10 and 25 d *in vitro* and may precede signs of growth in parallel extrafusal cultures by several days. Microscopic examination at this early stage reveals, however, only mononucleate cells and it is likely that a large proportion of these are fibroblasts derived from the relatively large amount of capsular connective tissue inevitably left within the explant.

Immediately following the initial proliferation of mononucleate cells, typically elongated and spindle-shaped in appearance, the majority of cultures show in addition a variable number of multinucleate cells. Figure 1 shows a multinucleate myoblast in an intrafusal culture at 36 d; such cells are visible within the first few days of growth following the lag period and continue to be found in cultures 70 d old. The cells show extreme variability of size, shape and number of nuclei and in older cultures there is, in addition, an increasing proportion of myotube forms, elongated syncitia in which some or all of the nuclei become separated or aligned in chains (Fig. 2). At a later stage peripherally situated nuclei are seen in many of these cells.

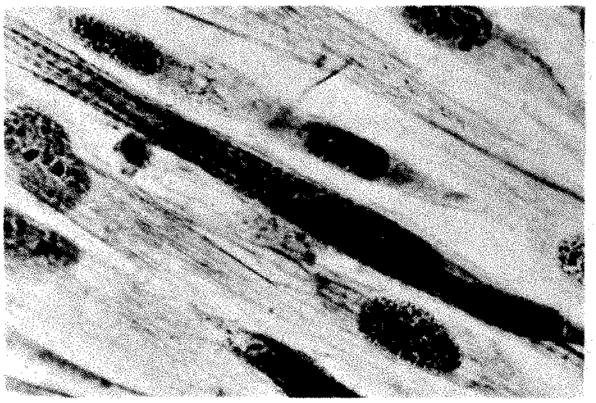

Fig. 3 Cross striations in a myoblast from a culture of intrafusal muscle after 70 d *in vitro* (×728).

Cross striations were observed in a small minority of myoblasts and myotubes in both intrafusal and extrafusal cultures (Fig. 3). They were seen in both mononucleate and multinucleate cells and when fully differentiated Z lines. A and I bands and occasionally H zones were visible, but at no time during the observation of any of our living cultures was spontaneous contraction observed.

Owing to the small number of cultures so far obtained and the widely varying appearance of the growing cells, statistical examination of results has not yet been undertaken, though some measurements of size have been made. In a culture of intrafusal muscle at 31 d in which the lag period was 20 d (that is, after 11 d growth) myotubes reached a maximum length of 720 μm. This value became 800 μm in another culture after 18 d growth. (These cells were less than 20 μm in width.) Another intrafusal culture after 35 d growth produced many shorter, broader myoblasts, commonly 100 μm long and 50–60 μm wide, containing numerous densely packed nuclei. The longest cell reached only 400 μm.

In parallel extrafusal cultures, cells also showed extreme variation of form, but in all cases measured, the maximum length of myotube exceeded the value for intrafusal cultures, for example up to 1,100 μm after 18 d growth. This observation, however, may only reflect the considerably larger number of extrafusal explants obtainable from any specimen and their relatively greater mass.

It is apparent that intrafusal muscle possesses a considerable regenerative capacity under tissue culture conditions and there is little doubt that regeneration of muscle is a function of satellite cells, of which there are many within muscle spindles[9]. No ultrastructural differences can be discerned between extrafusal and intrafusal satellite cells and our preliminary observations indicate that the growth and differentiation of intrafusal muscle *in vitro* closely parallels the behaviour of extrafusal muscle. If confirmed by further investigation, for instance of the histochemical and ultrastructural properties of the growing cells, it would suggest that a critical factor for the differentiation of muscle spindles is trophic rather than genetic and is absent under these conditions. A strong possibility is that such a factor derives from the neural influence and it is interesting to consider to what extent this could be supplied in a tissue culture system and how much its precise nature may be analysed by this means.

Multiple control mechanisms underlie initiation of growth in animal cells

THE understanding of the control of cell proliferation and differentiation requires the unravelling of the early events that trigger the initiation of growth. An *in vitro* system to study the initiation of growth is provided by the mouse 3T3 cell line. These cells exist in two alternative growth states: either reversibly arrested in the G_0 phase of the cell cycle or in active proliferation. When resting 3T3 cells are exposed to fresh serum they recommence DNA synthesis and cell division[1]. Functional membrane changes are among the earliest events associated with the reinitiation of growth[2]. Within minutes of serum addition, the rate of transport of inorganic phosphate, nucleosides and glucose is increased several fold[2–6], while cyclic AMP, which has been implicated in the regulation of growth of cultured fibroblasts, shows an opposite change[7–11].

The coordinated expression of these membrane changes raises the possibility that some of these events are cause-effect related to each other[12,13]. Two different hypothesis concerning this important problem have evolved. A unifying view holds that cyclic AMP acts as a pleiotypic modulator that regulates the overall rates of all the membrane transport systems affected by changes in cell growth[5,14]. The alternative view proposes that cyclic AMP might control some specific changes in membrane transport but not a general change in cell permeability [10,11]. The first hypothesis predicts that there should be a high degree of coupling between the various biochemical changes stimulated by serum or insulin while the second envisages the changes as dissociable, since they are supposed to be controlled by several distinct mechanisms.

The experiments presented here were conducted to differentiate between these alternative possibilities. Our results substantially support the hypothesis of specific changes and suggest that at least three distinct mechanisms of control of membrane transport operate when growth is initiated.

Uridine and phosphate transport systems respond to separate control mechanisms as shown by the differential effects produced by the addition of ouabain, cycloheximide and cyclic AMP elevating agents. Typical experiments illustrating this point are shown in Fig. 1. Ouabain, an

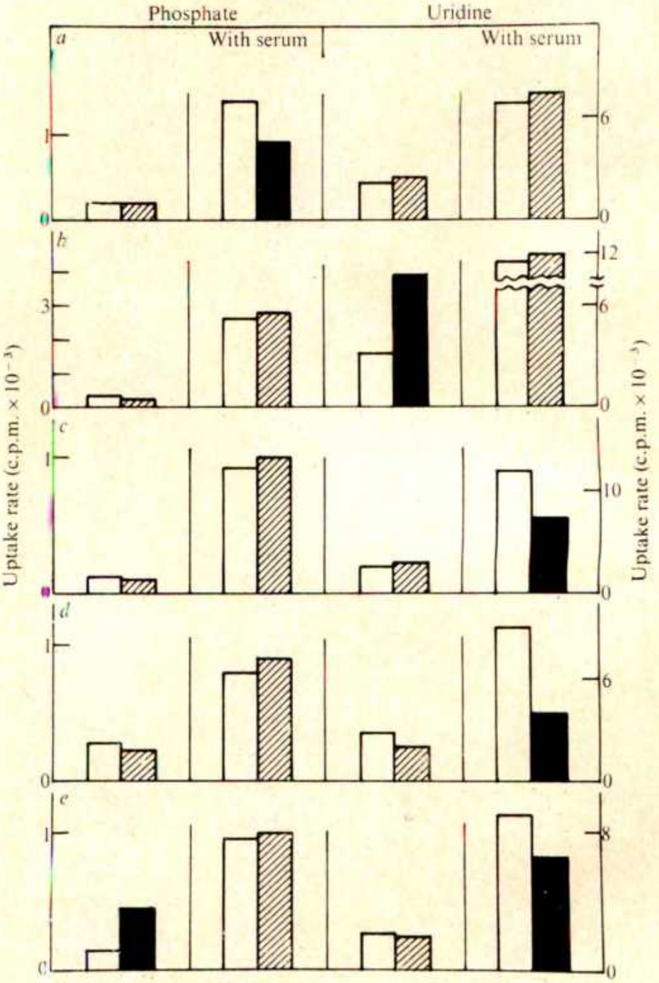

Fig. 1 Differential effects of, *a*, 1 mM ouabain; *b*, 10 μg ml^{-1} cycloheximide; *c*, 1.5 mM theophylline; *d*, 0.2 mM SQ 20006 and *e*, 40 μg ml^{-1} PGE$_1$ on uridine and phosphate uptake rates. Swiss 3T3 fibroblasts were maintained in Dulbecco's modified Eagle's medium supplemented with 10% foetal calf serum, 100 units ml^{-1} penicillin and 100 mg ml^{-1} streptomycin in Nunc Petri dishes. Transport was measured on cells attached to 30 mm dishes. Confluent cultures were used usually 3 d after the last change of medium. First, the cells were washed with phosphate-free medium and incubated in this medium with (hatched bars) or without the above mentioned compounds at the concentrations indicated. After 10 min, dialysed foetal calf serum (10% final concentration) was added to some dishes and the culture incubated for additional 20 min. Then, the cells were labelled with ^{32}P-phosphate (75 μCi μmol^{-1}) 3.75 μCi ml^{-1}) and ^{3}H-uridine (29 mCi μmol^{-1}, 2.5 μCi ml^{-1}) for 5 min. Uptake into acid-soluble pools and all other materials and methods were measured as described previously[10–11]. Each bar represents the average of two transport determinations. Each experiment was repeated at least three times. The treatments that produced effects were shown with dark bars.

inhibitor of the (Na^+, K^+) APTase, significantly decreases the activation of phosphate transport produced by serum but has no effect either on the increase of uridine uptake or on cyclic AMP levels. Conversely, elevation of the intracellular levels of cyclic AMP by prostaglandin E_1 (PGE_1), theophylline or 1-ethyl-4-hydrazino-1H-pyrazolo-(3,4-b)-pyridine-5-carboxylic acid, ethyl ester, hydrochloride (SQ 20006) (ref. 15), depresses the activation of uridine transport by serum while the stimulation of phosphate uptake is unaffected. In the absence of serum, PGE_1 stimulates the uptake of phosphate but not that of uridine. Further, cycloheximide added in the absence of serum activates uridine uptake, in agreement with earlier results[5,12] but it does not modify the basal uptake level of phosphate. In addition, when the uridine transport rates determined in the presence of different compounds are plotted as a function of cyclic AMP levels measured in parallel cultures, an inverse correlation is obtained. On the other hand, no correlation is obtained when phosphate transport rates are plotted as a function of cyclic AMP concentration (data not shown). All these results show that the early transport changes of uridine and phosphate are dissociable.

In addition to stimulating phosphate and uridine transport, serum brings about a large increase in 2-deoxyglucose uptake in resting 3T3 cells[4-6]. A third level of transport control was identified when this phenomenon was carefully examined. The activation curve as a function of time is clearly biphasic (Fig. 2). The early phase was unaffected by the presence of cycloheximide while the second was completely prevented by this inhibitor. Other experiments reveal that the kinetic parameter modified as a function of time is the maximum velocity (L. J. de A., and E. R., unpublished). Thus, in addition to changing rapidly the uptake of 2-deoxyglucose, serum seems to induce also the synthesis of new carrier molecules. For comparison, uridine and phosphate transport rates were measured in similar conditions (Fig. 2). A biphasic activation curve with a cycloheximide-sensitive second phase was also seen with phosphate uptake but not with uridine up to 5 h after serum addition.

The induction of the second phase of glucose transport is not triggered by a drop in cyclic AMP since SQ 20006 does not block it (Table 1) and insulin which decreased cyclic AMP in resting cells[7,8,10] and increases cyclic GMP in different tissues[16] does not induce it. Cyclic AMP, however, could modulate the activity of the transport system when it is already inserted in the membrane (Table 1) which may account for the rapid phase stimulated by serum.

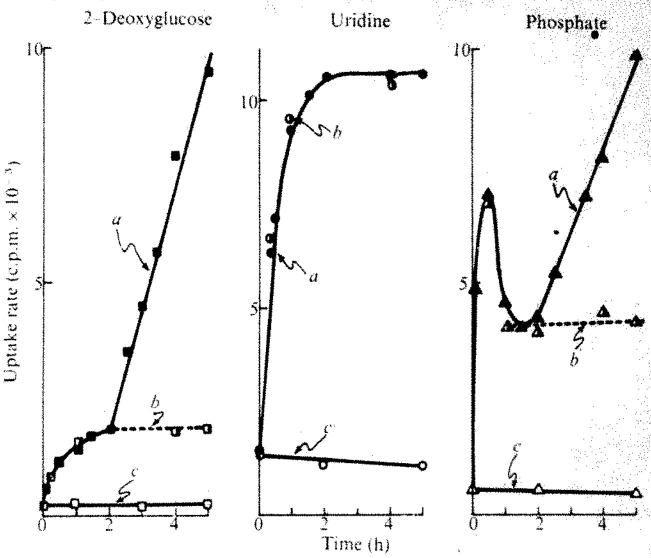

Fig. 2 Kinetics of the changes in 2-deoxyglucose, uridine and phosphate transport produced by the addition of fresh serum to resting cultures of 3T3 cells in the absence or presence of cycloheximide (10 μg ml^{-1}). The inhibitor was added at time 0. The uptake of ^3H-2-deoxyglucose was determined as follows: the cells were washed four times with prewarmed serum-free medium minus glucose and incubated for 10 min in this medium with or without dialysed serum or other additions. The cells were then exposed to labelled substrate (3 μCi ml^{-1}; 5×10^{-5} M) for 10 min. Uptake into the 5% TCA soluble fraction was linear for 15 min and was measured as described earlier[10-11]. The other determinations were carried out as indicated in the legend to Fig. 1. *a*, Serum; *b*, serum + cycloheximide; *c*, serum-free medium.

Table 1 Effect of SQ 20006 on the uptake of 2-deoxyglucose stimulated by serum*

	Additions		Uptake rate
	Serum	SQ 20006	(c.p.m. per dish)

	+	–	7,751
	+	+†	4,256
	+	+‡	5,179
	+	+§	7,002

* Resting cultures of 3T3 cells were exposed to 15% foetal calf serum for 40 min (A) or 4 h 30 min (B). Then, the uptake of 2-deoxyglucose was measured as described in the legend to Fig. 3.

† Added at time 0.

‡ Added 4 h after serum.

§ Added at time 0 and removed 4 h later by washing four times with prewarmed medium.

The possibility of eliciting or inhibiting selectively some early biochemical events by using a variety of compounds clearly shows that these membrane changes are dissociable. All these results support the hypothesis that conceives distinct mechanisms of control switched on when growth is initiated and seem incompatible with a pleiotypic role for cyclic AMP in the control of all the changes in membrane transport produced by serum. In fact from the present and previous findings[10,11] it is possible to define at least three distinct mechanisms of control, that can be differentiated on the basis of temporal expression, dependence on cyclic AMP levels and on (Na^+, K^+) ATPase activity and requirements for protein synthesis.

The various metabolic changes studied here might be produced independently by different factors present in serum or by different chemical signals synthesised by the cells when exposed to a single factor. Another important question that can now be asked is whether or not all the biochemical changes stimulated by serum are required for the initiation of cell division. Our studies offer experimental basis for attacking these problems, the clarification of which will contribute substantially to our understanding of the initiation of growth.

L. J. de A. is a Fellow of the Leukemia Society of America, Inc. We thank Drs R. Burk, R. Dulbecco and M. Stoker for critical discussions and Miss H. Wiltshire for technical assistance. PGE_1 and SQ 20006, a new inhibitor of cyclic 3′,5′-nucleotide phosphodiesterase activity were gifts of Dr Pike, Upjohn, and Dr Chasin, Squibb, respectively.

Control of cell division in yeast using the ionophore, A23187 with calcium and magnesium

A23187 is an ionophore which exhibits specificity for divalent cations and promotes their passive transport across biological membranes[1]. It therefore effects equilibration of divalent ions between the cell sap and the surrounding medium and counteracts any active accumulation of ions within the cell. Evidence, mainly from studies on sea urchin eggs, supports the hypothesis that calcium ions play an important part in bringing about cell division[2-4]. We have found that division in the fission yeast, *Schizosaccharomyces pombe*, is associated with a doubling in magnesium concentration within the cells[5]. It, therefore, seems likely that, if accumulation of divalent ions within the cell were an essential prerequisite of cell division, this should be inhibited by A23187 and cell division should not take place, and so we have investigated this possibility.

S. pombe, strain 132, was grown in the defined medium, EMM2 (ref. 6). Once the cells were growing exponentially and had reached a concentration of 10^6 cells ml^{-1} or more, 1.0 ml of the stock solution of A23187 was thoroughly mixed with 100 ml of culture. The stock solution was prepared by dissolving 0.5 mg A23187 in 0.05 ml of Analar acetone and adding 1 ml of absolute ethanol[7]. Subsequently, cell division was inhibited quite rapidly, only 10–15% of the cells dividing before inhibition was complete. The ethanol/acetone mixture on its own had no effect.

If cells which had been left in growth medium with A23187 as above for 3 h at 30° C were collected and immediately inoculated into fresh medium, synchronous division (cell plate index = 25–30%) ensued about 30 to 40 min after transfer. The next division was also synchronous. DNA measurements showed that the cells had been inhibited by A23187 in the G2 phase of the cycle. Following staining with Giemsa[8], up to 47% of the cells appeared to be binucleate. Cells with a complete cell plate, but in which division had not started as indicated by formation of a 'waist' at the cell plate, were taken as one cell. Thus, slightly more than half of the binucleate cells contained cell plates. Occasionally a cell was observed containing two cell plates close together and, in between, a piece of cytoplasm undergoing autolysis.

To define more precisely the point at which inhibition of division was occurring, a synchronous culture of *S. pombe* was established using selection of newly divided cells from a sucrose gradient[6]. Samples were taken from this culture at suitable intervals and A23187 added to give the same final concentration as above. These samples were left for 3 h at 30° C and the cell number measured. In the absence of inhibition, division should have occurred within this time. This was verified using controls without A23187 but with the ethanol/acetone solvent. Even with a sample of cells taken only 10 min before division could be detected, A23187 completely prevented division taking place. Thus the block to cell division must occur very close to the end of the cell cycle. Possibly the initial blockage is at a stage just before nuclear division, whereas any cell at a point after nuclear division and before cell division is blocked at other stages which are particularly sensitive to the changes brought about by the ionophore.

Table 1 Change in calcium and magnesium content of cells following addition of 5 μg ml^{-1} A23187 and incubation at 30° C for 3 h

Before addition of A23187	Ca (g per cell)	Mg (g per cell)
Supernatant liquid	3.0×10^{-14}	0.5×10^{-14}
Pellet	37×10^{-14}	1.3×10^{-14}
After addition of A23187 and incubation		
Supernatant liquid	5.0×10^{-14}	0.9×10^{-14}
Pellet	5.0×10^{-14}	0.6×10^{-14}

Since A23187 is supposed to make membranes permeable to divalent ions, it was decided to investigate in general terms what happened to calcium and magnesium within the cell. Samples of cells were taken before and after A23187 treatment in EMM2 for 3 h as described above. These samples were quickly washed twice in glass-distilled water and homogenised in 5 ml glass-distilled water in an Eaton press[9]. The homogenate was centrifuged at 40,000g (R_{av}) for 30 min. The supernatant liquid was analysed without further treatment, using atomic absorption spectrophotometry to measure calcium and magnesium. The pellet was solubilised by digestion overnight at 40° C with 3 ml of a 1:2 (v/v) mixture of 60% perchloric acid and 30% hydrogen peroxide. The resultant solution was diluted to 10 ml with glass-distilled water and analysed for calcium and magnesium in the same way as the supernatant. The results obtained are shown in Table 1. It is clear that, following A23187 treatment, calcium in the pellet has dropped dramatically (sevenfold) while magnesium has dropped by half. The supernatant values have increased, but to a lesser extent. Since the pellet almost certainly contains mitochondrial vesicles, and there is evidence from other eukaryotic cells that mitochondria accumulate calcium and, to a must lesser extent, magnesium[10], this may reflect leakage of ions from the mitochondria brought about by A23187. The supernatant levels would then reflect altered steady state concentrations in the cytosol. Overall, the total calcium content of the treated cells has dropped to 25% of that of untreated cells while the magnesium content has dropped to 80%. This probably reflects the differential gradients for these ions between the cell and the medium where the calcium concentration is 0.07 mM and the magnesium concentration 2.5 mM.

Finally, we attempted to reverse the effects of A23187 by adding calcium and magnesium to cells which had been treated with A23187 in EMM2 as previously described for 3 h. Increasing the calcium concentration of the medium tenfold (to 0.7 mM) and the magnesium concentration likewise (to 25 mM) enabled division of about 90% of the cells to occur between 15 and 20 min after adding the ions as their chloride salts. This is somewhat faster than the recovery when the cells are transferred to fresh medium (see above) but no further divisions ensue whereas the cells in fresh medium recover completely.

Similar results to the above have been obtained for the budding yeast, *Kluyveromyces fragilis* (Penman, unpublished). We therefore conclude that a pool of calcium and magnesium is essential for cell division in yeast. It may be required to promote the breakdown of microtubules involved in nuclear division and cell plate formation[11] and this possibility is being investigated.

This work was supported by a grant from the Science Research Council. A23187 was a gift from Eli Lilly and Company.

Antigen of mouse bile capillaries and cuticle of intestinal mucosa

CELL surface antigens have been isolated by solubilisation and fractionation of membranes[1-3]. Here we present data on the membrane antigens of mouse liver cells soluble in the nonionic detergent Triton X-100.

Mouse liver cell ghosts were obtained as in ref. 4. Triton fractions (TF) from ghosts and from whole mouse liver cells were obtained as in ref. 5. TFs were also prepared from mouse kidney, intestine, spleen and the mouse ascitic hepatoma 22-a.

Liver TFs were analysed by gel double diffusion[6] and by immunoelectrophoresis[7] using rabbit antisera to liver cell ghosts. These sera do not react with soluble antigens of the liver cell and in immunofluorescent studies they stain predominantly the plasma membranes of parenchymal cells[8] (Fig. 1*a*). Before analysis all the TFs were concentrated 10–20 times and anti-ghost sera were concentrated four times. Each TF of mouse liver was checked by the precipitin reaction with 40 samples of rabbit anti-ghost sera obtained from different animals and in different cycles of immunisation.

In all TFs of mouse liver cells or ghosts studied, six antigens were found which were precipitated by the analysed rabbit anti-ghost sera. These antigens were presumably membrane antigens. One of them, called here BCCA (bile capillary-cuticular antigen) was regularly found in each liver TF whereas the other five antigens were detected in only some of the TFs. The latter five antigens are probably present in too small amounts to be detected consistently. It seems however, that modifications in the method of preparation of TF will eventually overcome these variations. Using immunoprecipitation and indirect immunoautoradiography the distribution of BCCA in different mouse organs and in the ascitic hepatoma 22-a was studied. BCCA is the dominant antigenic component of the TFs from the liver cells and ghosts and it is stable during storage. It is detected in considerable amounts in TFs of the mouse kidney. In TFs of the ascitic hepatoma 22-a it is determined only by immunoautoradiography. It is not detected in concentrated saline extracts of mouse liver, kidney spleen or intestine by either the agar precipitation test or immunoautoradiography.

BCCA was partly purified by agar-gel preparative electrophoresis[7]. The combined and concentrated TFs of the mouse liver were electrophoresed in buffered 1% agar (0.5 N barbital buffer, *p*H 8.6). The electrophoretic fractions (in the region of β_1-globulin) with maximal BCCA concentration and minimal amounts of other antigens were collected and combined.

This partially purified BCCA and the anti-ghost serum containing antibodies predominantly to BCCA were used for the preparation of monospecific antibodies to BCCA[10].

The cell localisation of the BCCA was studied by indirect immunofluorescence. The acetone-fixed cryostat sections of mouse organs were treated with monospecific antibodies to the BCCA and then by FITC-labelled purified donkey antibodies to rabbit IgG. The specificity of the fluorescence was checked by fluorescence inhibition.

Distinct, bright fluorescence was found on the liver cell surface surrounding the bile capillaries between two hepatocytes (Fig. 1*b*). The Kupfer cells, the epithelium of the bile duct and the vascular endothelium were not stained. The fluorescence of bile capillaries disappeared after the absorption of the monospecific antibodies to the BCCA with the BCCA-containing electrophoretic fraction. The native anti-ghost serum used for the preparation of the BCCA monospecific antibodies also selectively lacked the ability to stain bile capillaries after the absorption with the electrophoretic fraction containing BCCA (Fig. 1*c*).

In the sections of intestine (Fig. 1*d*) the monospecific antibodies to the BCCA stained the cuticle of the mucosa epithelial cells of villi and crypts. This distinct cuticular fluorescence, at different intensities, was observed for the whole length of the intestine from the duodenum to the rectum. The other morphological structures in the sections of the intestine were not stained. The cuticular fluorescence disappeared after the absorption of the monospecific antibodies to BCCA with TFs of the liver or intestine.

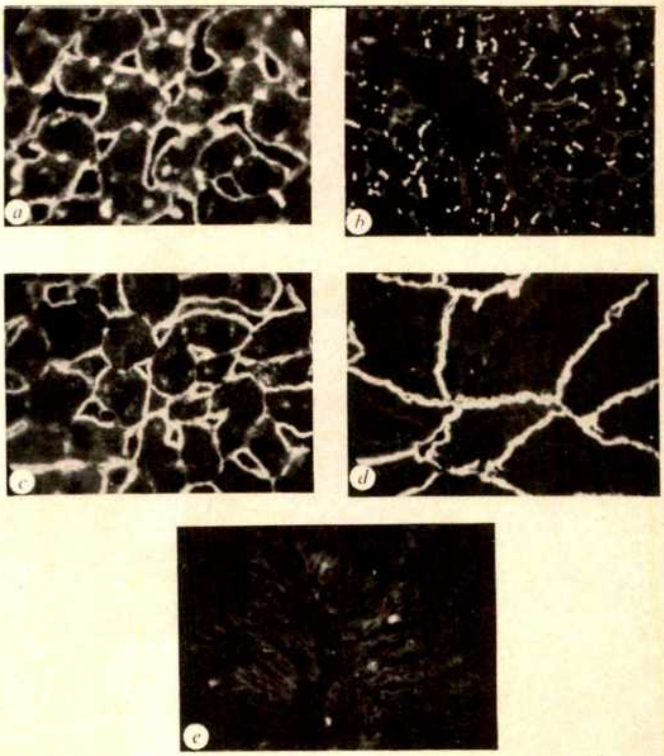

Fig. 1 *a*, Mouse liver section treated with native antiserum to liver cell ghosts. × 162. *b*, Mouse liver sections treated with monospecific antibodies to the BCCA. × 72. *c*, Mouse liver section treated with antiserum to liver cell ghosts absorbed by the partially purified BCCA (electrophoretic fraction). × 162. *d*, Sections of mouse intestine and *e*, stomach treated with monospecific antibodies to BCCA. × 162.

The monospecific antibodies to BCCA did not stain sections of the mouse oesophagus, stomach, kidney, spleen, pancreas and sections of the solid variant of the mouse ascitic hepatoma 22-a (the ascitic hepatoma, inoculated subcutaneously) (Fig. 1*e*).

So, BCCA is specifically localised in the bile capillaries of the mouse liver and the cuticle of the intestinal mucosa epithelial cells. A small amount of BCCA (or an antigen with a similar determinant) is also found on the plasma membrane of each liver cell. The absence of BCCA in the cytoplasm of liver cells suggests that it is synthesised on the cell surface.

The specific antigen of rat liver bile capillaries was described by Sulitzeanu *et al.*[12]. They also found it in kidney proximal tubule cells. Another antigen of rat bile capillaries has been reported[13]. The authors considered this antigen to be organo-specific but they did not demonstrate its absence in the intestine and other rat organs.

Ultrastructural analysis of toxin binding and entry into mammalian cells

VERY low concentrations of phytotoxins can kill mammalian cells, and some of them, such as ricin and abrin, isolated from *Ricinus communis* and *Abrus precatorius*, have been reported to suppress protein synthesis in cells [1–3] and cell-free systems[4,5]. Ricin inhibits peptide chain elongation by catalytically inactivating the 60S subunits of ribosomes[5–7]. It is a galactose-binding glycoprotein of molecular weight 60,000, containing two nonidentical subunits linked by disulphide bridges[8–11] and seems to be identical to the lectin *R. communis* agglutinin II (RCA_{II}) isolated by affinity chromatography[8–12]. Ricin, or RCA_{II}, has been used to suppress the growth of ascites tumour cells *in vivo*[13], and as a cell surface probe for oligosaccharide receptors[14–17] containing terminal D-galactose or N-acetyl-D-galactosamine-like saccharides[11,14,18,19]. I have found that RCA_{II} enters mammalian cells by endocytosis (similar to the findings of Oliver *et al.*[20]) and is then released into the cytoplasm, where it apparently acts directly on protein synthesis.

Although ^{125}I-labelled RCA_{II} binds rapidly to mammalian cell surfaces[14,21] (saturation < 10 min at 5° C)[14], there is a significant lag before protein synthesis is inhibited (> 30 min at 37° C)[21,22]. This suggests that events subsequent to cell binding are essential for RCA_{II} toxicity[21,22]. Also, the toxic action of RCA_{II} can be prevented by addition of lactose[21] or antitoxin[22] within 15–30 min. In cell-free systems RCA_{II} suppresses protein synthesis almost immediately ($\approx$1–5 min)[4,6,21], and this action is not sensitive to RCA_{II} saccharide inhibitors[21]. To investigate the ultrastructural events subsequent to cell binding I have used an electron-dense ferritin-conjugate of RCA_{II} (Fer-RCA_{II})[23,24].

Fer-RCA_{II} was synthesised as described before[23–25] and purified by affinity chromatography on Biogel A-1.5 m[24]. After elution of column-bound Fer-RCA_{II} by 0.2 M D-galactose, the conjugate was dialysed extensively. Affinity purified Fer-RCA_{II} was active in suppressing murine 3T3 fibroblast protein synthesis, and the inactivation required much more time than required for simple binding to the cell surface (Table 1). The Fer-RCA_{II} conjugate was not as active in suppressing protein synthesis as native RCA_{II}; this might reflect some inactivation during the coupling process or a steric interference of ferritin with the enzymatic properties of RCA_{II}. But, as with RCA_{II}, the conjugate was blocked by the addition of D-galactose to the incubation medium (Table 1). To study the ultrastructural interaction of Fer-RCA_{II} with cells, the conjugate was added to 0.02% EDTA-dissociated, washed, confluently grown murine 3T3 cells suspended in Dulbecco's modified Eagle's minimal essential medium[26] (DMEM) containing 5% calf serum for various times at 4°, 20° or 37° C. Alternatively, cells were pulsed with Fer-RCA_{II} for 5–15 min at 4° C, washed by centrifugation and suspended in DMEM and then incubated further at 37° C for different times. Controls were labelled identically except that 0.1M D-galactose was present in the labelling and wash solutions. In some of the samples D-galactose was added at specific times during Fer-RCA_{II} labelling. Incubations were terminated by washing the cells in fresh DMEM and then adding 1.5% glutaraldehyde in sodium phosphate-buffered saline (*p*H 7.2; 310 mosmol). Fixation proceeded for at least 1 h, the first 30 min at the incubation temperature. The cells were washed again and postfixed in 1% osmium tetroxide in 0.1 M sodium phosphate buffer, *p*H 7.2, for 1 h at 20° C, washed, dehydrated in ethanol-propylene oxide and embedded in Epon 812. Thin sections were stained with 1% uranyl acetate and observed in a Hitachi HU-12 electron microscope.

3T3 cells labelled with Fer-RCA_{II} for 5–30 min at 0°–4° C or 5–10 min at 20°–37° C before fixation showed continuous labelling of RCA_{II} receptors, exclusively at the cell surface (Fig. 1*a*). Labelling was specific as D-galactose inhibits conjugate binding (Fig. 1*b*), as previously demonstrated[24]. Labelling at higher temperatures (20°–37° C) resulted in eventual lectin-induced receptor clustering of some but not all RCA_{II} receptors and subsequent endocytosis. At 37° C this sequence of events was more rapid than at 20° C, and significant endocytosis was seen within 60 min (Fig. 1*c*). With times greater than 60 min at 37° C most Fer-RCA_{II} molecules were localised inside intact or broken endocytotic vesicles and free in the cell cytoplasm (Fig. 1*d*).

To determine the sequence of Fer-RCA_{II}-receptor interaction and endocytosis, pulse labelling experiments were performed. Cells were labelled with Fer-RCA_{II} for 5–10 min at 0°–4° C, washed by centrifugation, and resuspended in DMEM at 37° C for various times. To duplicate samples, D-galactose was added immediately after the Fer-RCA_{II} pulse at 0°–4° C, or after 5, 15, 30 and 60 min subsequent incubation at 37° C. After the 5 or 10 min pulse of Fer-RCA_{II} at 0°–4° C, the ferritin-lectin molecules located at the cell periphery could be completely or almost completely removed from the cell surface by addition of D-galactose (0.05 M final). After shifting Fer-RCA_{II}-labelled cells to 37° C following labelling and then washing at 0°–4° C, progressively less Fer-RCA_{II} could be removed from cells with time by addition of D-galactose. Also, the location of Fer-RCA_{II} changed from exclusively extracellular in a dispersed distribution (0–5 min after shifting to 37° C), to both extracellular and intracellular (clustered at the

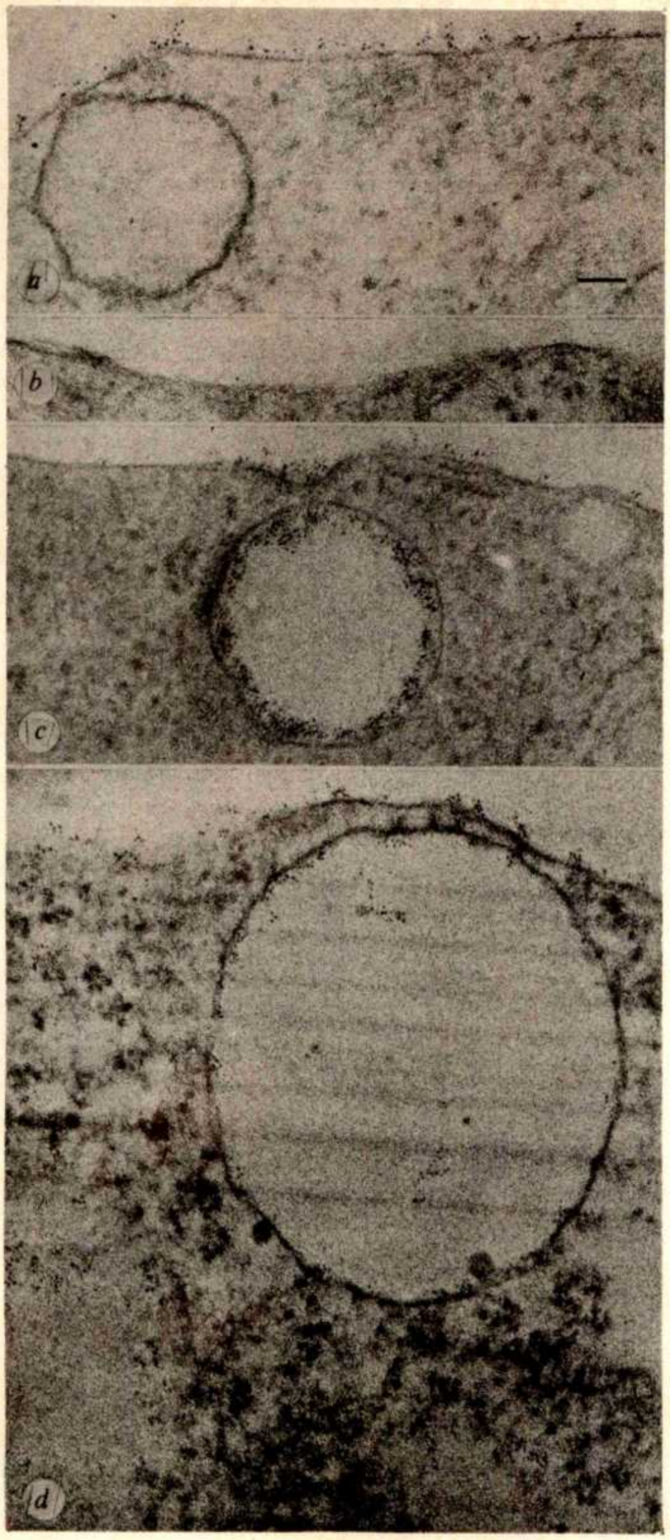

Fig. 1 Fer-RCA$_{II}$ binding to murine 3T3 cells at 37° C. *a*, After a 10 min incubation, ferritin was localised exclusively at the cell surface more or less randomly distributed. Note that the vesicle to the left is unlabelled. *b*, Labelling is specific as D-galactose abolished Fer-RCA$_{II}$ binding activity. *c*, Between 30 and 60 min of incubation Fer-RCA$_{II}$ clustered at the cell surface and endocytosis has begun. *d*, After 60–90 min incubation ferritin was localised inside the cell in intact or broken endocytotic vesicles and free in the cell cytoplasm. * Confluently grown 3T3 cells were removed from substrate with 0.02% EDTA in TC-PBS and washed twice in DMEM containing 5% calf serum. The cells were adjusted to a concentration of 5×10^{6} per ml and 0.5 ml aliquots were incubated with or without Fer-RCA$_{II}$ (~100 μg ml^{-1} total protein) for various times in DMEM at 37° C in a CO$_2$ incubator.

† Cells were treated with Fer-RCA$_{II}$ and washed in DMEM minus leucine and incubated in DMEM plus ^{3}H-leucine (3 μC ml^{-1}) for 60 min at 37° C in a CO$_2$ incubator. The cells were washed three times in TC-PBS and dissolved in 1 ml of 1 M sodium hydroxide containing 0.1% bovine serum albumin. Protein was precipitated by addition of 4–5 ml cold 10% trichloroacetic acid. After a 60 min incubation at 4° C, the contents of each tube were filtered through Whatman G F/C glass filters with vacuum. The filters were washed twice with 5% trichloroacetic acid and once with 95% ethanol and dried. The dried filters were placed in scintillation fluid and counted using a Beckman Model LS200 scintillation counter.

¶ Final concentration (total protein), approximately 100 μg ml^{-1}

Fer-RCA$_{II}$ that had moved into cells by endocytosis was not susceptible to removal by addition of D-galactose.

Results consistent with these have been obtained with ^{125}I-RCA$_{II}$ (ref. 21). After a 10 min pulse (1 μg ml^{-1} ^{125}I-RCA$_{II}$) at 4° C, approximately 95% of the cell-bound ^{125}I-RCA$_{II}$ could be removed by lactose, but less than 20% could be removed after a 60 min subsequent incubation at 37° C (ref. 21). In parallel experiments less than 5% inhibition of protein synthesis was obtained after the 10 min pulse of RCA$_{II}$ at 0°–4° C. By 30 min after shifting to 37° C, inhibition was approximately 10–20%, and by 60–90 min, it was >80%, similar to the results obtained with ferritin-RCA$_{II}$ (Table 1). In cell-free protein synthesis systems inhibition was almost complete within 1–2 min under these conditions[21]. These studies also stress the importance of performing quantitative lectin labelling experiments for short times at low temperatures to preclude endocytosis of the surface bound lectin molecules[14-16,27,28].

Refsnes *et al.*[22] proposed a two-step model for the toxic action of abrin[15,22,29] and ricin on mammalian cells: in the first step the toxin binds to the cell surface, and in the second step it (or portion of it) is transported into the cytoplasm. My results are consistent with this model, and further suggest that lectin-induced surface aggregation[30-33] and endocytosis[20,21,22] are important in the entry of toxin into mammalian cells. The ultrastructural fate of Fer-RCA$_{II}$ after endocytosis suggests that the lectin molecules are released from endocytotic vesicles, perhaps by breakdown. Lysosomes do not appear to be involved in this process, because I did not observe fusion of lysosomes with the endocytotic vesicles; however, this cannot be ruled out for all vesicles. The fact that simple RCA$_{II}$ binding to cells is not sufficient to cause inhibition of protein synthesis suggests that the endocytosis and release into the cell cytoplasm of RCA$_{II}$ where it can directly interact with polyribosomes is the natural mode of action of this toxin. Other toxins such as diphtheria toxin may enter the cell to act in similar fashion[34,35].

Serum dopamine β-hydroxylase activity in developing hypertensive rats

SPONTANEOUSLY hypertensive (SH) rats[1] have increased[2,3] tyrosine hydroxylase and dopamine β-hydroxylase (DBH) activities in the adrenal glands. They also show a pronounced hypotensive reaction[2,3] to the specific microbial inhibitors of these enzymes[4]. The results suggest some involvement of the adrenergic nervous system in the hypertension. But the activity of DBH in serum of SH rats, which is released from the sympathetically innervated organs and adrenals[5], does not differ significantly from that of normotensive Wistar rats[6].

We have now compared the developmental change in serum DBH activity in SH rats with that in normotensive Wistar–Kyoto rats. It was from rats of this strain that SH rats were bred, so we felt that they would be better controls than the previously used normotensive Wistar rats. We found that the serum DBH activity in young rats was higher in the SH than in the Wistar–Kyoto strain. We also examined the effect of NaCl administration on serum DBH activities. We found that in 10-week-old rats it caused the enzyme activity to increase simultaneously with a rapid increase in blood pressure, indicating activation of the sympathetic nerves.

SH rats and Wistar–Kyoto rats of the same age were raised in the same conditions. Blood pressure was measured in unanaesthetised animals using the indirect plethysmograph[1]. Blood samples were obtained from rats by decapitating and exsanguinating them into a test tube kept in ice, and serum was removed after centrifuging at 10,000*g* for 10 min. The enzyme activity was assayed by sensitive dual-wavelength spectrophotometry using tyramine as substrate[7]. This method permits the assay of the maximum velocity at a saturated substrate concentration (20 mM) under the optimum *p*H (5.0). The incubation mixture (total volume 1.00 ml) contained: 100 μl of serum diluted to 400 μl with water, 200 μl of 1 M sodium acetate buffer, *p*H 5.0, 100 μl of 0.1 M N-ethylmaleimide, 50 μl of 20 μM $CuSO_4$, 50 μl of 0.2 M sodium fumarate, 50 μl of 0.2 M ascorbic acid, 50 μl of 20 mM pargyline, 1,500 units of catalase in 50 μl of aqueous solution (1 mg ml^{-1}), and 50 μl of 0.4 M tyramine. A sample of boiled enzyme preparation was used as control. Incubation was carried out for 45 min at 37° C. The product, octopamine, was isolated by a microcolumn (0.5 × 10 cm) of Dowex-50-H^+ (packed volume, 0.2 ml), and converted by $NaIO_4$ (10μl of 2% aqueous solution) to *p*-hydroxybenzaldehyde which was then isolated by successive extractions with ether and ammonia, and finally measured by a dual-wavelength spectrophotometer at 333 nm and 360 nm. Octopamine (2.00 nmol) was added to a control incubation as internal standard. The activity was expressed as nmol octopamine formed per min per ml serum.

Table 1 shows that serum DBH activity of both SH and Wistar–Kyoto rats decreased markedly with age after 6 week. This contrasts with the situation in which humans DBH activity increases with age, especially after an erect posture is assumed[8]. The decrease in serum DBH activity could not result from formation of endogenous inhibitors in serum during development, since recovery of pure DBH from bovine adrenal glands added to a rat serum sample was similar (95%) from rats of various ages. One possibility is that the rate of development of the sympathetic nerves in rats may be slower than the increase of blood volume, so that the DBH activity in a volume of serum may decrease with age. The difference between humans and rats in this respect may have the same explanation as the observation that human serum contains a much higher enzyme activity than sera from various animals[9].

The enzyme activity in SH rats after 6 weeks of age is not significantly different from those in Wistar–Kyoto rats. This agrees with our previous result on serum DBH activities of SH rats and normotensive Wistar rats at 16 weeks of age[6]. But at 3 weeks of age, serum DBH activity of SH rats was about two times higher than that of Wistar–Kyoto rats, indicating that the sympathetic nerve activity in SH rats may be increased only when SH rats are very young. The loss of difference between serum DBH activities of SH rats and Wistar–Kyoto rats during development may

†NaCl was administered from 10 weeks of age for 4 weeks. Differs from control (SH rats without NaCl administration), $P<0.05$. Numbers in parentheses refer to no. of rats.

be due to a secondary compensatory mechanism in the course of the development of hypertension.

In order to determine the reactivity of the sympathetic nervous system of SH rats, we administered NaCl by supplying 1% NaCl-aqueous solution for drinking instead of tap water after 10 weeks of age for 4 weeks. The blood pressure of control SH rats without NaCl administration was increased from 170 ± 3 mm Hg (at 10 weeks) to 189 ± 3 mm Hg (at 14 weeks), whereas that of SH rats with NaCl administration increased from 173 ± 2 mm Hg (at 10 weeks) to 204 ± 5 mm Hg (at 14 weeks). Thus NaCl administration to SH rats increased blood pressure more pronouncedly. After NaCl administration serum DBH activities were also increased significantly as shown in Table 1. The results suggest that the sympathetic nerve activity in SH rats may be increased only when they are very young and decreased by a compensatory mechanism during the development of hypertension, but may be easily activated if blood pressure is raised acutely.

The elevated serum DBH levels when SH rats are very young and the rapid increase in serum DBH activity during the rapid increase of blood pressure by NaCl administration suggest some role for the sympathetic nervous system in the onset and maintenance of hypertension in SH rats.

We thank Professor K. Okamoto and Dr Y. Yamori (Kyoto University, Kyoto) for spontaneously hypertensive rats and Wistar–Kyoto rats and Miss N. Yamada and Miss M. Suzuki for technical assistance. This work was supported by a grant from Science and Technology Agency, Japan.

Enzymatic synthesis of acetylcholine by a serotonin-containing neurone from *Helix*

ACETYLCHOLINE (ACh) and serotonin are strong neurotransmitter candidates in the snail species *Helix aspersa* and *Helix pomatia*[1,2]. Experiments[1] have indicated that the enzymes responsible for their biosynthesis, choline acetyltransferase (ChAc, EC 2.3.1.6.) and L-aromatic amino acid decarboxylase (AAD, EC 4.1.1.26.), were specifically localised to separate populations of neurones in *H. aspersa*, and similarly for *H. pomatia* (M.R.H., unpublished). Out of 150 neurones, 36 were found to contain ChAc only (detection limit 2 pmol h^{-1}) and 20 were found to contain AAD only (detection limit 8 pmol h^{-1}). This clear biochemical differentiation between presumably 'cholinergic' neurones and presumably 'serotonergic' neurones has been previously noted in other invertebrates[3,4]. It was therefore surprising when, in two laboratories (St Andrews and Kjeller), we independently found that the two homologous giant metacerebral neurones, which contain serotonin[5] and are thought to use it as a neurotransmitter[6], could also enzymatically synthesise ACh. The coincidence of these two enzymatic activities in the giant serotonin cell (GSC) is a unique and therefore intriguing situation among characterised invertebrate nerve cells.

In experiments at Kjeller, ChAc was assayed as described by Fonnum[7] with modifications in the incubation medium to yield optimal activity for *Helix*[8]. In experiments at St Andrews, ChAc was assayed by the same method as modified by Coggeshall *et al.*[9] using the following incubation medium (final concentration): 200 μM ^{14}C-acetyl-CoA, 20 mM choline chloride, 300 mM NaCl, 1 mM EDTA. $2H_2O$, 80 mM sodium phosphate buffer (*p*H 7.4), 0.1 mM eserine, and 0.5% (v/v) Triton X-100. The cells were incubated for 1 h at 37° C (to give maximal *in vitro* activity), and the blanks were 1.5–2.0 pmol. In one series of experiments, both ChAc and AAD were assayed in the same incubation, using the following medium: 0.45 mM ^{3}H-acetyl-CoA, 0.2 mM D,L-1-^{14}C-DOPA, 8 mM choline bromide, 250 mM NaCl, 20 mM sodium phosphate

Table 1 ChAc activity of the giant metacerebral cells (GSCs) after different treatments

buffer (*p*H 7.4), 0.1 mM eserine, 0.1 mM pyridoxal phosphate, 0.125 mM nialamide, 11.5 mM EDTA, and 0.2% (v/v) Triton X-100. The assay was based on the absorption in hyamine of the evolved ^{14}C-CO$_2$ from DOPA, and the extraction of ^{3}H-ACh by Kalignost as before[7]. Animals were maintained in artificial hibernation by storage in a humid environment at 10° C. The dissection was performed as described elsewhere[1]. In some experiments, the removal of single cells was expedited by conducting the dissection under 70% ethylene glycol (−20° C). Enzyme activities were found to be unaffected by the choice of dissection solution, as noted earlier[4]. All experiments were conducted in late spring and summer.

The identification of the extractable radioactivity as acetylcholine was based on the following observations (see Table 1). First, electrophoresis of the extract gave a single radioactive product comigrating with standard ACh (Fig. 1) in two sets of conditions[4,10]; second, no activity was found in the absence of choline; third, no activity was found in the presence of acetylcholinesterase and the absence of cholinesterase inhibitor and, fourth, Kalignost extraction completely separated ACh from acetylcarnitine and other possible acetylated contaminants[11].

Synthesis of ACh was abolished on boiling the cells or after trichloroacetic acid (TCA) precipitation (Table 1), indicating that it is enzymatically mediated. The enzymatic ACh synthesis was inhibited by the presence of MgCl$_2$, CaCl$_2$, ACh, CoA, acryloylcholine, and chloroacetylcholine, in concentrations known to similarly affect the partially purified ChAc from whole snail brain[8]. The latter two substances should be regarded as fairly specific ChAc inhibitors, and inhibited the GSC enzyme to the same degree as they did other choline acetyltransferase-containing neurones.

The level of ACh synthesis by the GSC was highly reproducible in this assay. It was lower than that of a neurone found on the posterio-dorsal surface of the visceral ganglion (known as cell no. 21 (ref. 1) on cell no. 4 (ref. 12)), but comparable to that of the medial buccal cell (cell no. 4 (ref. 1)), which was considered to have a relatively low ChAc activity. Other cells known to contain large amounts of serotonin or AAD, such as the one localised near the right parietal ganglion in the posterio-dorsal surface of the visceral ganglion (known as cell no. 11 (ref. 1) on cell no. 4 (ref. 13)), contained insignificant ChAc activity. These cells served as controls that the observed ACh synthesis in the GSC was not in any way associated with serotonin-metabolising enzymes. Using the double assay, the uniqueness of the GSC was reaffirmed as both enzymes could indeed be measured simultaneously, whereas in control cells, either one activity or none was observed (Table 2). A control extract of 0.5 µl dissecting medium taken from the area of the GSC dissection did not reveal any background activity liberated by tissue disruption (Table 2).

Examination of related species having GSCs[5] revealed that they also share this dual-enzyme characteristic in these neurones, albeit the activity varies somewhat (M.R.H., G.A.C., P.C.E., and F.F., unpublished).

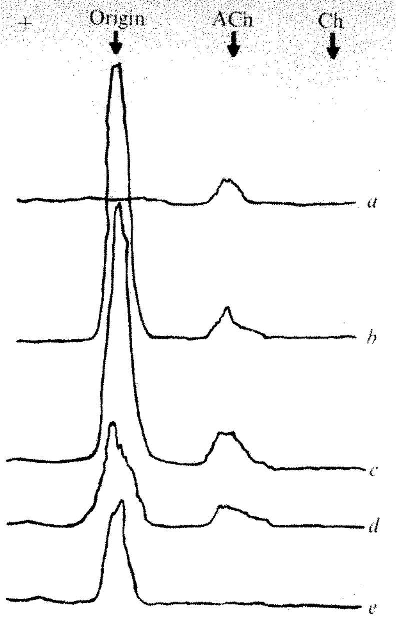

Fig. 1 Electrophoresis of the choline acetyltransferase assay product. Samples were electrophoresed for 50 min in the conditions of Potter and Murphy[9], and subsequently scanned for radioactivity in a Nuclear Chicago Actigraph III (960 V high voltage, 1 s counting, chart speed of 240 cm h^{-1}, 6 mm collimator slit width). Scans *a* and *b* represent the results of assays using a 0.8 µl extract of snail brain homogenate as the source of enzyme. In *a*, 50 µl of Kalignost extraction of the completed incubation was applied. In *b*, 2 µl of the unextracted, completed incubation was applied. In *c*, six GSCs were used as the enzyme source, and in *d*, one cell 21 neurone. Scan *e* is the control to which no enzyme was added. Acetylcholine (ACh) and choline (Ch) mobilities were determined by staining added standards with iodine vapour.

There is consequently strong evidence that acetylcholine can be synthesised in a known serotonin-containing neurone by a choline acetyltransferase.

Assuming that the ChAc serves a physiological role of ACh production in the GSC, it is worthwhile considering the functions of ACh and serotonin within the neurone. Both may serve as neurotransmitters, in which case the long-held dogma of each neurone making and utilising a single neurotransmitter must be abandoned[14]. In this regard, it should be noted that the GSC ChAc is more active than the base levels we quote here during those months when it is difficult to elicit responses to serotonin from the follower cells[6]. Far more likely is the possibility that either the ACh or serotonin (or both) serves as alternative cellular or hormonal function besides classical neurotransmission, perhaps modulating metabolic activity of innervated regions. Last, it should be considered that the ChAc activity might arise from contamination, either by invaginating glia or adhering microneurones. This can never be excluded when work-

Table 2 Enzyme activities of single neurones using both single and double assays for ChAc and AAD in *Helix aspersa*

Neurone	Location	ChAc activity pmol cell^{-1} h^{-1}	Double assay	
			ChAc activity pmol cell^{-1} h^{-1}	AAD activity
GSC	Ventral surface of metacerebral ganglion, near input of inner lip nerve	22.3±6.3(4)*	19.8±9.0(6)	26.0±14.3(6)
Medial buccal cell	Lateral edge of dorsal surface of buccal ganglia. Medial of group of three giant neurones	21.0±5.0(4)	20.3±10.2(3)	<8 (3)
Cell 21	Posterio-dorsal surface of visceral ganglion, between inputs of cutaneous pallial nerve and visceral nerve	65.6±7.9(5)	56.3±12.0(3)	<8 (3)
Cell 11	Posterio-dorsal surface of visceral ganglion, bordering right parietal ganglion	<2 (5)	<2 (3)	56.4±7.5(3)
Posterior buccal cell	As medial buccal cell. Posterior of group of three giant neurones	<2 (5)	<2 (3)	<8 (3)
	Control extract from area of GSC dissection (0.5 µl)	<2 (8)		

* Numbers in parentheses refer to number of determinations used to derive figure.

ing with hand-dissected preparations[15]; but the specific localisation of the enzymes to particular neurones and the absence of ChAc activity from the dissection area do not support this objection.

The possibility that the ACh in the conditions of the assay, is synthesised by an enzyme other than ChAc cannot be excluded. It seems very unlikely, however, in view of the effect of the ChAc inhibitors. Carnitine acetyltransferase (EC 2.3.1.7.) and aryl amine N-acetyltransferase (EC 2.3.1.5.) have been discounted on the basis of their hundredfold lower activities and different kinetic parameters (P.C.E., and M.R.H., unpublished).

Further work will focus on the direct measure of ACh and its functional role in the GSC.

We thank Dr A. Butler of the Chemistry Department of the University of St Andrews for the use of the liquid scintillation spectrometer, and Dr Catherine Hebb for advice. P.C.E. is a Beit Memorial Fellow.

Assignment of the gene for galactokinase to human chromosome 17 and its regional localisation to band q21-22

PROGRESS in somatic cell genetics now allows more rapid and precise localisation of genes within the human genome. A large number of mouse × human hybrid cell lines are available, permitting the investigator to choose, for phenotype assay, lines with a particular reduced human chromosome complement. An increasingly large number of hybrid lines carrying rearranged chromosomes are also becoming available for regional localisation studies. We have used such hybrid cell lines to assign a gene coding for galactokinase (EC 2.7.1.6) to human chromosome 17 and to further localise the gene to band 21–22 on the long arm of the chromosome. Results from this study have provided new information regarding the functioning of the genes coding for the Leloir pathway enzymes in man[1], and have revealed a relatively close and potentially useful linkage between the genes for galactokinase and for thymidine kinase (EC 2.7.1.21).

The 70 mouse × human cell lines used in this analysis were produced, selected and propagated by methods reviewed elsewhere[2]. Hybrid series 41 is composed of 14 primary cell lines, 11 of known independent origin, isolated after fusion of mouse temperature sensitive line ts-1 (ref. 3) with GM 126, human skin fibroblasts. Series 50c consists of 5 primary lines, 4 of known independent origin, isolated after fusion of mouse line TA3 (ref. 4) with human peripheral blood leukocytes. The AIM series consists of 11 primary lines, 9 of known independent origin, isolated after fusion of mouse line A9 (ref. 5) with human skin fibroblasts. The YA series consists of 20 primary lines, 8 of known independent origin, isolated after fusion of A9 with human skin fibroblasts.

We also used a panel of unrelated hybrid lines chosen from a collection of mouse × human hybrids on the basis of their specific partial human karyotypes. Only a few different human chromosomes are represented within a given hybrid line, the same chromosomes being present in many or most of the individual cells. The specific human chromosomes represented varied widely between hybrids of the panel. Analysis of this set of cell lines, then, generally allows the rapid and unequivocal correlation of a given human phenotype with a particular human chromosome. Hybrids which composed the panel were five subclones of JFA-14a and six of JFA-16a (two independent hybrid lines resulting from a fusion of A9 with human skin fibroblasts[6]), WA-Ia-D6[6] (A9 × WI-38[7], human embryonic lung fibroblasts) and IL-II-5[8] (mouse L cell line LM(TK$^-$)[9] × IMR 32, human neuroblastoma).

For regional localisation studies we used two hybrid lines from the WL series[10], WL-24a-2-A and WL-24a-5-C, plus five subclones of WL-24a-2-A isolated after treatment of the hybrid line with adenovirus-12 (ref. 11). WL hybrids originated from a fusion of LM(TK$^-$) with WI-38. They were maintained in HAT selective medium[12] in which cells retaining the human thymidine kinase gene complementing the mouse deficiency survive. Neither of these two hybrids, however, retained an intact human chromosome 17, the chromosome to which the cytosol form of thymidine kinase has been assigned[13-15]. In WL-24a-5-C a portion of the long arm of 17 persists as a marker chromosome, t(11; 17) (q22; q21), which arose

Table 1 Enzymatic activities assayed in hybrids and their respective human chromosome assignments

Chromosome	Enzyme	
1	Pep C	peptidase C (EC 3.4.3.–)
2	IDH-1	isocitrate dehydrogenase (EC 1.1.1.42)
2	MDH-1	(NAD)-malate dehydrogenase (EC 1.1.1.37)
6	ME-1	(NADP)-malic enzyme (EC 1.1.1.40)
7	MPI	mannose phosphate isomerase (EC 5.3.1.8)
10	GOT	glutamate oxaloacetate transaminase (EC 2.6.1.1)
11	LDH A	lactate dehydrogenase (EC 1.1.1.27)
12	Pep B	peptidase B (EC 3.4.3.–)
14	NP	purine nucleoside phosphorylase (EC 2.4.2.1)
16	APRT	adenine phosphoribosyltransferase (EC 2.4.2.7)
18	Pep A	peptidase A (EC 3.4.3.–)
19	GPI	glucose phosphate isomerase (EC 5.3.1.9)
20	ADA	adenosine deaminase (EC 3.5.4.2)
21	SOD-1	cytoplasmic indophenol oxidase or superoxide dismutase-1
X	G6PD	glucose-6-phosphate dehydrogenase (EC 1.1.1.49)
X	PGK	phosphoglycerate kinase (EC 2.7.2.3)

Table 2 Number of hybrids showing presence (+) or absence (−) of the two given human enzymatic activities

	+/+	+/−	−/+	−/−	Total
GaK/IDH-1	5	18	3	24	50
GaK/MDH-1	6	17	7	20	50
GaK/Pep A	17	6	10	17	50
GaK/TK	16	2	0	20	38

Hybrids assayed for IDH, MDH-1 and Pep A are from series 41, 50c, AIM and YA. Hybrids assayed for TK are from series AIM, YA and WL.

spontaneously in the hybrid[16]. In WL-24a-2-A the entire long arm of 17 has been translocated to a mouse chromosome, (M; 17q). In both cases, the translocated product represents the sole identifiable human chromosome element in the hybrid. Treatment of WL-24a-2-A with adenovirus-12 induced breaks in the translocation chromosome (M; 17q) specifically in the region 17q21-22. In subclones A12/1B and A12/1D, the break occurred in 17q21. In subclones A12/2A, A12/2C, and A12/2D, a break occurred in 17q22. Terminal deletions occurred distal to these breaks. These lines have been used previously to assign the gene coding for thymidine kinase to human chromosome band 17q21-22 (ref. 11).

Extracts of the hybrid lines were assayed by vertical starch gel electrophoresis for the presence of human electrophoretic forms of 16 enzymes. Genes coding for these enzymes have previously been mapped to specific human chromosomes, thus the presence of the human isozyme is considered to be strong evidence for the presence of the corresponding human chromosome in the hybrid line. The enzymes used as markers in this study are listed in Table 1 with their chromosome assignments. Methods of assay have been described elsewhere[17]. Thymidine kinase activity was assayed on Cellogel (Chemetron, Milan, Italy) using the method of Migeon *et al.*[18]. Electrophoresis was carried out at 4° C for 4 h at 30 V cm^{-1} using a buffer of 50mM TES (N-*tris*(hydroxy-methyl)methyl-2-aminoethane sulphonic acid) adjusted to *p*H 6.2 with triethanolamine. Our method used to assay galactokinase activity on vertical starch gels has been described[19], (Fig. 1).

Enzymatic analysis of the hybrids from series 41, 50c, AIM and YA indicated that galactokinase (GaK) activity segregated discordinately with the 16 enzymes used as chromosome markers. A representative data sample given in Table 2 shows discordant segregation of GaK with IDH-1 and MDH-1, two markers on chromosome 2 and with Pep A, a marker for chromosome 18. These two chromosomes plus 12 others corresponding to the remaining 13 enzymes could thus be eliminated from consideration in attempts to assign the gene coding for GaK activity to a particular human chromosome. When the panel of well-karyotyped hybrid lines were assayed or GaK activity (Table 3) and conversely the 11 AIM hybrids were karyotyped this conclusion was further substantiated. The 14 chromosomes which were eliminated from consideration on the basis of the enzyme assays could also be eliminated on the basis of chromosome analysis of the hybrids. Nine additional chromosomes which either carried no easily assayed enzyme marker or carried markers which were not included in our assays could also be eliminated from consideration on the basis of chromosome analysis. It then became clear that only chromosome 17 segregated concordantly without exception with GaK activity. The gene for GaK was assigned on this basis to human chromosome 17. The assignment was reinforced by thymidine kinase (TK) assay of the AIM, YA, and WL hybrids. With only two exceptions where human GaK appeared to be present in a hybrid and TK not, the two enzymatic activities segregated concordantly (Table 2).

More precise localisation of the GaK gene along the length of chromosome 17 was made possible by analysis of the WL hybrids. Cell line WL-24a-2-A carrying the (M; 17q) translocation chromosome retained human GaK activity restricting the map position of the gene to the long arm of the chromosome. Hybrid WL-24a-5-C which carried the t(11; 17)(q22; q21) marker likewise showed human GaK activity further restricting the gene to a position in or distal to 17q21. WL-24a-2-A subclones A12/1B and A12/1D which had lost the chromosome portion distal to a break in 17q21 had also lost GaK activity. Subclones A12/2A, A12/2C and A12/2D in which the chromosome loss involved only regions distal to the break in 17q22 retained GaK activity. The GaK gene, from this evidence, must be located between the two breakpoints, and we have accordingly assigned the gene to human chromosome 17 band q21-22 (Fig. 2).

Analysis, then, of the chromosome and enzyme complement of a large number of independent hybrid cell lines of diverse mouse × human parentage has yielded compelling evidence for the assignment of the galactokinase gene to human chromosome 17. GaK activity segregated discordantly with 16 marker enzymes and concordantly with only chromosome 17 and TK activity. Data from two WL subclones which were functionally back-selected for loss of TK activity indicate that GaK activity is lost concordantly with the loss of a portion of chromosome 17. Information obtained from the WL hybrids allowed us to further restrict the map position of the galactokinase gene to band q21-22. The discrepant data which we have obtained, that regarding discordant segregation of TK with GaK in two YA hybrids, could be explained either by the difficulty in assaying TK or by a possible breakage and rearrangement of chromosome 17. We have not been able to identify an intact 17 in one of the discrepant hybrids.

Only chromosome 17 is consistently present in hybrid lines which show human GaK activity as substantiated by the chromosome data (Table 3) and the complementary results

Table 3 Human GaK activity and human chromosomes present in hybrid cell lines

Hybrid	Human GAK	Human chromosomes																							
		1	2	3	4	5	6	7	8	9	10	11	12	X	13	*14	15	16	17	18	19	20	21	*22	Y

*t(14;22).

Karyotypes of hybrids were analysed using air dried preparations[24] stained with quinacrine mustard or Atebrin to produce fluorescent banding of the chromosomes[25] and stained subsequently with Giemsa to reveal constitutive heterochromatin[26]. At least 20 cells from each hybrid line were analysed for the presence of human chromosomes. In all cases specific chromosomes were scored as present in the hybrid if they were found in at least 10% of the cells examined.

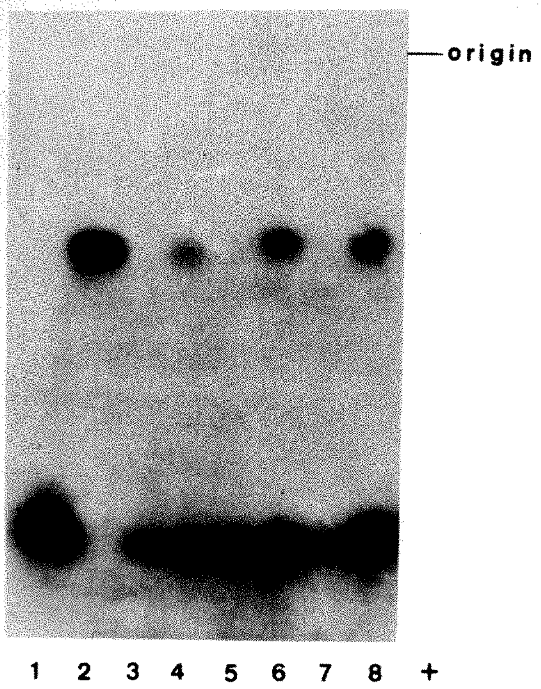

Fig. 1 Galactokinase assay of five WL-24a-2-A subclones. After electrophoresis in citrate phosphate buffer at *p*H 6.8, the gel was incubated in the reaction mixture of Mayes and Guthrie[27]. ^{14}C-galactose-1-phosphate produced by the enzyme was then precipitated in the gel with lanthanum chloride and subsequently detected by autoradiography[28]. Omission of ATP from the reaction mixture prevented the appearance of the reaction spots. Addition of 10 mM D-glucose did not. Mouse control, LM(TK$^-$), was run in channel 1. Human control, KB, is shown in channel 2. Channels 4, 6 and 8 represent extracts of subclones A12/2C, A12/2A and A12/2D, respectively, all of which show both mouse and human forms of the enzyme. Channels 3 and 7 represent extracts of A12/1B and channel 5 represents A12/1D, neither of which shows the human activity band.

from enzyme analysis (Table 2). In addition, hybrid WL-24a-2-A which shows human GaK activity carries the long arm of 17 as its sole human chromosomal element. For this reason we feel that the genetic locus which we have mapped codes for a structural element of the enzyme. In this respect it might be noted that galactokinase purified from human red blood cells is reported to consist of two subunits of approximately equal size with only the dimeric form showing enzymatic activity[20]. We find only one spot of activity for human galactokinase by our assay method and might suppose that it represents this dimer. It is surprising then that no heteropolymer of intermediate electrophoretic mobility forms between human and mouse isozymes in the hybrids as has been observed with numerous other multimeric enzymes[17].

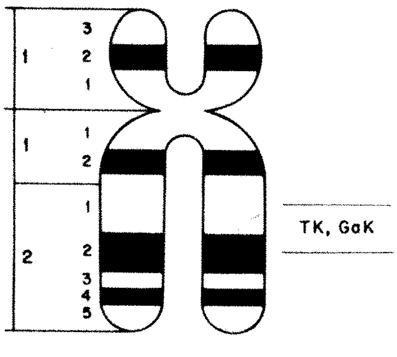

Fig. 2 Chromosome 17 as given by the Paris Conference (1971) (ref. 29) indicating the assigned map position for GaK.

Galactokinase is the first of three enzymes of the Leloir pathway. Since the structural genes for these enzymes map within the same operon in *Escherichia coli*[21] and are closely linked also in yeast, *Saccharomyces cerevisiae*[22], it is interesting to know whether the corresponding genes are linked in man. Human galactose-1-phosphate uridyltransferase (EC 2.7.7.12) has been assigned in two conflicting reports to chromosome 2 (ref. 23) and 3 (personal communication from T. A. Tedesco), and we assign galactokinase to 17. It seems, then, that the genes coding for these two enzymes of the pathway in man are probably not linked.

Linkage of the gene coding for galactokinase with that for thymidine kinase on the other hand, is one of the closest linkages to be detected using the techniques of somatic cell genetics. Since thymidine kinase is a widely used selective marker, these two genes form an especially useful gene pair. For example, it will be of interest to test the possible coordinate transfer of these markers in gene transfer experiments.

5-Methylcytosine localised in mammalian constitutive heterochromatin

DEOXY-5-METHYLCYTIDYLIC acid (5-MeC) is an almost universal, although minor component of DNA in plants and animals. It makes up 4–7% of the bases in plants[1], no more than 1.5% of the bases in the mouse[2] and even less in the human[3]. 5-MeC itself is not incorporated directly into DNA. Instead, specific deoxycytidylic acid residues in preformed DNA are methylated enzymatically by a highly specific DNA methylase, which transfers a methyl group from S-adenosyl methionine to specific sites in DNA[4]. In the mouse, as in other mammals, virtually all of the 5-MeC is in the 5-MeCpG doublet[5], which is distributed nonrandomly in the DNA. Mouse satellite DNA contains about 3% 5-MeC in comparison to about 1.3% in main band DNA[2] and is located at the centromeric end of nearly every chromosome[6].

Antisera to 5-methylcytosine (anti-5-MeC) are available (ref. 7 and Sawicki, Erlanger and Beiser, unpublished) and these can react with 5-MeC residues in single-stranded DNA. Earlier we showed that antibodies specific for particular purine or pyrimidine bases[8], which react with denatured DNA but not native DNA[9], can bind to fixed metaphase chromosomes. The major sites of binding can be localised by immunofluorescence[10,11]. These antibodies can therefore serve as probes of mammalian chromosome organisation. After ultraviolet irradiation, for example, of fixed mouse or human chromosomes, anti-adenosine (anti-A) and anti-thymidine antibodies bound intensely to the AT-rich constitutive heterochromatin[12].

We have now investigated the chromosomal location of 5-MeC residues in both the mouse and the human. Chromosome preparations which had been either ultraviolet irradiated or heated to 85° C in 0.07 M Sorensen's buffer at *p*H 6.5 for 15 or 30 min and chilled suddenly to prevent reassociation, were exposed to one or other of two different anti-5-MeC antisera. These antisera showed no cross reaction with thymidine or with cytidine after absorption with an excess of cytidine conjugated to rabbit serum albumin. The immunofluorescent banding of chromosomes with these two antisera was thus a result of specific binding to 5-MeC residues in the DNA and could be totally abolished by competition with added 5-MeC.

In the mouse, anti-5-MeC showed preferential binding to the C-band regions of centromeric heterochromatin (Fig. 1). The fluorescent regions were very small on a few of the larger chromosomes. These appeared to be the same chromosomes (1 and 3) which have very little centromeric heterochromatin in the AKR strain of mouse used in these experiments[13]. The intense fluorescence of the C-band regions partly reflects the greater concentration of 5-MeC in mouse satellite DNA than in main band DNA[2], but also the greater degree of ultraviolet-induced strand separation in the very AT-rich satellite DNA, which contains sequences of up to four thymine residues in a row in its light strand, and up to five in its heavy strand[14].

The presence of 5-MeC in mouse satellite DNA indicates that the repeating nucleotide sequence in this DNA contains the 5-MeCpG doublet. The amount of 5-MeC, 3 mol% (ref. 2), sets a lower limit on the length of the repeating sequence in the satellite DNA. Assuming that each strand is methylated equally, and taking into account the presence of a small proportion of non-identical sequences, this repeating sequence must be about 30 nucleotides long or some multiple of this. This fits rather well with the estimates of Hutton and Wetmur[15] and Sutton and McCallum[16]. Sutton's estimate of 8–13 nucleotides[17] is clearly too short unless the repeating sequence contains even shorter repeating sequences, some of them not containing 5-methylcytosine.

In the human, the pattern of anti-5-MeC binding was virtually identical whether strand separation was achieved by ultraviolet irradiation or by heating to 85° C. In both cases anti-5-MeC showed preferential binding to the C-band regions of constitutive heterochromatin of chromosomes 1, 9 and 16, the centromere–short arm region of chromosomes 15, and the distal part of the Y (Fig. 2). The C-band region of chromosomes 10, 17, 22 and Y sometimes showed a small region of enhanced anti-5-MeC binding. The observed pattern of binding, and the absence of comparable binding of anti-5-MeC to the C-band regions of most of the chromosomes suggests that methylation occurs only in certain clases of repetitive DNA. For example, the strongly positive regions in chromosomes 1 and 16 are the chief sites

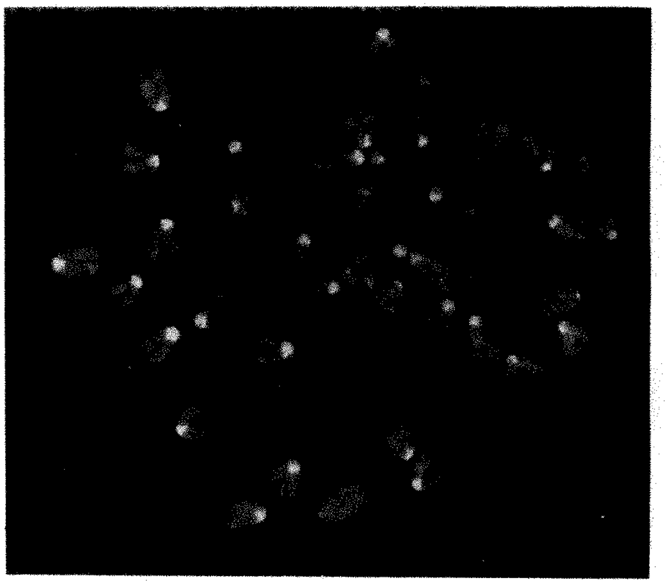

Fig. 1 Metaphase spread from an AKR strain mouse showing sites of anti-5-MeC binding. Note the bright fluorescence at the centromeric end of most chromosomes and the low level of fluorescence of the remainder of all the chromosomes. Mitotic cells from a primary embryonic culture were expanded with 0.075 M KCl hypotonic solution, fixed in three changes of methanol:glacial acetic acid (3:1) and air dried. The spreads were ultraviolet irradiated for 16 h (30 cm from a germicidal lamp) either dry or in Sorenson's buffer, incubated for 30 min with anti-5-MeC at room temperature, washed thoroughly with phosphate buffered saline (PBS: 20 g NaCl, 85 ml 0.25 M Na_2HPO_4, 15 ml 0.25 M KH_2PO_4 in 2,400 ml distilled water H_2O, *p*H 7.2–7.4), incubated for 30 min with fluorescein-tagged anti-rabbit gammaglobulin prepared in sheep, washed thoroughly with PBS, mounted in PBS and analysed by fluorescence microscopy using transmitted light from an HBO 200 W high pressure mercury lamp delivered through a cardioid condenser, BG-12 exciter filter and K530 barrier filter. The photograph was taken on Kodak Plus X film with a 2 min exposure, developed with Acufine and printed on Ilford No. 4 grade paper.

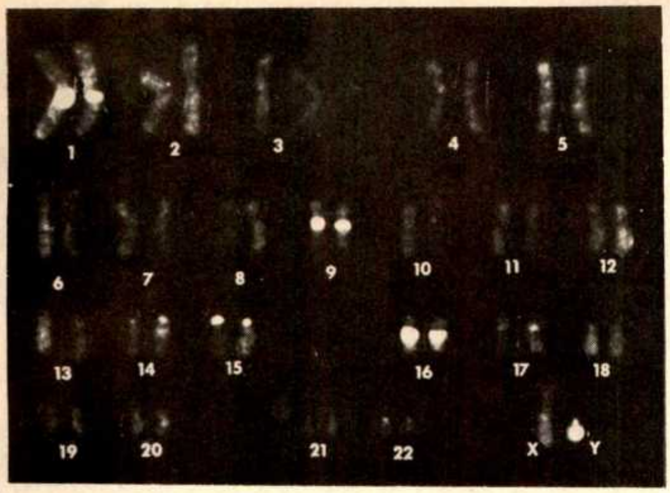

Fig. 2 Karyotype of a human cell showing sites of anti-5-MeC binding. Note the intensely bright fluorescent regions on chromosomes 1, 9, 15, 16 and the Y, and the difference between homologues in each case in the size of this region. Smaller bright centromeric dots are present on one or both copies of chromosomes 14, 17, 22 and Y. Technique as in Fig. 1. Chromosomes were identified by restaining the cell with quinacrine mustard and rephotographing, using the same fluorescence microscopy system and film but with an exposure of only 9 s instead of the 2 min necessary with the antibody.

of human satellite II DNA as revealed by in situ DNA–RNA hybridisation[18], whereas the corresponding 5-MeC-positive region of chromosome 9 contains both satellite II DNA[18] and satellite III DNA[19]. Our results suggest that satellite II, and perhaps satellite III, contain 5-MeC. We are unaware of a direct chemical analysis of the 5-MeC content of the various human satellite DNAs. Since neither satellite II nor satellite III is abundant in chromosome 15 or the Y, these chromosomes must contain different types of highly repetitious, methylated DNA.

The immunofluorescence approach described here can be used to locate classes of highly repetitive DNA which contain 5-MeC. It is already apparent that these classes show remarkable quantitative variation between homologues and among individuals. These differences provide chromosome markers which can be used in genetic linkage studies or in the analysis of structurally altered chromosomes. This might be particularly useful in identifying a structurally altered chromosome 15, since its proximal portion can now be more specifically identified than before. Striking differences have been noted in comparing anti-5-MeC binding to chromosomes of gorilla, chimpanzee and orang utan (unpublished data); and the technique seems to offer a promising approach to the evolution of satellite or other classes of highly repetitive DNA.

Structure of DNA in DNA replication mutants of yeast

As in higher eukaryotes[1,2], the nuclear DNA of the simple eukaryote *Saccharomyces cerevisiae* is replicated from multiple internal initiation sites along the chromosome[3–5]. The very small size of the chromosomal DNA in yeast[3,6,7] and the availability of temperature-sensitive DNA synthesis mutants[8,9] make a detailed study of DNA replication easier in yeast than in most other eukaryotic systems. In this report, nuclear DNA molecules from several DNA synthesis mutants which had been classified as DNA initiation or DNA propagation mutants on the basis of incorporation kinetics were examined with the electron microscope. Our results provide independent criteria for the classification of DNA initiation and propagation mutants on the basis of the structure of the nuclear DNA at the restrictive temperature.

Three temperature-sensitive DNA replication mutants were used in these studies: *cdc*4, *cdc*7 and *cdc*8 (refs 8,9). If synchronous cultures of cells carrying mutations in *cdc*4 or *cdc*7 are shifted to the restrictive temperature immediately after initiation of DNA synthesis has occurred, approximately a complete round of DNA is made before synthesis stops[8,9]. It is been suggested, therefore, that the gene functions *cdc*4 and *cdc*7 are required for the initiation of nuclear DNA synthesis[8,9]. The gene function *cdc*8 is necessary for DNA propagation since cells carrying this mutation abruptly shut off nuclear DNA synthesis when shifted to the restrictive temperature[8].

When DNA molecules from *cdc*4 at the restrictive temperature were examined in the electron microscope, all molecules (126/126) were simple linear structures, containing neither replication 'bubbles' ('eye-forms') nor Y-shaped replication forks. In DNA isolated from *cdc*7 at the restrictive temperature (36° C), 144/150 molecules were simple linear structures. Six of the molecules contained replication forks, possibly the result of some leakiness of DNA syn-

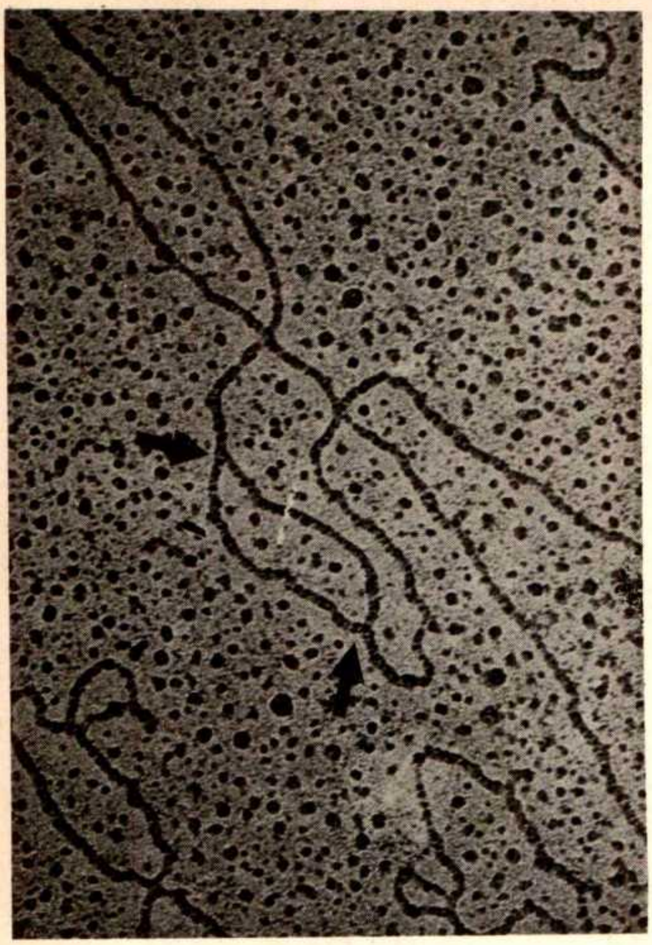

Fig. 1 Small DNA replication bubble in DNA isolated from a temperature-sensitive DNA propagation mutant (*cdc*8) at the restrictive temperature. A culture of *cdc*8 (strain 198–1) was grown at 23° C in 10 ml of Y-minimal media[6] supplemented with 0.2 g glucose, 5 mg yeast extract, 200 μg uracil, 200 μg adenine, 500 μg tyrosine, 500 μg histidine and 500 μg lysine. The doubling time of the culture under these conditions is approximately 3 h. At a cell density of 2×10^6 cells ml^{-1}, the culture was shifted to 36° C for 5 h. Cells were then collected and spheroplasted as described previously[6]. 0.2 M hydroxyurea (Matheson, Coleman and Bell, Norwood, Ohio) was added to the spheroplasting solutions. Nuclear DNA was separated from other cellular components by centrifugation in sucrose gradients[3]. Methods for spreading DNA for electron microscopy have been described[3]. Each branch of the bubble in the photographed molecule is 0.4 μm in length; arrows show the forks. Nuclear DNA was prepared from *cdc*4 (strain 135.1.1.) and *cdc*7 (strain 4008) as described above. For both initiation mutants all the DNA molecules observed in the experiments should come from cells arrested in the cell cycle at the beginning of the S period[8,9]. For *cdc*8, however, although most of the molecules of DNA should come from cells blocked near the beginning of the S period, some DNA molecules should come from cells within the S period. Since only 3–5% of the DNA molecules in an asynchronous culture are replicating at any given time[3], most of the DNA molecules observed in the *cdc*8 experiment should contain no replication structures before the shift to the restrictive temperature.

thesis at the restrictive temperature. This allele of *cdc*7 (4008) is somewhat leaky at 36° (ref. 9) synthesising nuclear DNA at approximately 10% the normal rate (C.S.N., unpublished observations). When the experiment is done at 38° C with *cdc*7, 149/150 DNA molecules were simple linear structures[4,5].

Hartwell[10] has pointed out the difficulties in distinguishing true DNA initiation mutants from mutants which have a leaky replication block, a replication block with a delayed onset of expression or a replication block early in the process of DNA replication. The observation that very few of the DNA molecules observed in DNA isolated from the initiation mutants *cdc*4 and *cdc*7 contain DNA replication intermediates argues that the cells are blocked before the onset of DNA replication. These data and the incorporation data from previous studies[8,9] indicate that *cdc*4 and *cdc*7 may be true DNA initiation mutants.

The findings with *cdc*8, the DNA propagation mutant, were quite different. Approximately half (114/240) of the DNA molecules isolated from *cdc*8 at the restrictive temperature contained one or more replication bubbles. Often these bubbles were very small, less than 2 μm in size (Fig. 1). Figure 2 is a histogram of bubble sizes. The average bubble (3 μm) observed in this experiment is less than that found in replicating molecules isolated from a synchronous early S-phase population of cells[4,5]. Figure 3 is a histogram of centre-to-centre distances between bubbles in molecules which contain more than one bubble.

The high proporation of DNA molecules with replication bubbles found in experiments with *cdc*8 indicate that this mutant can initiate DNA synthesis at the restrictive temperature. The spacings between adjacent bubbles (Fig. 3) are similar to those observed during normal DNA replication[4,5] suggesting that DNA synthesis may be initiating in *cdc*8 at the restrictive temperature at the same sites as during normal DNA replication. The small size of the replication bubbles probably reflects a much reduced rate of chain propagation at the restrictive temperature. The rate of nuclear DNA synthesis in *cdc*8 at the restrictive temperature is less than 1% the normal rate (C.S.N., unpublished observations). An alternative explanation for the small replication bubbles is that the *cdc*8 gene function is not required for replication of a small amount of DNA at the initiation site but is required for subsequent chain propagation. This explanation seems somewhat unlikely but cannot yet be ruled out. The small proportion of molecules with large replication bubbles may be molecules which contained replication intermediates at the time of the shift to the restrictive temperature (as discussed in the legend to Fig. 1). Therefore, the large number of DNA molecules in *cdc*8 at the restrictive temperature which contain small replication bubbles confirms the classification of *cdc*8 as a DNA propagation mutant. Hartwell[9] has recently classified another cell cycle mutant, *cdc*21, as a possible DNA propagation mutant on the basis of incorporation kinetics. Preliminary

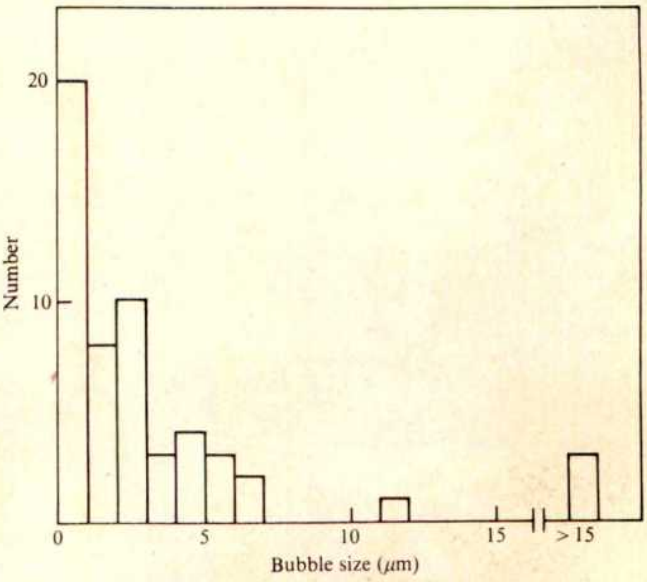

Fig. 2 Histogram of bubble sizes from DNA molecules isolated from *cdc*8 at the restrictive temperature. Photographs were printed at a final magnification of 10,000 to 25,000 and contour measurements were made with a Keuffel and Esser map measurer.

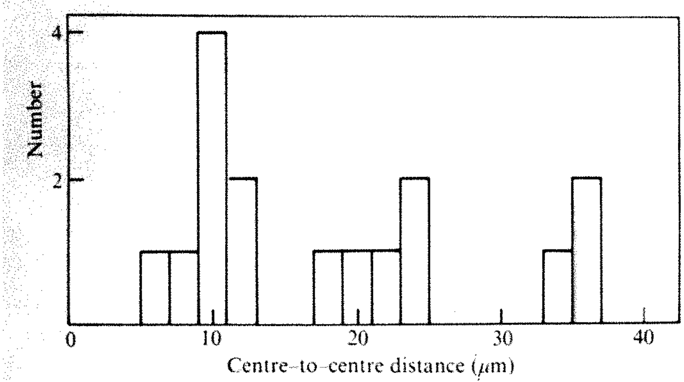

Fig. 3 Distribution of centre-to-centre distances between bubbles on molecules containing more than one bubble. Measurements were made on DNA molecules isolated from *cdc8* at the restrictive temperature.

experiments with *cdc21* at the restrictive temperature have shown that these DNA molecules also contain small replication bubbles (T.D.P., unpublished observations).

The appearance of small replication bubbles in the elongation mutant *cdc8* but not in the initiation mutants *cdc4* and *cdc7* cannot be explained by suggesting that *cdc8* is more leaky at the restrictive temperature than *cdc4* or *cdc7*. As already discussed, at 36° C, *cdc7* is considerably more leaky than *cdc* 8. These results, therefore, also imply a qualitative difference in the leakiness of *cdc7* and *cdc8* (ref. 10). In *cdc8* at the restrictive temperature, a high proportion of cells are apparently synthesising DNA at a slow rate of chain propagation (since many of the DNA molecules contain small bubbles). In *cdc7* at the restrictive temperature, the leakiness of synthesis may be the result of a small proportion of cells which escape the initiation block and replicate their DNA at a normal or nearly normal rate of chain propagation (since very few of the DNA molecules contain DNA replication intermediates).

This work was supported by a grant to Dr W. L. Fangman, University of Washington from the US National Institutes of Health. T.D.P. was supported by a US National Institutes of Health genetics training grant at the University of Washington. C.S.N. was a recipient of an American Cancer Society postdoctoral fellowship. We thank Dr W. L. Fangman for support and encouragement and Drs D. H. Williamson and L. H. Hartwell for suggestions concerning the manuscript and Dr Hartwell also for providing the three mutants.

Radiological mapping of the ribosomal RNA transcription unit in *E. coli*

THE ribosomal RNA genes of *Escherichia coli* are arranged in tandem behind a common promotor in the order of 16S, 23S, 5S (for review see ref. 1). In this report we redetermine the positions of the 16S (0.55×10^6 dalton), 23S (1.10×10^6 dalton), and 5S rRNA (0.04×10^6 dalton) cistrons on their unit of transcription (scripton) by the ultraviolet light mapping technique[2–9] principally to demonstrate the applicability of this technique to the determination of the transcriptional linkage of genes in *E. coli*.

The ultraviolet light technique for mapping transcriptional linkage is based on the observation that certain lesions induced in DNA by ultraviolet light cause premature termination of transcription at the site of the lesion and that no reinitiation occurs beyond the lesion up to the next promotor[5,6,10,11]. Therefore, the expression of promotor distal genes is more sensitive to ultraviolet irradiation than that of promotor proximal ones.

Rates of synthesis of 23S, 16S and 5S rRNA after irradiation of *E. coli* with various doses of ultraviolet light were determined by ^{3}H-uridine pulses and quantitation of the RNA species after polyacrylamide gel electrophoresis. Errors originating with the isolation procedure were minimised by providing internal standards through prelabelling of the mature rRNAs with ^{14}C-uridine. In Fig. 1 (left and right panels) frames (*a*) display rRNAs synthesised in the unirradiated sample, frames (*b*) to (*f*) (left panel) and (*b*) to (*d*) (right panel) the synthesis in ultraviolet-light-irradiated cultures in the order of increasing dose. As Fig. 1 shows, synthesis of 23S rRNA was reduced more by ultraviolet light irradiation than was the synthesis of 16S rRNA. Synthesis of 5S rRNA was very sensitive to ultraviolet light. A greater reduction in 23S rRNA synthesis compared with 16S rRNA synthesis after ultraviolet irradiation has been observed previously[12–14].

Evaluation of a series of such experiments leads to the dose-effect curves in Fig. 2. The straight line parts of the curves, which extrapolate to 160 and 170% at the ordinate, yield inactivation coefficients of -3.7×10^{-2} s^{-1}, -0.12 s^{-1}, and -0.12 s^{-1} for synthesis of 16S, 23S and 5S rRNA, respectively. The ratio of 16S *versus* 23S rRNA synthesis as a function of dose is given in the insert of Fig. 2. We have utilised this RNA ratio curve in determining the extent of photoreactivation of RNA chain terminating lesions.

Inactivation curves for 16S, 23S and 5S rRNA synthesis all have shoulders in a semi-log plot, but with ultraviolet doses greater than 10 s they all enter into a straight line portion (Fig. 2). From this it can be concluded that all six rRNA transcription units[1] in a single *E. coli* chromosome are structurally identical.

We suggest that the shoulders of the survival curves are caused by the following effect. Not all ribosomal RNA scriptons are transcribed at the maximal rate in the unirradiated cell. As the number of unhit scriptons decreases within a cell with increasing ultraviolet dose, dormant rRNA scriptons become activated, or the remaining rRNA scriptons are utilised better. When cells are irradiated for more than 10 s the rates of rRNA synthesis are exclusively determined by the number of unhit cistrons for the mature rRNA species.

16S, 23S and 5S rRNA can be positioned fairly accurately on p30, the precursor RNA containing the mature rRNA species, if the inactivation coefficients and molecular weights of

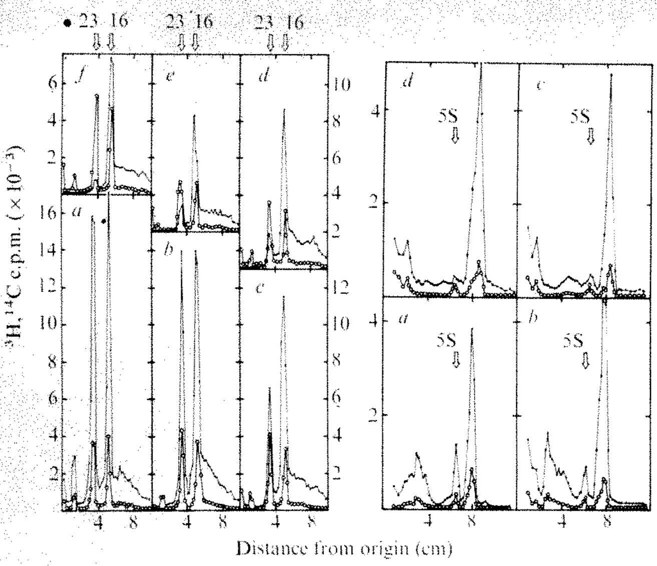

Fig. 1 Left panel: tritiated uridine labelling of 16S and 23S rRNA as a function of ultraviolet irradiation dose. A 20 ml culture of the ultraviolet-light-sensitive strain *E. coli* B_{s-1} (ref. 24) was grown in M-9 medium (M-9 plus 5% (w/v) casamino acids) at 37° C. At a concentration of 0.5×10^8 cells per ml, ^{14}C-uridine (54 mCi mmol^{-1}, Amersham-Searle) was added (0.01 µCi ml^{-1}) and cells were grown for approximately two more generations, about 90 min. This prelabelled culture was chilled on ice, centrifuged (5,100*g*, 15 min), resuspended in 30 ml fresh M-9 medium (approximately 10^8 cells ml^{-1}) and incubated for another 45 min at 37° C. The culture was then chilled on ice, split into six equal 5 ml portions and all but one irradiated at 0° C with a GE G4T4/1 low pressure mercury lamp for various times (incident dose rate at the position of the sample was 14 erg mm^{-2} s^{-1}, the effective dose rate was 10.5 erg min^{-1} s^{-1}). The unirradiated and five irradiated samples were transferred to culture tubes and incubated with vigorous shaking for 5 min. Tritiated uridine (42 Ci mmol^{-1}, Amersham-Searle) was added to a concentration of 1 µCi ml^{-1} to each culture. At 12.5 min after ^{3}H-uridine addition, the cultures were poured into ice cold centrifuge tubes, the cells were pelleted, resuspended in 2 ml 3mM EDTA (*p*H 7.2) and lysed by addition of 0.2 ml 10% Na dodecyl sulphate (SDS, Biorad) in a 1 min, 80° C incubation. RNA was extracted from the lysates with H_2O-saturated phenol, precipitated and resuspended in 0.30 ml 3 mM EDTA. To these RNA preparations sucrose was added to 15% and SDS to 1%. Samples of 0.10 ml of each RNA preparation were layered onto 15 cm 2.6% acrylamide gels and electrophoresed at 70 V for 5.5h; the gels were sliced into 2 mm fractions, digested in peroxide and counted in a liquid scintillation counter. The counts in the ^{3}H-pulse-labelled RNA and ^{14}C-prelabelled RNA were corrected for interchannel spillover. Right panel: tritiated uridine labelling of 5S and 4S RNA as a function of ultraviolet irradiation dose. Samples of 0.10 ml of the same RNA preparations used in the left panel were layered on to 8.0% polyacrylamide gels and electrophoresed at 75 V for 6 h in order to resolve the 5S and 4S RNAs. The major peak to the right of 5S rRNA is the 4S tRNA fraction. In both panels the ultraviolet irradiation times were (*a*) 0 s; (*b*) 8 s; (*c*) 15 s; (*d*) 23 s; (*e*) 31 s; (*f*) 38 s. No tritium counts in the 5S region were detectable at irradiation times in excess of 23 s (data not shown). ●, ^{3}H c.p.m.; ○, ^{14}C c.p.m.

the rRNAs are known. Since synthesis of the 23S is 3.25 times more sensitive than that of 16S rRNA, its 3′ terminus must be located at least $3.25 \times 0.55 \times 10^6$ daltons $= 1.80 \times 10^6$ daltons away from the p30 promotor. Since the molecular weight of the 5S rRNA is 0.04×10^6 and since 5S synthesis has essentially the same inactivation coefficient as 23S (Fig. 3), 5S must follow the 23S very closely on the transcriptional map. Thus, by converting ultraviolet-light-inactivation coefficients into molecular weights, using the molecular weight of 16S rRNA as a standard, and assuming the 16S RNA cistron to be adjacent to the promotor locus, we project a molecular weight of about 1.85×10^6 for p30. This size is close to previous determinations of the p30 molecular weight between 1.75 and 10^6 (ref. 15) and 1.85×10^6 (ref. 16). If this size for p30 is correct, our data would locate the 16S, 23S and 5S rRNA as shown in Fig. 3*a*, with the 3′ terminus of p30 at about 1.85×10^6 daltons. If the molecular weight of p30 were about 2.1×10^6 (ref. 17) the 16S rRNA could be preceded by approximately 0.09×10^6 daltons of non-conserved spacer RNA and the second spacer situated between 16S and 23S would be about 0.30×10^6 daltons (Fig. 3*b*). Alternatively, the additional 0.25×10^6 daltons of non-conserved RNA could be located beyond the 3′ end of the map as drawn (dashed line) in Fig. 3*a*. Figure 3*a* and *b* gives the extreme positions of 16S, 23S and 5S rRNA on p30. Any intermediate position that places the 3′ end of the 23S at 3.25 times the distance of the 16S 3′ end from the promotor would be consistent with our data.

From the inactivation coefficient for the synthesis of 16S rRNA, the dose required to produce 1 transcription terminating

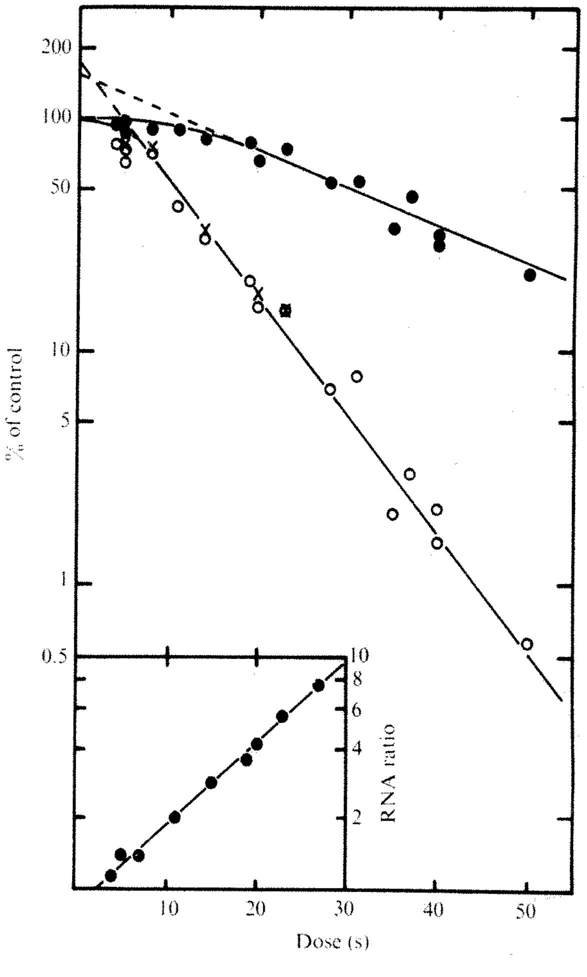

Fig. 2 Reduction of synthesis of rRNA species as a function of ultraviolet light dose. Data are taken from several experiments of the type shown in Fig. 1. The relative amount of 23S, 16S (converted from 17S values) and 5S rRNA can be calculated accurately, using the ^{14}C-prelabelled rRNA as an internal standard, from the expression:

$$\% \text{ of control synthesis} = \left[\frac{^{3}\text{H c.p.m. RNA}_x}{^{14}\text{C c.p.m. RNA}_x}\right]_d \cdot \left[\frac{^{14}\text{C c.p.m. RNA}_x}{^{3}\text{H c.p.m. RNA}_x}\right]_{\text{control}}$$

where *x* refers to the species of rRNA under consideration, the RNA in the brackets subscribed with a *d* is from a culture irradiated with a dose *d*, and the RNA in the brackets subscripted with 'control' is from the unirradiated culture. Background radioactivity due to non-rRNA was subtracted from the total radioactivity in the peak fractions for 23S, 17S and 5S rRNA. The exponential slopes, determined from least squares analyses of all points greater than 10 s, were $K_{16} = -3.7 \times 10^{-2}$ s^{-1}, $K_{23} = K_5 = -0.120$ s^{-1}. The ordinate intercepts of the exponential portions of the RNA synthesis dose-effect curves for 16S and 23S rRNA were 160% and 170% respectively. ●, 16S rRNA; ○, 23S rRNA; ×, 5S rRNA. The inset shows the increase in 16S rRNA synthesis relative to 23S rRNA synthesis (the RNA ratio) with increasing ultraviolet light dose.

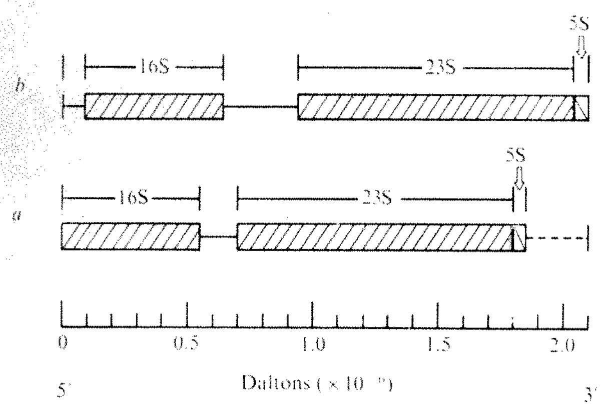

Fig. 3 Map of the *E. coli* ribosomal RNA transcription unit determined by radiological mapping. Two possibilities for the arrangement of the rRNAs (hatched areas) and non-conserved spacer RNAs (solid or dashed lines) are shown; model *a* assumes the molecular weight of p30 is 1.85×10^6 (refs 15 and 16) and model *b* assumes the molecular weight is 2.1×10^6 (ref. 17).

lesion per 1,000 DNA base pairs in the p30 scripton was determined to be between 550 and 640 erg mm^{-2}.

From the extent to which ultraviolet-light-induced transcription terminating lesions in DNA can be eliminated by photoreactivation, one can estimate what fraction of these lesions comprises pyrimidine dimers. After maximal photoreactivation, 70% of the transcription terminating lesions were repaired as determined from the shift in the ratios of 16S to 23S rRNA (ref. 7 and inset, Fig. 2). This suggests that at least 70% of the transcription terminating lesions comprises pyrimidine dimers[18]. Photoreactivation of ultraviolet-light-induced lesions which impair RNA synthesis in general has been reported earlier[19].

Actinomycin D has been used in studies of transcriptional linkage[20,21] with the same rationale as we use in the ultraviolet light mapping technique. The ribosomal genes of *E. coli*, however, were incorrectly assigned to separate transcription units through the actinomycin D technique[20], and the transcriptional linkage of the β-galactosidase and transacetylase genes of the *lac* operon of *E. coli* (ref. 22) was determined correctly only through an error in evaluating the experimental data. The transcriptional arrangement of the rRNAs in mouse L cells was incorrectly inferred from actinomycin D inhibition of RNA synthesis (see ref. 7). Thus far, actinomycin D has failed as an agent for transcription mapping in both prokaryotes and eukaryotes[7], whereas ultraviolet light mapping has been used successfully in both systems (for review see ref. 23).

Distribution of DNA in dividing spinach chloroplasts

SPINACH chloroplasts, like other higher plant chloroplasts, contain DNA[1] and divide[2]. It has been estimated[3-5] that chloroplasts contain many copies of DNA, but in higher plants, which contain large numbers of chloroplasts per cell[2,6] it is not known when the DNA of chloroplasts replicates and how it is distributed when they divide. In the unicellular alga, *Ochromonas*, which contains a single chloroplast, ^{3}H-thymidine is readily incorporated into chloroplast DNA and is distributed equally among the progeny chloroplasts[3]. On the other hand, in *Acetabularia*, which contains large numbers of chloroplasts per cell, DNA could not be detected in 65–80% of the plastids, but could easily be detected in the remainder[7].

Disks of spinach leaves grown in sterile culture were used to study the distribution of DNA in dividing chloroplasts in both pulse and pulse/chase experiments. In this system chloroplast number per cell increases 5–10-fold over a 7 d culture period in the light[2]. There is virtually no cell division during this time[2].

Using ^{3}H-thymidine and autoradiography on EDTA-separated cells dried on to glass slides (Fig. 1) we found that in spinach leaf discs both chloroplast and nuclear DNA synthesis continues during cell expansion. The specificity of incorporation into DNA was established using DNase, RNase and acid extractions[8].

The distribution of label amongst daughter chloroplasts was followed in freshly excised spinach disks (2 mm dia-

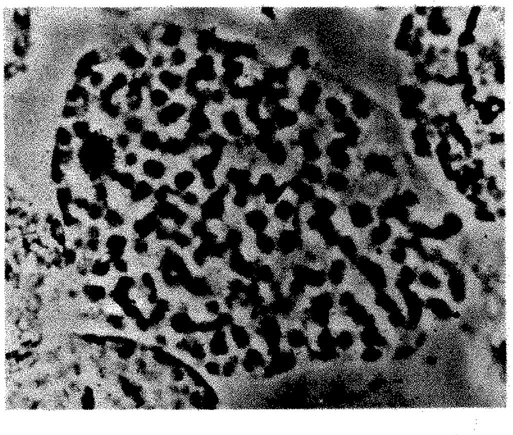

Fig. 1 Autoradiograph of leaf cell showing ^{3}H-thymidine incorporation. Tissue was incubated in ^{3}H-thymidine for 24 h and chased 4 d as indicated in Table 1 (×400).

Table 1 ^{3}H-Thymidine incorporation into spinach chloroplasts

	End of pulse	End of chase
Grains per chloroplast	23.9	4.5
Labelled chloroplasts	100%	99%
Chloroplasts per cell	23	148

Spinach disks 2 mm in diameter were excised from the base of leaves 2 cm long and grown on sterile agar[4]. 1 ml of 50 μCi 6-^{3}H-thymidine (27 Ci mM^{-1}, The Radiochemical Centre, Amersham, UK) was added under sterile conditions to the 20 ml of medium in 9 cm Petri dishes. The tissue was incubated for 24 h (14 h d^{-1}, 20,000 l×) in a growth cabinet. After incubation, nine disks were fixed in 3% glutaraldehyde after a rinse in 2.07 mM cold thymidine. The other nine disks were transferred to fresh medium (see text), containing approximately a 1,000 times excess of cold thymidine. After 4 d in the fresh medium, the nine remaining disks were fixed in 3% glutaraldehyde. The disks from both the pulse and chase were treated with 0.05 M EDTA (pH 9) overnight at 60° C to separate the cells. The cells were spread on to slides, air dried and dipped in Ilford L4 nuclear emulsion. The slides were exposed 13 d at 5° C before developing and mounting as permanent slides. The data for the pulse was obtained from 10 cells with all plastids scored as labelled or unlabelled, and 10 plastids from each cell scored for grain number. The chase data was obtained in the same way except that 20 plastids per cell were scored for grain number. Independent counts were made by two observers and only chloroplasts clearly separated from each other were scored. Background corrections were made; these varied from zero to two grains per chloroplast.

meter) incubated in ^{3}H-thymidine for 24 h. At the end of the incubation period, one half of the disks were collected for autoradiography, and the other half rinsed with sterile water and transferred to fresh medium containing an excess of cold thymidine for a further 4 d growth period.

At the end of the ^{3}H-thymidine pulse there were 23 plastids per cell and this increased to 148 at the end of the chase (Table 1). This represents approximately 2.7 generations. Almost all plastids were labelled both at the end of the pulse and at the end of the chase (Table 1). These results indicate that the label is distributed to virtually all daughter chloroplasts. The mean number of grains decreased from 23.9 at the end of the pulse to 4.5 at the end of the chase (Table 1), which is close to the 3.7 expected if the grain number was halved at each generation. This is consistent with the chloroplast DNA being conserved during the chase period. The nuclear DNA also appears to be largely conserved as there were 44% labelled nuclei at the end of the pulse and 36% at the end of the chase. We have also found a fourfold increase in the total DNA of discs, over a 6 d growth period, even though there is no significant cell division during this time.

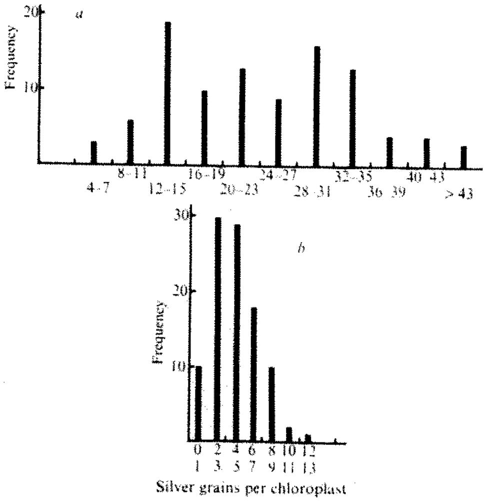

Fig. 2 Frequency distribution histograms of silver grains over a 100 chloroplasts after, *a*, a 24-h pulse in ^{3}H-thymidine, and, *b*, a 4-d chase as indicated in Table 1. The observed distribution of the pulse differs from that of the chase. The distribution of the chase does not differ significantly from a Poisson distribution having the same mean (chi-square test: $P > 0.05$). An autoradiograph of a cell after the chase is shown in Fig. 1.

The distribution of silver grains at the end of the pulse probably reflects the different times at which plastids completed their last division (Fig. 2). No highly labelled chloroplasts were found at the end of the chase and the labelling pattern corresponds closely to a Poisson distribution. This is good evidence that the label distributes almost equally amongst daughter chloroplasts as is the case in *Ochromonas*[3].

Our results differ from those of Woodcock and Bogorad[7] with *Acetabularia* where there are large variations in the DNA content of chloroplasts. Herrmann[9,10] has found, using chloroplast preparations, isolated from whole or parts of *Beta vulgaris* leaves, that large chloroplasts contain more DNA than small chloroplasts. He did not look at variations in the DNA content of chloroplasts in single cells. Some of the variation in DNA amongst chloroplasts of different sizes can be related to developmental and nuclear genotype changes. We consider these differences are unrelated to the segregation of DNA that occurs in a rapidly dividing chloroplast population which is concomitantly synthesising DNA.

The data we have obtained establish that there is active chloroplast DNA synthesis in expanding leaf cells of spinach and that chloroplast DNA segregates to all daughter chloroplasts during chloroplast replication. The data further suggest that all chloroplasts of the cell divide rather than a small subpopulation as has been proposed from chloroplast size and observations[6].

We thank Mrs J. Nikandrow for technical assistance.

Friend virus release and induction of haemoglobin synthesis in erythroleukaemic cells respond differently to interferon

EXPERIMENTS with intact cells have provided the firmest evidence that the synthesis of viral proteins is the main function inhibited in cells treated with interferon. Changes

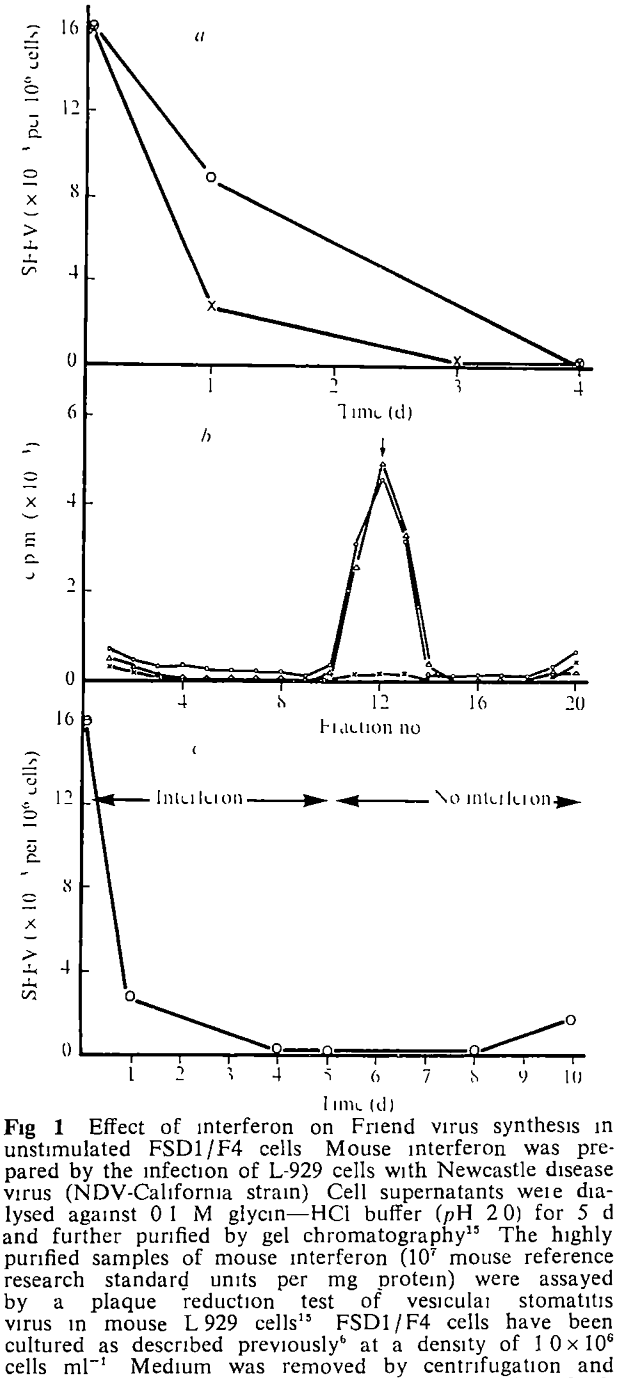

Fig 1 Effect of interferon on Friend virus synthesis in unstimulated FSD1/F4 cells Mouse interferon was prepared by the infection of L-929 cells with Newcastle disease virus (NDV-California strain) Cell supernatants were dialysed against 0 1 M glycin—HCl buffer (*p*H 2 0) for 5 d and further purified by gel chromatography[15] The highly purified samples of mouse interferon (10^7 mouse reference research standard units per mg protein) were assayed by a plaque reduction test of vesicular stomatitis virus in mouse L 929 cells[15] FSD1/F4 cells have been cultured as described previously[6] at a density of $1\ 0 \times 10^6$ cells ml^{-1} Medium was removed by centrifugation and cells transferred to the same volume of either fresh medium or fresh medium containing 300 or 900 U ml^{-1} mouse interferon, respectively Cells were transferred in daily intervals to fresh medium with or without interferon After removal of the cells, aliquots of cell supernatants were assayed for SFFV in DBA-2 mice[16] Total synthesis of C type particles was analysed by measurement of ^3H uridine incorporation into cell supernatant particles banding at 1 16–1 18 g cm^{-3} Cells were exposed to either 600 U ml^{-1} mouse interferon or 500 U ml^{-1} chicken interferon from 0–48 h and 25 $\mu Ci\ ml^{-1}$ 5,6 ^3H-uridine (Amersham, specific activity, 50 Ci $mmol^{-1}$) from 24–48 h Cell supernatants were cleared from debris at 8,000*g*, 10 min and centrifuged at 60,000*g* 1 h 4° C Pellets were resuspended in a buffer containing 0 1 M NaCl, 0 01 M Tris-Cl, 0 001 M EDTA, *p*H=7 4, layered on top of a 15–60% (w/v) sucrose gradient in the same buffer and centrifuged for 75 min in a Spinco SW 50-1 rotor at 42,000 r p m Acid precipitable radioactivity was determined in each fraction *a*, Reduction of Friend virus (FV) release by interferon Spleen focus formation of supernatant particles ○, 300 U ml^{-1} interferon, ×, 900 U ml^{-1} interferon *b*, Reduction of FV release by interferon, uridine incorporation into viral particles, density 1 16–1 18 g cm^{-3} (↓), sucrose gradient ○, Untreated cells, ×, mouse interferon 600 U ml^{-1}, △, chicken interferon 500 U ml^{-1} *c*, Aftereffect of interferon treatment 900 U ml^{-1} treatment as in *a* Interferon-free medium from day 5 on

in an interferon-treated cell which lead to the development of resistance may be reflected also in a cell-free system for protein synthesis Thus, polyribosomes of interferon-treated L cells were found unable to translate either mengovirus mRNA or haemoglobin mRNA—in contrast to the endogenous mRNA synthesis which was not impaired[1] A similar inhibition of the translation of exogenous viral or cellular mRNAs was reported for cell-free extracts from interferon-treated Ehrlich ascites cells[2] These observations raise the question of whether the expression of some cellular functions is as equally affected as that of viruses The inhibition of haemopoietic colony growth and of phytohaemagglutinin stimulation of lymphocytes by interferon seems to indicate that interferon does have such a dual effect[3,4] We show here, however, that interferon inhibits virus release or replication but that it does not interfere with DMSO-induced differentiation

Friend virus-transformed erythroleukaemic spleen cells can be maintained in culture They can be induced to differentiate[5] and to synthesis haemoglobin[6] Some of the erythroleukaemic cell lines (clone FSD1/F4) liberate biologically active Friend virus (FV), that is, spleen focus forming virus (SFFV) (ref 7) and lymphatic leukaemia

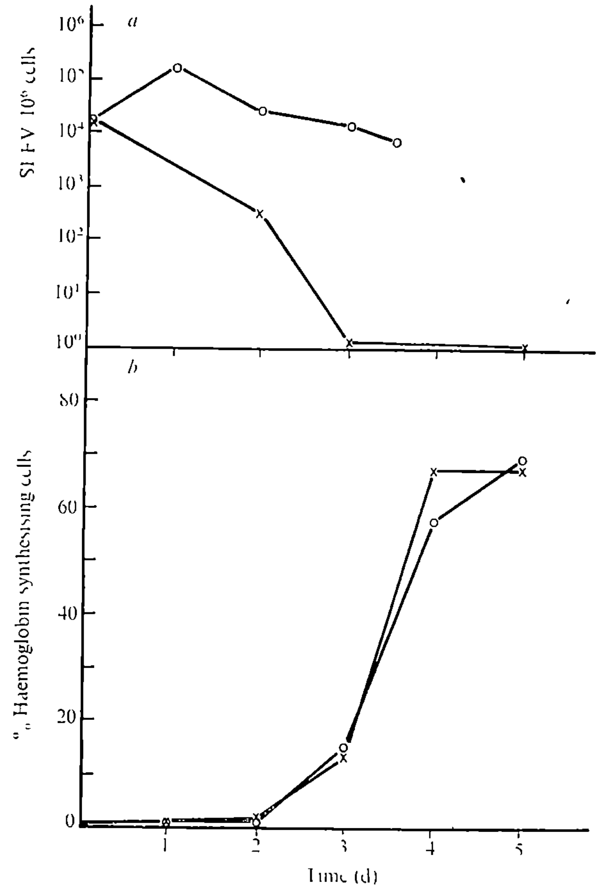

Fig 2 Effect of exogenous interferon on the production of FV (SFFV) and on haemoglobin synthesis during dimethylsulphoxide (DMSO)-induced differentiation of FSD1/F4 cells Stimulation of FSD1/F4 cell cultures by DMSO treatment has been described[6] Interferon was added to the culture medium at a concentration of 900 U ml^{-1} During the course of stimulation, cells were transferred daily to fresh medium containing 1 5% DMSO with or without interferon The production of SFFV was tested at various intervals during stimulation as described previously[16] Erythroid differentiation of cells was estimated by staining cells with benzidine *a*, Effect of interferon on virus synthesis in DMSO stimulated cells ○, DMSO 1 5%, no interferon, ×, DMSO 1 5%, 900 U ml^{-1} mouse interferon *b*, Lack of effect of interferon on haemoglobin synthesis The % of benzidine-positive cells is plotted ○, DMSO 1 5%, no interferon, ×, DMSO 1 5%, 900 U ml^{-1} mouse interferon.

virus (LLV) LLV acts as a helper in spleen focus formation This cell line can therefore be used to study the effect of exogenous homologous (mouse) interferon on the release of C-type viruses and on the induction of erythroid differentiation (haemoglobin synthesis)

Interferon inhibits tumour formation by RNA tumour viruses[8,9] In some instances, however, interferon can be used to enhance neoplastic development[10] Interferon also interferes with the transformation of fibroblasts by sarcoma viruses[11] Mice with Friend erythroleukaemia have been reported to display a reduced capacity to respond to inducers of interferon[12 13] No interferon could be detected in the supernatants of FSD1/F4 cells or two other lines of SFFV-transformed cells when proliferation was either in the absence or presence of dimethylsulphoxide (DMSO), indicating that FV does not trigger the interferon response in these cells Although interferon production can be induced in these cells by an exogenous viral inducer (Newcastle disease virus) no response to poly(I) poly(C) (ref 12) was observed (P S and W O, unpublished) Similar observations on differential inducibility of interferon in transformed mouse cells were made by others (F Ruddle, unpublished)

The effect of interferon on FV release in unstimulated cells was demonstrated by the addition of 300–900 mouse reference research standard units (U) interferon ml^{-1} to cell clone FSD1/F4 We find a more than 100-fold reduction both of spleen focus formation with cellular supernatants and of uridine label in C-type particles (Fig 1*a*, *b*) Heterologous chicken interferon does not reduce the virus yield (Fig 1*b*) The recovery of virus production after interferon treatment for 5 d and then the omission of interferon is slow and possibly incomplete Five days after the omission of interferon only 10% of the normal virus level is obtained (Fig 1*c*) The growth rate of the interferon treated cells was only slightly reduced

When FSD1/F4 cells are exposed to growth medium which contains 1–1 5% DMSO, not only the onset of erythroid differentiation but also a 5–10-fold increase in released virus particles during the first and second day of differentiation can be observed The titre of released virus increases 10–100-fold as assayed either by the XC-test (LLV) or by the spleen focus forming test (LLV+SFFV)[7] Interferon, however, depresses the virus synthesis below background level (Fig 2*a*) Differentiation as measured by globin synthesis is only slightly inhibited by 300–900 U ml^{-1} interferon If interferon is added 3 d before the onset of DMSO induced differentiation, perfectly normal differentiation is observed The course of differentiation, that is the number of benzidine positive cells after adding DMSO or DMSO and interferon, remains unchanged (Fig 2*b*) The amount of globin synthesised after 4 d stimulation with DMSO is not reduced by adding 300–900 U ml^{-1} interferon (Fig 3)

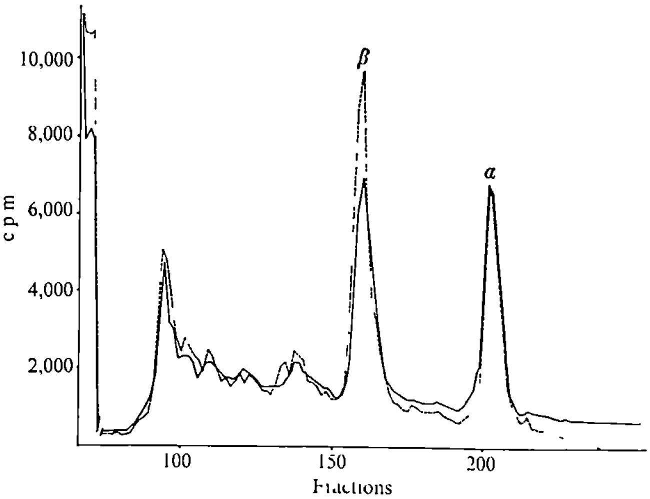

Fig 3 Stimulation of globin synthesis with 1 5% DMSO, Effect of interferon Cells were pretreated with interferon 900 U ml^{-1} for 3 d DMSO (1 5%) was then added and incubation with DMSO+interferon continued for another 4 d Medium was replaced daily Cells were labelled with ^{3}H- or ^{14}C-leucine in leucine-free medium for 16 h Extraction of NP40 soluble cytoplasmic proteins and separation of globin chains on carboxy methylcellulose columns was done as described previously[6] ----, DMSO 1 5% no interferon, ^{14}C-leucine, ——, DMSO 1 5% 900 U ml^{-1} mouse interferon, ^{3}H-leucine

As the degree of purity of interferon often reflects on the meaningfulness of results we confirmed our data obtained with partially purified interferon (1 5×10^{5} U mg^{-1} protein), by using a highly purified interferon preparation (10^{7} U mg^{-1} protein) We found that within our limits the degree of purity had no effect on the interferon action

The data above make possible, for the first time, the differentiation between the effect of exogenous interferon on C-type virus release in transformed cells and the effect on induced differentiated cellular functions in the same cell While virus synthesis is strongly inhibited, differentiation remains unaffected Interferon neither changes the time course nor the amount of haemoglobin synthesis It does not change the number of cells involved in haemoglobin synthesis either We conclude that the release of Friend virus is not required for *in vitro* erythroid differentiation of these cells

We thank Mrs H Wocelka, A Rohmann, B Neu and Miss W Domenig for assistance The work was supported in part by a grant of the Deutsche Forschungsgemeinschaft We thank Dr Bodo for supplying some of the interferon

Erythropoietin responsiveness of differentiating Friend leukaemia cells

INCLUSION of dimethylsulphoxide (DMSO) in the media of suspension cultures of Friend leukaemia cells (FLC) results in the erythroid differentiation of more than 50% of the cells[1] This differentiation is demonstrated by morphological and biochemical alterations which are characteristic of normal erythroid maturation[2-5] We report here that the differentiation of these leukaemic cells is accompanied by the development of responsiveness to erythropoietin (Ep), the physiological regulator of erythropoiesis

Friend leukaemia cells (clone 745A) were grown in suspension culture in media consisting of basal Eagle's medium with Earl's balanced salts (GIBCO), made 15% with foetal calf serum (GIBCO) at 37° C in a humidified atmosphere of 5% CO_2 and 95% room air The cultures were passaged at 3 or 4 d intervals at a seeding concentration of 1×10^5 cells ml^{-1} DMSO (Fisher Sci) was added (2% v/v) where appropriate at the time of seeding the cultures Erythropoietin (human urinary erythropoietin 75 4 IU mg^{-1}) was added to the suspension cultures at the times indicated

To assess the rate of haem synthesis, 0 5 μCi of mouse transferrin-bound ^{59}Fe was added to culture plates containing 3 ml of the suspension culture and after 4 h further incubation the cells were collected, washed twice with isotonic saline and the haem extracted with cyclohexanone according to the method of Krantz[6], and counted This procedure provides an accurate assessment of the rate of haem synthesis by Friend leukemia cells[7] We have already shown that during DMSO-induced differentiation of Friend erythroleukaemia cells, increased iron incorporation into haem was coordinated with increases in the rate of synthesis of globin, haemoglobin, and globin mRNA[8] To assess the rates of DNA, RNA and protein synthesis, 5 μCi of ^{3}H-thymidine, ^{3}H-uridine or ^{3}H-leucine (New England Nuclear Co) were added to appropriate culture plates containing 4 ml of suspension cell and after 40 min of incubation the cells were collected, washed twice, and the rate of precursor incorporation determined according to the method of Schneider as discussed by Shatkin[9] All radioactive assays were determined using three plates for each experimental point and each experiment was carried out at least three times

Ep was added to suspension cultures of erythroleukaemia cells which had previously been grown in the presence of DMSO for 3 d (Table 1) This significantly stimulated the rate of haem synthesis of the cells Ep had no significant effect on the rate of increase in cell numbers in the culture (which increased from 0 95±0 03×10^6 cells ml^{-1} on day 3 to 1 24±0 04×10^6 cells ml^{-1} on day 4) nor did it result in an increase in the proportion of benzidine-positive cells in the culture Ep had no effect on the rate of haem synthesis by cells which had not been cultured in the presence of DMSO (Table 2)

The stimulatory effect of Ep on DMSO-treated cells was not limited to haem synthesis The effects of Ep on the rate of precursor incorporation into DNA, RNA and protein are given in Table 2 The increases in leucine and uridine incorporation were quantitatively similar to that observed for ^{59}Fe, the rate of DNA synthesis also increased These effects of Ep on the rates of macromolecular synthesis by these differentiating leukaemic cells were similar to those reported for normal rat bone marrow cells[10] and foetal liver erythroid cells[11] Although Ep had no effect on the rates of haem, RNA or protein synthesis by cells which had not been cultured in the presence of DMSO, the addition of Ep to suspension cultures of these cells resulted in a decrease in the rate of thymidine incorporation into DNA

During cell growth and replication, Ep responsiveness could be reliably detected when Ep was added on the third day of culture and haem synthesis assayed 1 d later The addition of Ep earlier during culture with assay of haem synthesis 24 h after addition produced no significant effect The addition of Ep to cultures which had been growing in the presence of DMSO for more than 3 d also resulted in an increase in the rate of haem synthesis By contrast, cultures to which Ep was added at the time of seeding in the presence of DMSO synthesised less haem on the fourth day of culture than cultures also seeded in the presence of DMSO but to which Ep was not added In six such experiments the rate of haem synthesis (mean c p m per plate ± s e for 17 degrees of freedom) was 16±4 8% less than cultures seeded without Ep

Table 1 Effect of Ep on erythroleukaemic cells grown in DMSO medium

Parameter	Mean % stimulation ± s e m	No experiments
(1) Haem synthesis		
a CPM-^{59}Fe per plate	+29 ± 4 6	29
b CPM-^{59}Fe per 10^6 cells	+29 ± 4 1	29
(2) Cell number	+3 ± 2 4	29
(3) % Benzidine-positive cells	+6 ± 4 7	20

Tissue culture plates were set up containing 4 ml of suspension culture which was made 2% (v/v) with DMSO at the time of seeding After 3 d of culture Ep (0 06 IU ml^{-1}) was added to appropriate plates and 24 h later, after removal of 1 ml from each plate for cell counts and morphological studies, ^{59}Fe was added and 4 h later the haem extracted For morphological studies, slides were made with a cytocentrifuge, were benzidine stained[13], and counterstained with Wright-Giemsa The proportion of benzidine-positive cells was determined by a single observer in a single-blinded position The following equation was used to determine % stimulation of each parameter

$$\frac{(\text{Parameter Ep culture}) - (\text{Parameter no Ep culture}) \times 100}{(\text{Parameter no Ep culture})}$$

The % stimulation was determined for each individual experiment and the data so derived pooled and used to calculate the grant mean and s e m for each parameter

Ep was an effective stimulant of haem synthesis within a broad range of concentrations A comparison of the stimulatory effects of 0 04 IU ml^{-1} and 0 2 IU ml^{-1} on the rate of haem synthesis revealed no significant difference (34 5±6 4% stimulation for 0 04 IU ml^{-1} compared with 44±6 6% stimulation for 0 2 IU ml^{-1})

We have tested three different human urinary Ep and three different Step III sheep plasma Ep and have found no significant differences in their effects

In a preliminary communication we reported that Ep stimulated the rate of haem synthesis by Friend leukaemia cells which had previously been cultured in the presence of DMSO[12] In those studies, however, the condition of culture were such that the cells were not replicating and the rate of haem synthesis in all the cultures was declining The studies reported here demonstrate that under conditions of growth the erythroid differentiation of these leukaemic cells is accompanied by the development of responsiveness to Ep It is the process of differentiation *per se* and not the penetrant carrier properties of DMSO, that is responsible for the responsiveness to Ep, since Ep stimulated the rate of haem synthesis when the differentiating cells had been transferred to fresh medium before adding Ep[12] It is of interest in this regard that under the conditions of culture reported here, the appearance of responsiveness to Ep correlated with a major increase in the proportion of recognisable differentiating cells in the culture (the percentage of benzidine-positive cells on days 1 and 2 of culture were 1% and 5%, whereas on the third day it was 50%) This suggests that under these conditions Ep affects cells which have differentiated to the point of having synthesised enough haem to be recognisable by benzidine staining The effects of Ep on normal erythroid precursor cells which are more differentiated than the committed erythroid stem cell have been reported by others[13-15] The apparent inhibitory effects of Ep on DNA synthesis by control cells and on the rate of haem synthesis by DMSO-treated cells when Ep was added at the time of seeding was unexpected and may have been due to other substances present in the preparation of human urinary Ep The resolution of this question awaits the availability of pure Ep

Table 2 Effects of Ep on synthesis of DNA, RNA and protein

Macromolecule	Ep	DMSO-containing cultures Mean c p m per 10^6 cells ± s e	Control cultures Mean c p m per 10^6 cells ± s e
(*a*) DNA	0	6,073 ± 1182	3,928 ± 158
	+	7,474 ± 161	1,501 ± 34
(*b*) RNA	0	1,737 ± 145	5,018 ± 254
	+	2,556 ± 174	5,381 ± 137
(*c*) Protein	0	4,408 ± 84	15,687 ± 310
	+	6,653 ± 557	15,553 ± 428
(*d*) Haem	0	1,169 ± 128	7
	+	1,796 ± 103	7

Suspension cultures were set up in bottles containing 40 ml each After 3 d of culture Ep was added to appropriate bottles (0 06 IU ml^{-1}) and after 24 h of additional culture, the suspension cultures were distributed into triplicate plates for determination of the rate of macromolecular synthesis The differences between the rates of macromolecular synthesis between Ep and non-Ep containing cultures were statistically significant (P < 0 05) for all of the DMSO-containing cultures and for the decrease in the rate of DNA synthesis of the control cultures

All determinations were done in triplicate

These observations suggest that erythroleukaemic cells, and perhaps leukaemic cells in general, possess the genetic information needed for the development of responsiveness to normal physiological regulators and that under appropriate conditions this information is expressed Responsiveness to Ep by a continuous suspension culture cell line promises of facilitate studies of the mechanism of action of this hormone

Growth of rust fungi of wheat and flax on chemically-defined media

THE rust fungi cause serious economic losses of wheat and other crops In nature, these organisms complete their life cycles only on living tissues of their hosts and, until recently[1], they have been regarded as obligate parasites due to their failure to grow in axenic culture on non-living substrates We have now obtained highly reproducible vegetative growth and sporulation of the flax rust fungus, *Melampsora lini* (Ehrenb) Lév (race 3) and vegetative growth of two North American races (15B-4 and 56) of the wheat stem rust fungus, *Puccinia graminis* f sp *tritici* (Eriks and Henn) on chemically defined liquid media, sterilised by millipore filtration and seeded with uncontaminated uredospores Vegetative growth and some sporulation were also obtained with an Australian isolate of wheat rust, race 126-ANZ 6, 7

Williams *et al*[2] reported the first successful establishment of axenic colonies of the wheat stem rust fungus, race 126-ANZ 6,7, starting with uncontaminated uredospores seeded on to an agar medium containing glucose, mineral salts, Evans's peptone and yeast extract Subsequently much progress has been made in the axenic culture of a number of rust fungi belonging to the *Pucciniaceae*[4-7] and *Melampsoraceae*[8-10] Nevertheless the results obtained suffer from a number of defects Most experimenters have employed agar media containing complex organic substances like peptone yeast extract and bovine serum albumin Only a few attempts[11-13] have been made to grow rusts on chemically defined media containing amino acids and growth on such media has not been equivalent to that obtained in the presence of peptone, yeast extract or bovine serum albumin Moreover, all the results reported thus far indicate that sporulation in axenic culture is erratic, and there are only two reports in which uredospores produced in axenic culture have been shown to be capable of reinfecting the host[3,6] Finally, the use of agar based media, sterilised by autoclaving, is itself a disadvantage, since the exact composition of the sterilised medium is not known Our objectives were to develop chemically defined media (see Table 1 legend) in order to examine the factors controlling sporulation and to compare the amino acid requirements of the wheat and flax rust fungi

Uncontaminated uredospores of both rusts were raised on susceptible hosts as described elsewhere[14] All media were sterilised, after the addition of amino acids, glutamine and glutathione as indicated in Table 1, by millipore filtration (pore size 0 22 μm) No agar was employed The pH of all media was adjusted to 5 0 Uredospores (1,000–2,000 mm^{-2}) were floated on the liquid surface (10 ml) in 50 ml flasks For each treatment five replicate flasks were incubated without shaking at 17° C in the dark The growth and development of the rust colonies were observed over a period of two months

The chief results are summarised in Table 1 Luxuriant growth of *M lini* was obtained on medium A with 45 mM aspartic or glutamic acid, plus cysteine (4 6 mM) and reduced glutathione (3 3 mM), or with 45 mM aspartic or glutamic

Table 1 Comparative behaviour of flax and wheat stem rust fungi *in vitro*

Fungus	Medium	Organic nitrogen source (mM) Aspartic acid*	Glutamine	Cysteine	Glutathione	Growth	Sporulation
Melampsora lini Race 3	A	45	0	4.6	3.3	Luxuriant	Frequent
	A	45	0	4.6 (or 2.3)	0	Luxuriant	Frequent
	A	0	42	4.6	0	Luxuriant	Nil
Puccinia graminis tritici Race 126-ANZ 6, 7	B	45	0	4.6	3.3	Luxuriant	Infrequent
	C	45	0	4.6 (or 2.3)	0	Luxuriant	Infrequent
	C	0	42	4.6	0	Luxuriant	Nil
	C	0	6	4.6	0	Poor	Nil
Race 15B-4 and Race 56	B	45	0	4.6	3.3	Nil	Nil
	C	45	0	4.6 (or 2.3)	0	Nil	Nil
	C	0	42	4.6	0	Luxuriant	Nil
	C	22.5	21	4.6	0	Luxuriant	Nil
	C	0	42 (Asp 45)	4.6	0	Luxuriant	Nil

*Aspartic acid can be replaced by equimolar glutamic acid with identical results. Asp 45 denotes that after 3 weeks' growth 42 mM glutamine was replaced by 45 mM aspartic acid. Basic components of media (l^{-1}): medium A: Sucrose, 50 g; $Ca(NO_3)_2 \cdot 4H_2O$, 2.0 g; KNO_3, 0.25 g; $MgSO_4 \cdot 7H_2O$, 0.25 g; KH_2PO_4, 0.25 g; K_2HPO_4, 0.75 g; NH_4NO_3, 20 mg; 0.8 ml micronutrient solution (containing 13% NaFe (Geigy), 10 g; $MnSO_4 \cdot 7H_2O$, 447 mg; KI, 10 mg; $NiCl_2 \cdot 6H_2O$, 18 mg; $Ti(SO_4)_2 \cdot 9H_2O$, 42 mg; $ZnSO_4$, 35 mg; $CuSO_4 \cdot 5H_2O$, 15 mg; $BeSO_4$, 20 mg; H_3PO_4 (85%), 10 mg; H_2SO_4 (concentrated), 0.2 ml; all in 200 ml glass distilled water). Medium B: glucose, 30 g; $NaNO_3$, 2.0 g; KCl, 0.5 g; $MgSO_4 \cdot 7H_2O$, 0.5 g; KH_2PO_4, 1.0 g; $Ca(NO_3)_2 \cdot 4H_2O$, 2 to 6 g; $FeSO_4 \cdot 7H_2O$, 10 mg, plus 0.8 ml micronutrient solution as in Medium A. Medium C: Major components as in Medium B, plus sodium citrate, 1.5 g; no micronutrients.

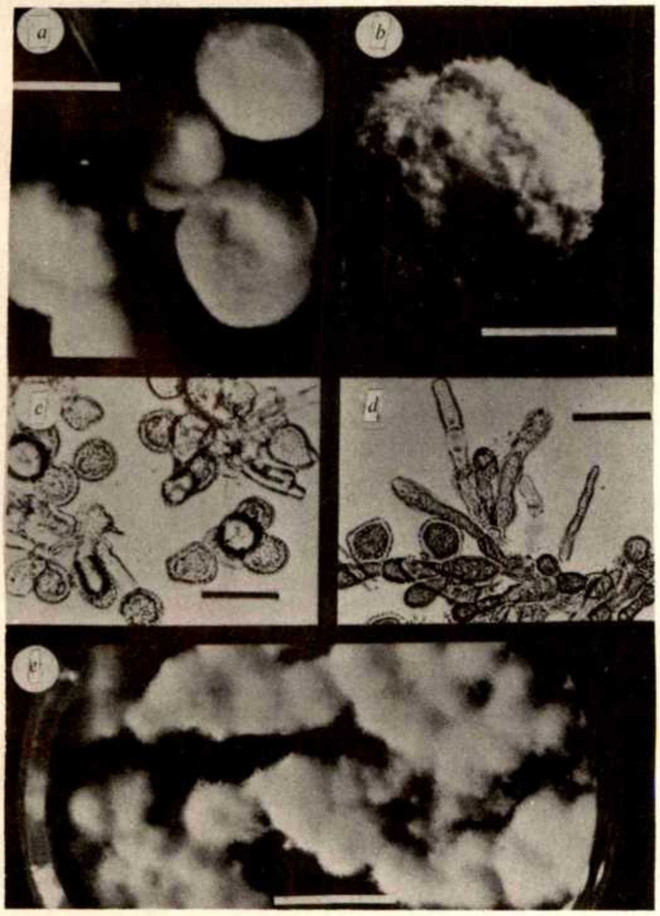

Fig. 1 Growth and development of *M. lini* (race 3) on liquid medium A (inorganic salts, sucrose, aspartic acid and cysteine). *a*, Fully developed vegetative colonies (1 month old) on liquid surface (scale bar, 0.5 cm); *b*, sporulating colony, 6 week old. The entire colony has developed into a uredosorus (scale bar, 0.5 cm); *c*, Uredospores (oblong cells) from colony like that in *b* (scale bar, 50 μm); *d*, teliospores from 2 month old colony (scale bar 50 μm); *e*, 1 month old vegetative colonies of *P. graminis* (race 15B-4) on liquid medium C (inorganic salts, glucose, glutamine and cysteine) (scale bar, 1 cm).

acid plus cysteine (2.3 or 4.6 mM). Sixty to seventy vegetative colonies per flask developed in 90–100% of the flasks within 4 weeks (primary axenic colonies). Two weeks later typical orange uredopustules were formed on the surfaces of most colonies (Fig. 1*a* and *b*) and dark brown teliosori appeared on some of them after 8 weeks growth. The uredospores and teliospores and their supporting hyphae were apparently closely similar to those found in nature (Fig. 1*c* and *d*). When uredospores produced *in vitro* were used to inoculate intact week-old flax cotyledons, infection and development of sporulating pustules occurred in a normal manner. When seeded on fresh medium, flax rust uredospores developed *in vitro* grew into secondary axenic colonies. These developed and sporulated in a manner indistinguishable from the primary axenic colonies. Uredospores from the secondary colonies also reinfected intact flax cotyledons. Decreases in the levels of aspartic or glutamic acid (22.5 mM) and cysteine (2.3 mM) resulted in poor growth and a low frequency of initiation of colonies, which failed to sporulate; glutathione was not essential for growth or sporulation. Replacement of aspartic acid with a high level of glutamine (42 mM) gave a high rate of colony initiation and excellent vegetative growth. These colonies were white and fluffy and had a yellowish stroma on the under surface, but did not sporulate and finally died.

An Australian isolate of *P. graminis tritici*, race 126-ANZ 6,7, developed large colonies on medium B plus high levels of aspartic acid (45 mM), cysteine (4.6 mM) and glutathione (3.3 mM); small areas of uredospores and teliospores developed on a few colonies in about 50% of the inoculated flasks. When uredospores formed by these colonies were placed on exposed mesophyll tissue they produced typical infections of seedling leaves of wheat[14]. Identical results were obtained on medium C plus 45 mM aspartic acid and 4.6 mM cysteine, so that glutathione and micronutrients were evidently not essential for growth. Of the three races of wheat stem rust, 126-ANZ 6,7 therefore most closely resembles race 3 of *M. lini* in its requirement for amino acids. Two North American isolates, races 15B-4 and 56, behaved in an entirely different manner and completely failed to grow on these media (Table 1).

Races 126-ANZ 6,7, 15B-4 and 56 all formed large vegetative colonies on medium C plus high levels of glutamine (42 mM) and cysteine (4.6 mM), but no sporulation occurred. Races 15B-4 and 56 also formed luxuriant vegetative colonies but did not sporulate on medium C plus aspartic acid, glutamine and cysteine (Fig. 1*e* and

Table 1). When glutamine was replaced with aspartic acid after 3 weeks' growth, vegetative growth continued and the stromata of individual colonies merged with each other, but there was no sporulation. Apparently aspartic acid will support vegetative growth of the wheat rust once it has started, but will not serve as a source of amino nitrogen for the initiation of colonies.

These results show that chemically-defined media can support luxuriant growth of wheat rust and both growth and sporulation of flax rust without the addition of complex organic substances like peptone or yeast extract. Further work will be required to discover the key to control of sporulation by the wheat rust fungus.

Anti-receptor antibody and resistance to graft-*versus*-host disease

GRAFT-*versus*-host (G*v*H) disease is a complex syndrome initiated by the reaction of donor lymphoid cells against histocompatibility antigens of the host. Although newborn hybrid animals injected with parental-strain lymphoid cells develop fatal G*v*H disease, adult hybrid animals receiving weight-adjusted doses of such cells develop no clinically evident disease[1,2]. This resistance to G*v*H disease is age-dependent and radiosensitive; resistance develops at 3–4 weeks of age and is abolished by sublethal total-body irradiation[1]. Immunologically specific suppression of G*v*H reactions has been achieved by immunisation of F_1 hybrid host to produce antibody reactive with receptors on donor lymphoid cells for host antigens[3,4].

The G*v*H reactivity of lymphoid cells from the appropriate parental strain was suppressed in F_1 hybrids producing such anti-receptor antibody (ARA)[3,4]. This finding led to the suggestion that ARA could suppress G*v*H reactivity by blocking receptors on aggressor lymphocytes. We have investigated whether the natural resistance of adult F_1 hybrids to G*v*H disease is associated with the production of ARA. We found ARA in rats not developing the disease, while those rendered susceptible to G*v*H by irradiation did not produce ARA.

The radiosensitivity of the processes responsible for the resistance of adult rats to fatal G*v*H disease was confirmed as follows: groups of five adult female Lewis×Brown Norway (LBN) F_1 hybrid rats each either received 400 rad of total-body X irradiation or were left untreated. Twenty-four hours later each group received from 2.7×10^6 to 2×10^8 normal adult female Lewis spleen cells intravenously. Animals were weighed three times weekly and deaths were recorded daily (Fig. 1). All non-irradiated animals receiving Lewis spleen cells survived; none lost weight or had clinically evident disease. All irradiated hybrid rats, however, receiving more than 10^7 Lewis spleen cells died. Weight loss of up to 30% initial body weight preceded death. Control animals receiving 400 rad only had no clinical ill effects. Thus, non-irradiated LBN rats were resistant to fatal G*v*H disease when injected with 100 times more Lewis cells than were required to induce significant and often fatal G*v*H disease in those LBN rats pretreated with 400 rad of X irradiation.

Similar results were obtained when spleen cells from the Brown Norway parental strain were injected in analogous experiments. All unirradiated LBN rats receiving BN spleen cells in doses as high as 2×10^8 survived. All irradiated rats receiving more than 1×10^7 BN spleen cells died of G*v*H disease.

Sera from irradiated and nonirradiated adult hybrid rats receiving parental-strain spleen cells were assayed for ARA by two methods. One method involves a complicated bioassay in which ARA inhibits the formation of a chemotactic factor (product of antigen recognition or PAR) generated when parental-strain lymphoid cells are cultured briefly with hybrid lymphoid cells[5]. The other method involves measurement of the interaction between the specific alloantibody used for immunisation and serum from the immunised hybrid animal[3,6]. Such interaction can be detected by precipitin reactions in gel[3]. In a more sensitive assay, anti-receptor antibody can be detected and quantified by agglutination of sheep erythrocytes to which specific alloantibody has been coupled. ARA produced by immunisation of hybrid rats with alloantiserum and ARA produced by immunisation with parental-strain spleen cells have similar reactivity in all these assays.

To determine whether production of ARA correlated with the resistance of LBN animals to G*v*H disease, samples of serum were obtained from adult female LBN rats that had been injected with normal Lewis spleen cells. Groups of five LBN F_1 hybrid rats were given 400 rad of total-body X irradiation or were left untreated. Twenty-four hours later, 5×10^7 or 1×10^7 Lewis spleen

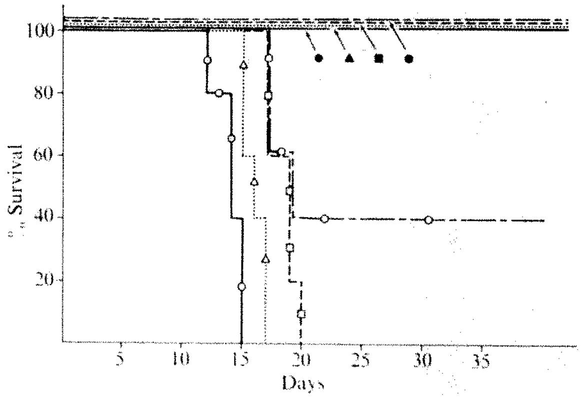

Fig. 1 Survival of adult female LBN F_1 rats after intravenous injection of normal adult female Lewis spleen cells. Groups of 5 F_1 rats each either received 400 rad of total body × radiation (open symbols) or were not irradiated (closed symbols). Twenty-four hours later, the rats were injected intravenously with either 2×10^8 (○ or ●), 5×10^7 (△ or ▲), 1.2×10^7 (□ or ■) or 2.8×10^6 (open and solid hexagons) normal Lewis spleen cells. No F_1 rats receiving 400 rad only (not shown) died.

	0	0	0	Dead		

* Reciprocal of the highest serum dilution which causes agglutination of sheep erythrocytes coated with the IgG fraction of Lewis anti-BN serum

† These sera failed to agglutinate SRBCs coated with IgG fractions of Lewis anti-DA serum, Fischer anti-BN serum or BN anti-Lewis serum

cells were injected intravenously and serum samples were obtained at weekly intervals A haemagglutinin assay, involving sheep erythrocytes to which IgG antibody was coupled, was used to measure anti-receptor antibody Lewis anti-BN antibody was purified by ammonium sulphate precipitation and elution from diethylaminoethyl-cellulose with 0 04 M phosphate buffer, *p*H 8 0 After dialysis against saline, the IgG antibody was coupled to sheep erythrocytes by means of chromic chloride[7] Serial dilutions of serum were incubated with sensitised erythrocytes for at least 3 h and the settling pattern was observed (Table 1) Serum samples were also titered with normal sheep erythrocytes, and with sheep erythrocytes to which normal Lewis IgG, Lewis anti-DA IgG, or BN anti-Lewis IgG had been coupled

As observed previously, all irradiated hybrid rats receiving 5 × 10^7 Lewis spleen cells and four or five irradiated rats receiving 1 × 10^7 Lewis spleen cells were dead within four weeks after cell injection ARA could not be detected in any serum sample from the irradiated rats None of the nonirradiated hybrid rats receiving Lewis spleen cells developed G*v*H disease By 4 weeks after injection, 9 of 10 nonirradiated hybrid rats receiving Lewis spleen cells had measurable serum ARA This antibody activity was first noted 3 weeks after injection and in most animals was no longer detectable 3 weeks later The specificity of the ARA reactivity is indicated by the failure of serum samples obtained at 28 d to agglutinate erythrocytes coated with Lewis anti-DA IgG or with BN anti-Lewis IgG The following observations indicate that ARA detected in the serum of hybrid rats receiving parental-strain lymphoid cells is an anti-idiotypic antibody and not a soluble complex of anti-BN antibody and BN antigen formed in antigen excess Such a complex would be expected to agglutinate sheep erythrocytes coated with anti-BN antibody of any idiotype, whereas anti-idiotypic antibody would agglutinate only erythrocytes coated with anti-BN antibody of the appropriate idiotype Fischer anti-BN and Lewis anti-BN IgG fractions possessing equivalent titres of anti-BN haemagglutinin antibody were used to coat sheep erythrocytes The two preparations of coated erythrocytes agglutinated to the same extent with a rabbit anti-rat immunoglobulin serum Serum from hybrid rats obtained 28 d after injection of Lewis spleen cells agglutinated Lewis anti-BN coated cells (Table 1), but did not agglutinate erythrocytes coated with Fischer anti-BN antibody This pattern of agglutination indicates the anti-idiotypic nature of ARA

Thus, ARA is detected in the serum of hybrid rats that do not develop G*v*H disease Irradiation renders hybrid rats susceptible to fatal G*v*H disease, irradiated rats do not produce detectable amounts of ARA Production of ARA may be a part of the radiosensitive process by which hybrid animals resist fatal G*v*H disease If ARA plays such a protective role, lymphoid cells from hybrid rats producing ARA should enable irradiated hybrids to resist fatal G*v*H disease To test this hypothesis, we gave LBN rats 400 rad of total-body X radiation Twenty-four hours later, they received one of the following 10^7 Lewis spleen cells, 10^7 Lewis spleen cells plus 5 × 10^7 normal LBN spleen cells, or 10^7 Lewis spleen cells plus 5 × 10^7 spleen cells from LBN rats that had previously received two injections of Lewis spleen cells All the previously injected LBN rats had ARA in their serum when their spleen cells were taken Irradiated LBN rats given spleen cells from the LBN rats that had resisted fatal G*v*H disease were protected from the lethal effects of injection of parental spleen cells (Fig 2) Normal LBN spleen cells were somewhat less effective in conferring protection to irradiated hybrid rats

Thymus-derived (T) lymphocytes must be present in the responder population[8] to produce G*v*H reactions Recent evidence obtained from G*v*H reactions *in vivo*[9] and mixed lymphocyte cultures *in vitro*[10] indicates that genetic disparity at one or more lymphocyte-defined (LD) loci closely linked to the serologically defined (SD) major histocompatibility complex is essential for a strong proliferative response The generation of cytotoxic effector cells appears to require in addition a disparity at one or more of the SD loci Cyto-

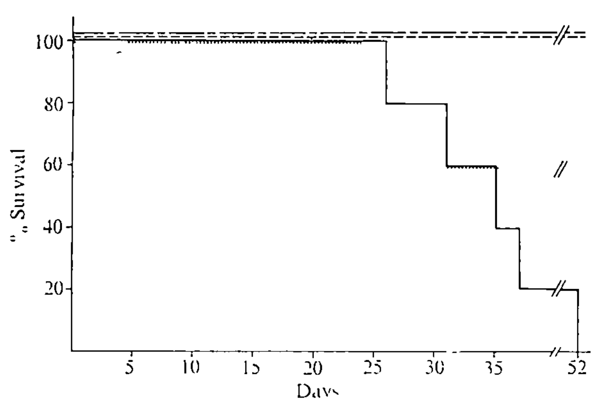

Fig 2 Protection of irradiated LBN F_1 rats from lethal G*v*H disease by adaptive transfer of F_1 spleen cells Irradiated LBN rats receiving 1 × 10^7 normal Lewis spleen cells only (———) all died of G*v*H disease Irradiated LBN rats receiving 1 × 10^7 normal Lewis spleen cells and 5 × 10^7 spleen cells from F_1 rats resistant to G*v*H disease (— — —) suffered no mortality or weight loss The group of irradiated LBN rats receiving 1 × 10^7 normal Lewis spleen cells and 5 × 10^7 normal LBN spleen cells (-------) had an intermediate mortality LBN rats receiving 400 rad of X radiation only (—— ——) all survived No additional mortality occurred in any group during the interval of 52–120 d

toxic effector cells, like the cells responsive to the LD loci, are believed to be T lymphocytes[11]

The generation of effector cells in culture requires DNA synthesis[12] Cultures treated so as to eliminate cells that have undergone DNA synthesis do not yield cytotoxic effector cells[13] Since treatment to eliminate cells that had undergone DNA synthesis could be delayed until placing the cells into the effector cell assay, the cytotoxic effector cells must have replicated during the sensitisation process Thus it seems that proliferation of both LD responsive and SD responsive lymphocytes is required for full cytotoxic expression

Several groups have suggested a model of cellular cooperation involving two populations of T lymphocytes to explain the apparent requirement for both LD and SD responsive T cells Hayry and Andersson[14] suggest that the effector cell responsive to SD antigen requires cooperative interactions of an LD responsive T lymphocyte (and perhaps an adherent cell as well) before it can divide and cause significant target cell lysis

Local GvH reactions may involve predominantly the recognition and proliferative phases of the immune response The syndrome of GvH disease, however, probably includes an additional component of cell-mediated injury initiated by effector lymphocytes[8] If such effector lymphocytes react with the SD antigens of the host through an immunologically specific receptor molecule, then blockade of that receptor may lead to a blunting or inhibition of the killer cell potential of these lymphocytes One immunologically specific receptor molecule able selectively to bind SD antigen is antibody We suggest that the anti-idiotypic antibody demonstrable in the serum of F_1 hybrid rats after injection of parental strain cells may function by blocking or eliminating those parental lymphoid cells which display receptors for the serologically defined histocompatibility antigens of the host

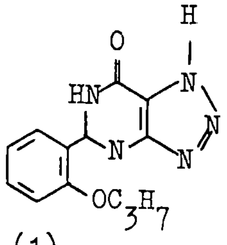
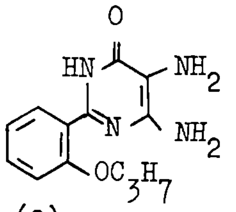
New inhibitor of reagin-mediated anaphylaxis

Methylxanthines, such as theophylline and caffeine, inhibit the antigen-induced release of histamine and of slow reacting substance of anaphylaxis (SRS-A) from passively sensitised human lung and human basophilic leukocytes[1,2] We have shown that these methylxanthines also inhibit a passive cutaneous anaphylactic (PCA) reaction mediated by reaginic antibodies in the rat The methylxanthines are, however, from 20 to 50 times less potent than disodium cromoglycate Because of the relatively low potency of theophylline and because of its other pharmacological actions, notably as a bronchodilator, it is not clear to what extent inhibition of reagin-mediated anaphylaxis may be important in its use for the treatment of allergic bronchial asthma

By progressive modification of the chemical structure of methylxanthines, we have found that certain 2-phenyl-8-azapurin-6-ones[3] possess high and selective anti-allergic activity In particular, 2-*o*-propoxyphenyl-8-azapurin-6-one, M&B 22,948 (1), is from 20 to 50 times more potent than disodium cromoglycate in inhibiting reagin-mediated anaphylaxis in a number of test systems and is also active by oral administration



(1)



(2)

2-*o*-Propoxyphenyl-8-azapurin-6-one is a white crystalline solid, melting point 241° C (decomp) It is less than 0 1 % w/v soluble in water but readily forms salts, for example the triethanolamine salt has a melting point of 138–139° C The azapurinone was prepared by nitrous acid treatment of the diamine (2) which itself was prepared from *o*-propoxybenzamidine by conventional methods

M&B 22,948 has been compared with disodium cromoglycate in three experimental models involving reagin-mediated anaphylaxis These were first, the inhibition of the allergen induced release of histamine and SRS-A from passively sensitised human lung *in vitro*[4], second, the inhibition of a reagin-mediated PCA reaction in the rat[5] and third, the inhibition of reagin-mediated anaphylactic bronchospasm in the guinea pig In experiments involving aqueous solutions, M&B 22,948 was used as its triethanolamine salt Doses refer to the parent azapurinone

M&B 22,948 was more potent than disodium cromoglycate in inhibiting the anaphylactic release of both histamine and SRS-A from human lung tissue (Fig 1) The effective concentration range for each drug was fairly narrow The optimum concentration for inhibition of mediator release determined in at least seven separate experiments was in the range of 1–3 μg ml^{-1} for M&B 22,948 and 30–100 μg ml^{-1} for disodium cromoglycate

The intravenous dose of M&B 22,948 causing 100% inhibition of the rat PCA reaction was from 35–50 times less than that of disodium cromoglycate Thus, complete inhibition of the rat PCA reaction was consistently obtained with intravenous doses

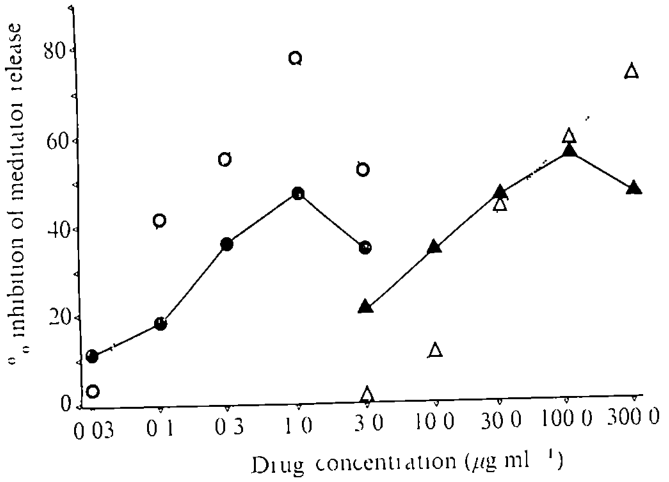


Fig 1 Inhibition of allergen-induced release of histamine and SRS-A from passively sensitised human lung tissue by M&B 22,948 and disodium cromoglycate in two separate experiments Using M&B 22,948 ●, histamine, ○, SRS-A Using disodium cromoglycate ▲, histamine, △, SRS-A Chopped human lung was incubated for 18 h with serum from asthmatic subjects Aliquots were challenged with extracts of *Dermatophagoides farinae* (500 µg ml⁻¹) immediately after the addition of graded concentrations of the test compounds Histamine was assayed fluorometrically SRS-A was assayed on the mepyraminised guinea pig ileum Points refer to single determinations from three pooled samples at each drug concentration

of 0 1 mg kg⁻¹ of M&B 22,948 and 2–5 mg kg⁻¹ of disodium cromoglycate Intravenous theophylline had approximately one-fiftieth the potency of disodium cromoglycate

When administered orally to rats 15 min before allergen challenge, M&B 22,948 was effective in inhibiting the PCA reaction The dose response curve was 'bell shaped' (Fig 2) and complete inhibition of the PCA reaction was rarely obtained Maximal inhibition was obtained with oral doses of between 0 5–2 0 mg kg⁻¹ Disodium cromoglycate showed poor to negligible activity, an oral dose of 500 mg kg⁻¹ produced less than 30% inhibition when administered either 15 or 40 min before allergen challenge Theophylline showed some oral activity with 80% inhibition of the PCA reaction occurring with a dose of 100 mg kg⁻¹

Anaphylactic bronchospasm was produced in the guinea pig passively, systemically sensitised with *Trichinella spiralis* antiserum and premedicated with propranolol (5 mg kg⁻¹, intraperitoneally) The mean preconvulsion time of groups of a minimum of six sensitised guinea pigs exposed to an aerosol of allergen was increased by 19%, 50% and 69% following intravenous doses of 5, 10 and 20 mg kg⁻¹ of M&B 22,948 (Table 1) Disodium cromoglycate (100 mg kg⁻¹ intravenously) produced a protection comparable to that of 10 mg kg⁻¹ of intravenous M&B 22,948 An oral dose of 200 mg kg⁻¹ M&B 22,948 produced a significant protective action Maximum protection was afforded when the animals were challenged 15 min after receiving 200 mg kg⁻¹ M&B 22,948 orally but a significant increase in the preconvulsion time was also seen when challenge was carried out 4 h after drug administration (Table 1) No reduction in the severity of anaphylactic bronchospasm was produced with oral doses of up to 200 mg kg⁻¹ of disodium cromoglycate, administered 15 or 40 min before antigen challenge Theophylline has not been studied in these tests

Table 1 Inhibition of reagin-mediated anaphylactic bronchospasm in the guinea pig by M&B 22,948 administered intravenously, orally or by the inhalation of an aqueous aerosol

Route of drug administration	Dose (mg kg⁻¹)	Time (min) between dose and bronchial allergen challenge	Mean % protection
Intravenous	5	1	19 (4)†
	10	1	50 (4)
	20	1	69 (4)
Oral	200	15	62 (4)
		40	54 (2)
		60	48 (6)
		120	43 (3)
		240	42 (3)
Inhalation	50 (mg ml⁻¹)	1	34(11)

The % protection was 100 [1−(*C*/*T*)] where *C* and *T* were the preconvulsion times of control and treated groups

*Concentration of aerosol generating solution Animals exposed to aerosol for 2 min

†Figures in parentheses refer to the number of experiments

M&B 22,948 antagonised some of the pharmacological effects of the mediators of anaphylaxis Thus, concentrations of M&B 22,948 of 1–30 µg ml⁻¹, which inhibit the anaphylactic release of mediators from human lung tissue, also antagonised the spasmogenic effects of histamine, SRS-A and $PGF_{2\alpha}$ on isolated human bronchial muscle In the rat, intravenous doses of 10–25 mg kg⁻¹ of M&B 22,948 were required to reduce the increase in capillary permeability produced by intradermal histamine and 5-HT These dose levels are considerably higher than that of M&B 22,948 required to inhibit the reagin-mediated PCA reaction (0 1 mg kg⁻¹ intravenously)

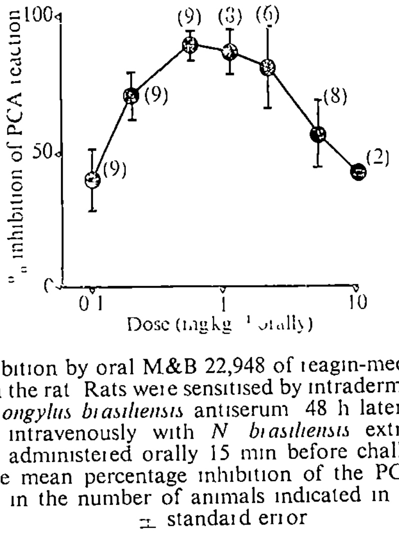

Fig 2 Inhibition by oral M&B 22,948 of reagin-mediated PCA reactions in the rat Rats were sensitised by intradermal injection of *Nippostrongylus brasiliensis* antiserum 48 h later they were challenged intravenously with *N brasiliensis* extract M&B 22,948 was administered orally 15 min before challenge Each point is the mean percentage inhibition of the PCA reaction determined in the number of animals indicated in parentheses ± standard error

The concentrations of M&B 22,948 (µg ml⁻¹) required to cause a 50% reduction in the heights of the contractions of superfused guinea pig ileum produced by various agonists were as follows histamine, 32, SRS-A, 7, acetylcholine, 1, PGE_2, 15, $PGF_{2\alpha}$, 2 5, 5-HT, 6 6 All these values were within the range of concentrations which inhibit the reagin-mediated anaphylactic release of histamine and SRS-A from human lung tissue As the histamine released from the human lung tissue was determined fluorimetrically, the antihistamine activity of M&B 22,948 would not have interfered in the assays M&B 22,948 showed no significant activity, either intravenously or orally, in protecting conscious guinea pigs from histamine-induced bronchospasm Similarly, in experiments carried out in the anaesthetised guinea pig, using either the Konzett–Rossler or the Dixon–Brodie method of recording bronchial tone, no indication was obtained of bronchodilator action or of a specific antihistamine or anti-5-HT action of M&B 22,948

Certain 2-phenyl-8-azapurin-6-ones, and in particular M&B 22,948, have been shown to have high activity in inhibiting the release of the pharmacological mediators of anaphylaxis from isolated human lung tissue *in vitro*, in a reagin-mediated PCA reaction in the rat, and in reagin-mediated anaphylactic bronchospasm in the guinea pig The potency of M&B 22,948 was up to 50 times that of disodium cromoglycate, depending on the test system and the method of drug administration M&B 22,948 may be of interest in the prophylactic treatment of allergic bronchial asthma Since this work was carried out, we have learnt of the oral activity of an oxoxanthene derivative (AH 7725) in inhibiting an allergen induced immediate-type asthmatic response in man[6]

Significance of immunofluorescent staining of lymphocytes with antisera to IgM immunoglobulins

IMMUNOLOGICAL reactions depend for their completeness on at least two different populations of lymphocytes, one derived from the bone marrow and the other from the thymus (B and T cells) B lymphocytes, precursors of the antibody-forming cells of vertebrates, are recognised *in vitro* by two characteristic reactions surface fluorescence with antisera to immunoglobulins[1] and rosette formation with red cells sensitised with some components of complement[2] Since the cells that show surface immunofluorescence are retained on columns of beads coated with antibodies to immunoglobulins[3], surface fluorescence is generally interpreted to mean that immunoglobulins are present on the surface of B lymphocytes[4]

Various means have been devised to prove this point primarily by using high resolution optical devices[5] or specific antisera[6] Although antisera to IgM immunoglobulins bind specifically to structures on the surface of lymphocytes, in only two cases to our knowledge have IgM immunoglobulins been separated from lymphocytes[7,8] and in such small quantities that the authors had to rely on measurements of radioactivity of subcellular fragments obtained by specific coprecipitations to support their assertions It is generally believed as a result of these and other experiments, that lymphocytes indeed bear immunoglobulins and in particular IgM immunoglobulin, on their surface We were therefore surprised to find that it was possible to

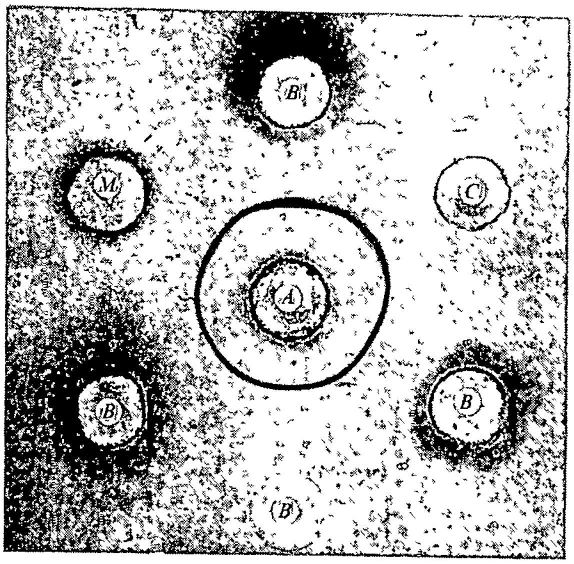

Fig. 1 Double diffusion in agar of IgM immunoglobulin (*A*) with anti-CHO (*C*), anti-μ (*M*), and anti-IgM (*B*) The reaction shows complete immunological identity of the three antisera with IgM immunoglobulin Purified IgM immunoglobulin was prepared by gel filtration of 1 4 l of normal human serum on columns of Biogel P300 resin The fraction eluting in the exclusion volume of the resin was concentrated over Ficoll and applied to a column of ethanolysed cellulose in a Tris borate buffer of *p*H 9 4 The colloids were electrophoresed at a potential of 240 V for 20 h at 4° C and eluted from the column at a rate of 10 ml h^{-1} The fractions reacting with an antiserum to human IgM immunoglobulin were pooled, dialysed against 0 15 M NaCl, and re-electrophoresed α-macroglobulin could be separated from the IgM in this way Fractions containing IgM immunoglobulin were chromatographed twice on Sephadex G200 resin to a single homogeneous chromatographic peak (0 330 g) By electrophoresis, sedimentation and precipitation with an antiserum to human IgM immunoglobulin over 98% of the protein contained in this fraction was shown to be IgM immunoglobulin At no time during this preparation were the soluted containing IgM immunoglobulin frozen The purified IgM was digested first with trypsin (1% w/w) at *p*H 8 0 in 0 65 M Tris HCl containing 0 01 M $CaCl_2$ for 24 h at 37° C, followed by pronase (1% w/w) under the same conditions for an additional 24 h at 37° C The digested protein was dialysed against distilled water The dialysate was concentrated *in vacuo* and applied to a column of Sephadex G25 (fine) resin (0 8 × 200 cm) in 1% ammonium bicarbonate Materials eluting from the Sephadex resin were analysed for carbohydrate by the Mohlish reaction and the Mohlish-positive materials were rechromatographed on Sephadex G25 to a single symmetrical peak The materials within this peak were concentrated *in vacuo* and separated by paper chromatography (butanol–ethanol–acetic acid–water 8 2 1 3) Five oligosaccharides were separated in this way The anti-CHO antiserum (*C* above) is specific for these five oligopeptides

quantify IgG separable from human B cells[9] and that human B lymphocytes could be induced to synthesise IgG *in vitro*[10], but we were unable either to quantify IgM or to show synthesis of IgM in these cells even though they fluoresced with antisera to IgM immunoglobulin Some infants with severe combined immunodeficiency possess in their serum a monoclonal IgG, we have shown that lymphocytes from the serum of one of these children could be induced to synthesise *in vitro* the monoclonal IgG that was in the child's serum[11] Yet all of his lymphocytes showed surface fluorescence with an antiserum to IgM We decided to study this apparent discrepancy We wish to present evidence which will show that surface immunofluorescence of lymphocytes with antisera to IgM is not caused by the presence of IgM on the surface of these lymphocytes

Human IgM was prepared by conventional physico-chemical procedures from normal human serum Over

94% of the protein in this preparation sedimented in the centrifuge as a single boundary with a sedimentation coefficient of 19S It precipitated quantitatively with an antiserum to human IgM

Proteolysis of IgM with trypsin and pronase has been shown to degrade extensively both μ and L chains of IgM[12] Five glycopeptides containing a minimum of 5 and a maximum of 13 sugar residues each, together with six to nine amino acids, represent the only material separable in the exclusion volume of a Sephadex G25 resin when a trypsin-pronase digest of IgM is analysed Each oligopeptide contains N-acetyl glucosamine as the reducing carbohydrate end group, and a fucose (oligopeptide 1 and 2) or a mannose (oligopeptide 3 to 5) in each case bound to an aspartic acid of the polypeptide chain, representing the non-reducing carbohydrate ends These five glycopeptides comprise all the carbohydrate of the μ chain[13] Purified IgM was digested with trypsin followed by pronase The glycopeptides obtained after hydrolysis were separated on Sephadex into Mohlish-positive materials that on paper chromatography (butanol–ethanol–acetic acid–water 8 2 1 3) were shown to be composed of five chemical entities each containing carbohydrate residues We obtained 10 mg of these glycopeptides (dry weight)

An immunoadsorbent resin was prepared by a modification of the method of Axen and Ernback[14] To assure that the carbohydrate moiety of the glycopeptides would bind to the immunoadsorbent, Sepharose 4B activated with CNBr was coupled to L-lysine CNBr-activated IgM glycopeptides were in turn, coupled to the Sepharose–lysine adduct Over 84% of the carbohydrate was bound to the Sepharose in these conditions

IgG globulin was separated (DEAE cellulose) from a rabbit antiserum to normal human IgM globulins The antiserum was rendered monospecific for the μ chains of IgM by passage through immunoadsorbents made by coupling human IgG and IgA immunoglobulins and BenceJones proteins to Sepharose 4B This rabbit IgG globulin (1 g) was incubated at 37° C for 2 h with the immunoabsorbent containing the glycopeptides of IgM in phosphate-buffered saline (PBS) at *p*H 7 2 The unbound globulin was eluted at room temperature, and the absorbent washed with PBS Bound antibodies were eluted with a glycine/HCl buffer, *p*H 2 0 (0 2 M) After five adsorption cycles, no antibodies remained bound to the immunoadsorbent A total of 3% of the rabbit IgG fraction was eluted as specific antibody to the glycopeptides (anti-CHO) The remainder was designated anti-μ even though antibodies to μ determinants of IgM were not specifically isolated Both fractions (anti-CHO and anti-μ) reacted with human IgM as shown in Fig 1 Both antisera gave reactions of complete fusion against IgM Immunodiffusion in agarose (1 5%) rather than agar did not alter the pattern of precipitation Neither the anti-CHO nor the anti-μ precipitated in agar with the glycopeptides isolated from IgM as described above, showing that the glycopeptide fraction did not contain large μ-chain fragments that could react with either the fractionated or non-fractionated antiserum The anti-CHO and anti-μ antibodies had sedimentation coefficients of 6 8 and 6 6, respectively, indicating that neither antibody contained aggregated γ globulin Fluorescent antisera were prepared by dialysing the proteins against fluorescein isothiocyanate buffered at *p*H 9 0 (ref 15) Fluorescein-labelled anti-IgM, anti-CHO, and anti-μ were reacted with B cells The results are summarised in Table 1

Table 1 Percentage of cells staining with fluorescein-labelled antisera to human IgG and Igm Immunoglobulins and the glycopeptides (CHO) or polypeptide chains (μ) of IgM

Cell type	Pre-incubation of Cells with antisera to	Pre-incubation of Antisera with antigen	Fluorescein-labelled antibody (% of cells staining) IgM	CHO	μ	IgG

BM		CHO	40	<2	40	

Fluorescent antisera were prepared by dialysing the protein to be labelled (1 ml of a 1% solution) against 300 ml of a solution containing fluorescein isothiocyanate (0 5 mg ml^{-1}) buffered at *p*H 9 0 for 72 h in the dark Labelled antisera were dialysed extensively against PBS and stored in the dark 0 1 ml of fluorescein-conjugated antisera was added to an equal volume of a suspension containing 2×10^6 cells ml^{-1} in medium 199 supplemented with 5% foetal calf serum and 10^{-2} mol l^{-1} sodium azide Cells were incubated for 45 min in the cold, washed three times in medium 199, and transferred to a glass slide in a drop of glycerol PBS (9 1) Slides were examined, and the percentage of fluorescent cells recorded

* Six determinations

† Four determinations

‡ Bone marrow from a patient with Waldenstrom's macroglobulinemia (one determination)

§ Cytoplasmic staining (all others were surface stained)

B cells were separated from peripheral blood lymphocytes or from tonsillar lymphocytes by density centrifugation on gradients of bovine serum albumin[16] Two different populations of B cells were obtained from the gradients, both of which possessed a complement receptor indicated by rosette formation of these cells with EAC1423 One cell population comprised large cells that sedimented in the upper region of the gradient (17–21% albumin, B1) These could not be induced to form IgG *in vitro* The second cell population comprised small cells with a high density which sedimented toward the bottom of the gradient (29–31% albumin, B2), and these could be induced to form IgG immunoglobulins *in vitro* Over 95% of B1 cells reacted with fluorescein-labelled anti-IgM or anti-CHO, but only 55% of B2 cells did so Less than 2% of either B1 or B2 cells reacted with anti-μ For comparison, less than 2% of B1 and 20% of B2 cells reacted with fluoresceinated anti-IgG Upwards of 80% of the fluorescence of B1 cells and 70% of B2 could be inhibited when the cells were preincubated with unlabelled anti-CHO or anti-IgM, but the fluorescence remained unaltered when either cell was preincubated with anti-μ The specificity of the antisera was tested by incubating the bone marrow of a patient with Waldenstrom macroglobulinemia with fluorescein-labelled anti-IgM, anti-μ and anti-CHO

Two types of fluorescent pattern were visible, cytoplasmic fluorescence and surface fluorescence The cytoplasmic fluorescence of the plasmacytoid cells of the marrow synthesising IgM was revealed both with the anti-IgM and anti-μ antisera This experiment (positive control for anti-μ) indicated that the anti-μ antiserum had activity against the μ chain determinants of IgM This activity could be inhibited by preincubating the antiserum with IgM but not with the glycopeptides of IgM, showing specificity of this antiserum for the polypeptide chains of IgM A small amount of B1 cells were present in the marrow (10%), and presumably it was these cells that reacted with the antiserum to IgM or to the glycopeptides in a pattern showing surface fluorescence This activity could be inhibited by preincubating the antiserum with the glycopeptides but not with IgM showing specificity of the antiserum for the glycopeptides of IgM but not for the polypeptide chains of IgM Comparable results were obtained when the following experiments were done Anti-IgM antiserum (5 ml) was adsorbed 10 times with 10^7 B1 cells each time at 37° C for 1 h The adsorbed antiserum showed unimpaired reactivity with IgM by double diffusion in agar It failed, however, when preincubated with either B1 or B2 cells to inhibit the fluorescence of the anti-CHO antiserum with both B1 and B2 cell populations

Immunoglobulins are glycoproteins Over 10% of the mass of IgM is carbohydrate so that antisera to IgM should contain antibodies directed to the carbohydrate, as well as to the polypeptides of the immunoglobulin chains The data presented here show that immunofluorescence of B lymphocytes with antisera to IgM is not caused by IgM immunoglobulin present on the surface of B lymphocytes It is rather caused by interaction of antisera to IgM immunoglobulin with carbohydrate on the surface of the lymphocyte This carbohydrate must be cross reactive and, therefore, structurally similar to the carbohydrate of IgM immunoglobulin

We thank Dr Chester Alper for the gift of the anti-IgM antiserum and Dr Harvey Colten for providing the sheep red cell intermediate This investigation was supported by a United States Public Health Service Grant J G is the recipient of a Queen Elizabeth II grant from the Canadian Government

Cellular immune response to a drug-treated L5178Y lymphoma subline

TUMOUR-specific transplantation antigens (TSTA), have been detected on a wide range of experimental tumour cells and elicit weak immunogenic activity As a rule, little immune response of the host to autocthonous tumours or to implanted syngeneic tumours has been detected Furthermore, immunological techniques, such as active immunisation, passive transfer of antibodies or adoptive transfer of immune lymphocytes, have not been entirely satisfactory Attempts have also been made to increase the immunogenic properties of tumour cells by *in vitro* enzymatic treatments[1] or *in vitro* coating of antigenic determinants on cancer cells[2]

Some studies have shown that it is possible to increase the immunogenicity of tumour cells[3]. In our laboratory immunogenic L1210 sublines were induced by prolonged *in vivo* treatment with the drug 5-(3,3-dimethyl-triazeno)imidazole-4 carboxamide (DIC)[4] Mice compatible with the untreated L1210 leukaemia were resistant to a heavy challenge of L1210/DIC cells, whereas host resistance could be abrogated by immunodepression The alteration of antigenicity acquired by L1210 DIC-treated cells (L1210/DIC) was found to be heritable[4,5]

We present evidence that a subline of L5178Y tumour, transformed by DIC *in vivo* (L5178Y/DIC) (manuscript in preparation) implanted into mice compatible with the parental leukaemia, stimulated a specific cell-mediated cytotoxic response

L5178Y/DIC was maintained by serial intraperitoneal (i p) passages in immunosuppressed 200 mg kg^{-1} (cyclophosphamide given intraperitoneally 24 h before tumour challenge) hybrid CDF_1 mice Other tumour lines used in this study were maintained by serial i p passages in compatible inbred mice

The cellular immune response was evaluated by the *in vitro* ^{51}Cr release assay[6], modified by Canty[7]

A sample of 10^7 spleen cells (attackers) from normal (control) or immune mice were suspended in a plastic Petri dish (Falcon, 35 × 10 mm) in 1 ml Medium 199 (DIFCO) supplemented with 10% heat inactivated foetal calf serum (GIBCO) and incubated for 4 h with 5×10^4 (50 µl) ^{51}Cr-labelled cells (targets) on a rocking platform at 37° C in a moist atmosphere of 10% CO_2–90% air Radioactivity released in the supernatant by labelled target cells was counted in an automatic scintillation counter

In each experiment quadruplicated samples were used for each experimental group and the data reported are from one out of three similar experiments The percentage cytotoxicity for each group was calculated as follows

$$\frac{\text{c p m } ^{51}\text{Cr released from incubated cells}}{\text{c p m } ^{51}\text{Cr released from frozen–thawed cells (4 times)}} \times 100$$

Experimental results were expressed as (% cytotoxicity in experimental samples)—(cytotoxicity in control samples) The ^{51}Cr release in control samples was 12 ± 3%

Spleen cells from mice immune to L5178Y/DIC tumour cells were highly cytotoxic *in vitro* to ^{51}Cr-labelled L5178/DIC cells Parental radiolabelled L5178Y cells and other tumour and thymus cells syngeneic or allogeneic with CDF_1 mice, did not release the isotope after incubation with anti-L5178Y/DIC attacker cells The specific cell-mediated ^{51}Cr release indicates

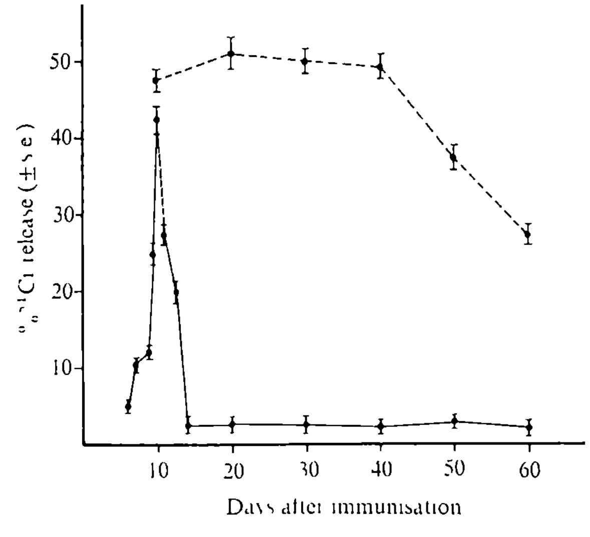

Fig 1 Kinetics of immune spleen cell activity —, Direct assay, ---, assay 24 h after incubation Attacker cells were from CDF_1 mice immunised with 10^7 L5178Y/DIC viable cells injected i p and assayed against ^{51}Cr-labelled L5178Y/DIC cells In these and the following assays the ratio of attacker cells to labelled target cells was 200 1

Table 1 Cytotoxic activity of spleen cells immunised against allogeneic antigens

Attacker cells	Target cells	^{51}Cr release (±s e)
S_{EL_4}	EL$_4$	14 1 (0 4)
	L5178Y	3 4 (0 4)
	L5178Y/DIC	2 8 (0 6)
$S_{E♂G_2}$	E♂G$_2$	16 6 (0 8)
	L5178Y	3 4 (1)
	L5178Y/DIC	−2 (0 9)
S_{C_3H}	C$_3$H	42 8 (0 7)
	L5178Y	3 3 (0 9)
	L5178Y/DIC	−1 8 (0 9)
$S_{C57BL/10\ Sc\ Cr}$	C57BL10/Sc Cr	12 4 (1)
	L5178Y	2 (0 6)
	L5178Y/DIC	3 5 (0 8)

Attacker cells (S) were spleen cells from CFD$_1$ mice 10 d after immunisation with an i p inoculum of 10^7 tumour cells (EL$_4$–E♂G$_2$) or a Sc implant of 1 mm^3 skin tissue pieces (C$_3$H—C57BL/10 Sc Ci) L5178Y and L1210 were from Microbiological Ass Bethesda EL4 and E♂G2 were obtained from Dr G Della Porta, National Cancer Institution Milan Moloney Sarcoma (MSV) and Gross leukaemia (GLV) were virus-induced by Dr A Di Marco, National Cancer Institution, Milan

that DIC treatment can induce transplantation antigen(s) on L5178Y/DIC cells, not detectable on the original L5178Y lymphoma and on other tumour, or normal thymus cells

The cytolytic activity of spleen cells from CDF$_1$ mice assayed at different days after administration of the immunising inoculum is shown in Fig 1 The activity reached a peak at 10 d after tumour cell inoculation and could not be detected after 13 d 24 h *in vitro* incubation fully reactivated the cytotoxic activity and it was still evident at 60 days following immunisation The immune cell reactivity, its disappearance a few days after the peak was reached as the result of a block by some still unknown factor and its reactivation by 24 h incubation, agree with previous observations involving the ^{51}Cr release assay technique[8]

Immune spleen cells from CDF$_1$ mice sensitised to allogeneic antigens were cytotoxic to ^{51}Cr-labelled tumour cells bearing the corresponding alloantigens (Table 1) The spleen cells failed to release the radiolabel from either the original L5178Y or the L5178Y/DIC suggesting that the cells of the subline had not acquired some nonspecific immunosensitivity Evidently neither L5178Y or L5178Y/DIC associated antigens can react with H—2^b or H—2^k associated antigens

The specificity of L5178Y/DIC antigen(s) was determined by using an assay for inhibition of cytotoxicity involving addition of unlabelled cells Addition of unlabelled cells to the mixture of immune lymphocytes and labelled L5178Y/DIC target cells would result in inhibition of ^{51}Cr release if the unlabelled cells shared some common antigen(s) with L5178/DIC cells Only unlabelled L5178Y/DIC cells elicited marked inhibitory activity (Table 2) All other normal or tumour cells added, including the parental L5178Y cells, did not modify ^{51}Cr release significantly The failure to detect L5178Y/DIC antigens on foreign cells provides strong evidence of the specificity of L5178Y/DIC induced antigen(s)

Table 2 Inhibition of immune spleen cell-mediated cytotoxicity by addition of unlabelled cells

Added inhibitor cells	% Reduction in lysis*	
	5 × 10^5	10^5
L5178Y/DIC	68 (7 8/24 9)	39 (15 3/24 9)
L5178Y	6 (15 6/16 6)	−6 (17 6/16 6)
L1210	8 (22 9/24 9)	4 (24/24 9)
E♂G$_2$	−2 (39/38)	−5 (40/38)
EL$_4$	13 (22 7/26 4)	13 (22 7/26 4)
MSV	12 (14 3/16 1)	4 (15 4/16 1)
GLV	16 (13 5/16 1)	0 (16 1/16 1)
Spleen DBA/2 Cr	−11 (21/18 8)	0 (18 8/18 8)
CDF$_1$	0 (18 8/18 8)	2 (19 1/18 8)
BALB/c	8 (23 5/25 5)	3 (24 7/25 5)
C57BL/10 ScCr	4 (18/18,8)	8 (17 2/18 8)
C$_3$H	8 (23 5/25 5)	4 (24 5/25 5)

Attacker cells were from CDF$_1$ mice i p challenged with 10^7 L5178Y/DIC viable cells and assayed after 10 d against ^{51}Cr labelled L5178Y/DIC cells

* $\frac{\%\ \text{lysis with inhibitor cells}}{\%\ \text{lysis without inhibitors}}$

Immune cells were assayed immediately or 4 h after X-ray treatments The activity of the attacker cells was only partially reduced even by heavy doses of X rays (2 00–4 00 r), in accordance with the known resistance of cytolytic cells (immune lymphocytes and macrophages) to X irradiation (Table 3)[9]

Our studies indicate that L5178Y/DIC lymphoid cells carry new antigen(s) not detectable on parental cells The mechanism, by which DIC alters the immunological properties of L1210 and L5178Y lymphomas is unknown The drug-induced antigen(s) were not found on normal lymphocytes or on cancer cells But the strong transplantation antigen(s) seems to be a permanent genetic feature, as the L5178Y/DIC cells maintained the acquired antigen(s) even when the drug treatment was discontinued over a long period

Table 3 Cytotoxic activity of X-irradiated immunised spleen cells

X-ray dose	% lysis (± s e)	% Reduction in lysis relative to non-irradiated cells
Immediate assay		
—	20 3 (0 9)	—

50	39	—	n d	50	n d	22,000
100	28	—	n d	100	n d	12,000

different preparations of liver antigen from human liver, led us to attempt to prepare a better defined antigen from human liver—already proposed[2] for this test system Besides a liver specific protein as previously described[11], our preparation yielded a soluble fraction, which inhibited the peripheral leukocytes of patients with active chronic hepatitis, but also inhibited the leukocyte migration of controls The migration inhibition in these cases was therefore not due to a cell-mediated immune reaction against liver antigen, but was caused by a previously unknown inhibiting substance, extracted from human liver Here we report some properties of this inhibitor

The inhibitor was isolated from the soluble supernatant after homogenising and centrifugation of normal human liver at 100,000*g* for 90 min in Hanks solution, *p*H 7 2 The supernatant was transferred to a Sephadex G-100 column, equilibrated with 0 01 M Tris-HCl buffer, *p*H 8 0 The inhibiting factor was eluted in the second (II) and third (III) fraction Rechromatography of these active fractions yielded a homogeneous peak, but no pure substance An ion exchange chromatography procedure was therefore added, and we obtained a pure substance with inhibiting properties

This inhibitor is a protein The molecular weight, estimated by gel filtration, is about 65×10^3–8×10^3 The electrophoretic mobility is slow, similar to the β-γ-globulins

The functional properties of this protein are characterised by a potent inhibition of lymphocyte transformation after stimulation by phytohaemagglutin (PHA), purified protein derivative (PPD) and by cellular antigens or transplantation antigens (mixed lymphocyte culture (MLC)) (Fig 1) Besides, the metabolism of *in vivo* activated lymphocytes[3,4] and the migration of the macrophages are inhibited also After PHA stimulation, most of all the *de novo* synthesis of RNA is inhibited

The specificity of lymphocyte metabolism inhibition seems to be very high Doses which cause a 100% inhibition of lymphocyte's metabolism lead only to a very slight reduction of the metabolic rate of HeLa cells (Table 1) On the other hand, no species specificity of the inhibitor could be found, since a preparation from rabbit liver has about 40% of the inhibiting potency on human lymphocytes compared with inhibitor prepared from human liver

The inhibitor reported here is not identical with the immunosuppressive α globulins from human serum[6,7], because the inhibitor from human liver has an electrophoretic mobility of a β or γ globulin We have isolated this inhibitor from the pooled serum of normal people also (by gel-filtration) but the inhibiting strength of this preparation was only 10% of that prepared from liver We therefore suppose that the inhibitor is released from the liver to the serum

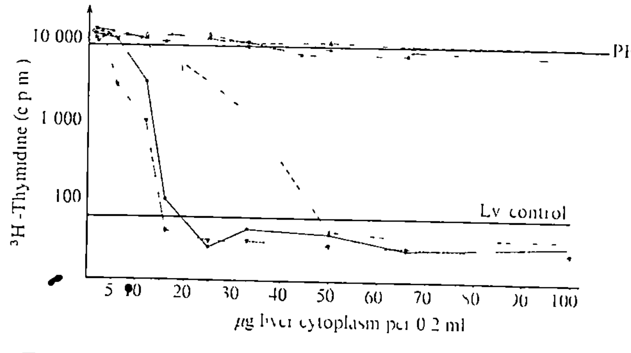

Fig 1 Dose-dependent inhibition of PHA-stimulated lymphocytes by fractions (Sephadex G100) from soluble liver cytoplasm ○ - - - ○, Fraction I, X — X, fraction II ▽ - - - ▽, fraction III, X —— X, fraction IV, △ — △, fraction V, ●—●, liver cytoplasm

Whether or not the prolonged survival time of skin allografts with simultaneous liver transplants on *Diemictylus viridescens*[7] was due to the immunosuppressive effect of the lymphocyte inhibitor from liver is unknown The clear cut time dependency of liver implantation and immunosuppressive effect and the survival of the skin allograft does not exclude this possibility

The inhibitor described here has some similarity with the inhibitor of protein synthesis in polyribosomes, reported by von der Decken[8] The fact that the polyribosomes were prepared from rat liver, however, makes it unlikely that the inhibitor of protein synthesis in polyribosomes and our inhibitor are identical or similar The inhibitor reported here seems to be lymphocyte specific

The inhibitor is not a chalone[9], because chalones are defined as non species-specific inhibitors, present in and produced by the tissue, the proliferation of which they specifically inhibit[10]

The physiological significance of this inhibitor remains to be elucidated, especially the mode of action and the question whether or not this substance has something to do with regulation or repair mechanisms Studies on the inhibitory effect on T or B lymphocytes are in progress

Two types of resistance to polyene antibiotics in *Candida albicans*

STUDIES reported during the past 15 years have led to the widely accepted conclusion that polyene antibiotics function

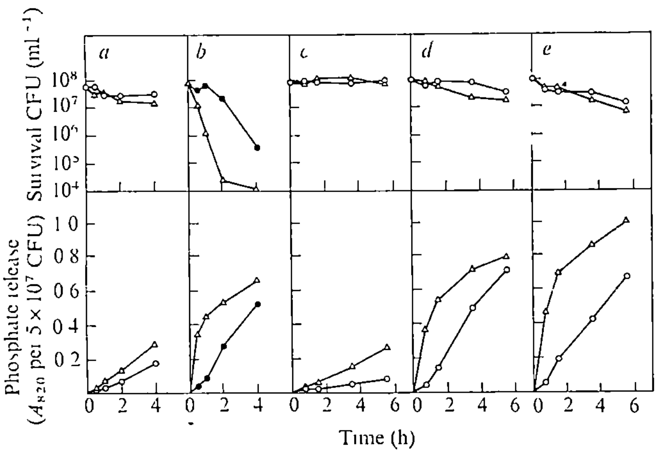

Fig 1 The effect of polyene on the viability (CFU ml^{-1}) and on the release of phosphate ($A_{820\,nm}$ per 5 × 10^{7} CFU) from mutants A1 (*a*), A2 (*b*), A3 (*c*), A4 (*d*) and A7 (*e*) at room temperature Only exponentially growing cells were suspended in saline After incubation with polyene for the periods shown, viability was determined by plate-counting and the release of phosphate was quantitated colorimetrically[21] on the supernatant fluid after centrifugation The amount of release in the blank control samples remained negligible ●, 10 μg amphotericin B ml^{-1}, ○, 40 μg amphotericin B ml^{-1}, △, 100 μg nystatin ml^{-1}

by binding with the sterol molecules in susceptible cells to cause permeability change and eventual death of the cell[1-3] In recent reports[4-6] based on liposomal model membrane studies, it has been suggested that susceptibility to polyene antibiotics is determined by organisation rather than by a single component of the membrane, namely sterol Here, through study of polyene-resistant mutants, we further propose that, at least in some cases, permeability alteration may not be the specific critical event in the fungicidal action of polyene antibiotics

Five mutagen-induced mutants were derived from a clinical isolate of *Candida albicans* (E139-A, wild type) as described by Hamilton-Miller[7] Their levels of resistance vary with inoculum size and with the medium (Table 1) For example, mutant A2 grew in 100 μg ml^{-1} nystatin on solid medium but was killed in saline Compared with E139-A, the mutants grew more slowly, responded differently in the Liebermann–Burchard colorimetric reaction (Table 1) and, in accordance with previous reports[8,9], contained proportionally more sterol (Table 2) In other laboratories, differences in the sterol pattern of polyene-resistant mutants have been observed[8-13], and the major sterols have been characterised completely in one set of mutants[14] Polyene resistance was attributed to altered patterns of sterols In several studies[10,11,13], decrease in ergosterol content has been singled out as the direct cause of polyene resistance For comparison, the ultraviolet absorption spectra of the non-saponifiable fraction extracted from E139-A and our polyene-resistant mutants were examined[10] In all cases, 5,7-diene sterols (for example, ergosterol and 24(28)-dehydroergosterol) were detected but not as major components This was confirmed by analysis of the sterol composition with thin-layer chromatography (Table 3) A similar situation has been reported in a strain of *Saccharomyces cerevisiae* in which ergosterol constituted only 10% of the total sterol[15]

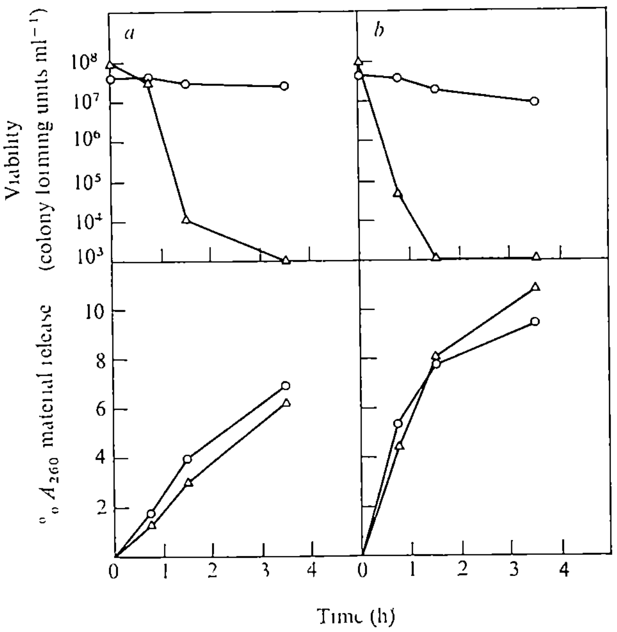

Fig 2 The effect of polyene on the viability (CFU ml^{-1}) and on the release of ultraviolet-absorbing substances (260 nm) from the wild type E139-A (△) and from mutant strain A4 (○) Exponentially growing cells were used In (*a*) amphotericin B was present at 20 μg ml^{-1}, in (*b*) nystatin was present at 100 μg ml^{-1} Experimental conditions were identical to those described for Fig 1 The maximal extractable ultraviolet-absorbing material from the cells was determined by treatment with 1 2 N perchloric acid[17] and taken as 100% release

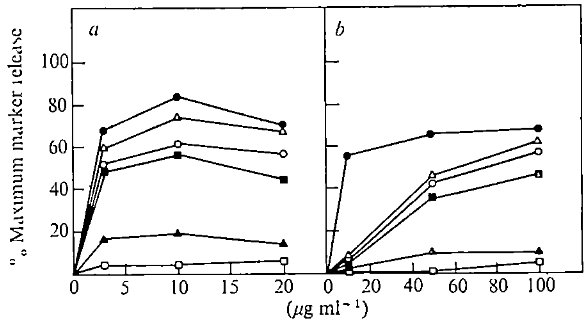

Fig 3 Polyene (*a*, amphotericin B, *b*, nystatin) susceptibility of liposomes derived from total lipid extracts of 139 (●), A1 (□), A2 (■), A3 (▲), A4 (○) and A7 (△) Liposomes with the test agents, as well as the blank control, were incubated at room temperature for 30 min The percentage maximum glucose released was calculated from the expression (glucose released in the presence of polyene — blank control)/(total amount of glucose trapped — blank control) × 100, as described previously[4 6]

We have found that effects on viability and cell leakage depend on temperature and phase of growth At room temperature (23°–24° C), nystatin and amphotericin B caused extensive killing and leakage of phosphate and ultraviolet-absorbing material from E139-A At 2° C, however, no cells were killed and we observed no leakage of phosphate and ultraviolet-absorbing material from them Similarly, cells in stationary

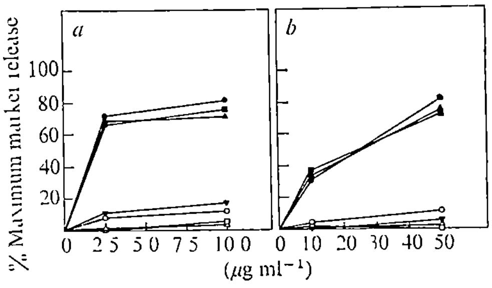

Fig 4 Polyene (*a*, amphotericin B, *b*, nystatin) susceptibility of mixed lipid liposomes Phospholipid and neutral lipid derived from one strain were mixed, respectively, with the neutral lipid and phospholipid derived either from the same strain (control liposome) or from a different strain (mixed lipid liposome) Experimental conditions were identical to those described for Fig 3 Neutral lipids of ●, E139-A, ■, E139-A, ▲, E139-A, ▼, A1, ○, A1, □, A3, △, A3 Phospholipids of ●, A1, ■, A3, ▲, E139-A control, ▼, E139-A, ○, A1 control, □, E139-A, △, A3 control

* Log phase cells were adjusted to approximately 5×10^4 colony forming units per ml in fresh growth medium, 2 ml of this dilution was added to tubes containing the given polyenes Dimethyl sulphoxide was present to 1% in all samples including the blank control After overnight incubation at 37° C, the turbidity was recorded

† A single colony of the given strain was streaked out on plate containing the given polyenes, and the growth was checked after 24 h of incubation at 37° C The nystatin (4530 U ml^{-1}) and the amphotericin B (876 µg ml^{-1}) were gifts from the Squibb Institute of Medical Research

‡ Liebermann–Burchard reaction used Total lipid extract of whole cells were used for assay Preparations from both log and stationary phase cells gave identical results

§ Growth was monitored turbidimetrically with a Klett–Summerson photoelectric colorimeter (green filter)

phase were affected far less than those in the logarithmic phase (Unless otherwise stated, only exponentially growing cells were used subsequently) These temperature and growth phase effects might be explained in three ways (1) changes of chemical composition in the membrane, (2) changes of effective pore size cell wall (a molecular sieving effect[16]), (3) a temperature-dependent metabolic process, operative only in growing cells, may be involved in the fungicidal action No decisive evidence favours any of these suggestions, and temperature dependence and growth phase dependence could be unrelated But, we have observed no appreciable difference in sterol patterns nor in the polyene-sensitivity of liposomes prepared from growing and stationary cells Furthermore, protamine (molecular weight approximately 18,500) can release ultraviolet-absorbing material from a strain of *C utilis* at both 30° C and 0° C (ref 17)

Table 2 Incorporation of sodium acetate-1-^{14}C into lipid fraction of wild type and mutant strains

	% Distribution of phospholipids PC	PE	PS+PI	Ratio of phospholipid/ neutral lipid*
E139-A	73 8	20 9	5 3	2 41
A1	60 6	28 0	11 4	1 74
A2	69 5	22 1	8 3	1 62
A3	68 7	19 9	11 3	1 63
A4	70 7	22 4	7 0	1 92
A7	76 5	13 1	10 4	1 46

Total lipid extract was subject to thin-layer chromatography on silica gel G plates with system $CHCl_3/CH_3COOH/H_2O/AcOH$ (65 43 3 1, v/v) Percentage distribution of phospholipids was calculated from the expression [(c p m of given phospholipid) (total c p m in phospholipid fraction)] × 100 PC, phosphatidylcholine, PE, phosphatidylethanolamine, PS, phosphatidylserine, PI, phosphatidylinositol

* Represent ratios of c p m in phospholipid fraction to c p m in neutral lipid fraction Preliminary experiments indicated that about 90% of the counts in neutral lipid fraction was associated with free sterols

Figure 1 shows the relationship of viability and leakage in mutants The release of cellular constituents did not result in or parallel extensive killing in mutants A4 (Fig 1*d*) and A7 (Fig 1*e*) The latter phenomenon is illustrated more clearly in Fig 2 In the presence of amphotericin B and nystatin, the viability of A4 was maintained, whereas E139-A was soon killed, the release of ultraviolet-absorbing material from both strains remained comparable If the alteration in permeability is a direct measure of membrane–polyene interaction, the data in Figs 1 and 2 suggest that there may be two mechanisms of polyene-resistance in yeast With type 1 mutants, A1 and A3, resistance arises from a reduced interaction between the cell membrane and the antibiotics as indicated by the low level of leakage With type 2 mutants, A2, A4 and A7, the antibiotics interact with the membranes, as evidenced by the altered permeability, but some critical step in the fungicidal effect fails to occur

The categorisation of mutants based on the loss of cell constituents can be reproduced in liposomal membrane systems derived from the total lipid extract of each strain (Fig 3) Liposomes prepared from mutants A2, A4 and A7 leaked glucose in a manner comparable with the wild type The apparent decrease in glucose release at high concentrations of amphotericin B was due to the interference of the antibiotic molecule at the absorption wavelength used in our assay Mixed liposomes were also prepared after fractionating total lipid extracts into phospholipid and neutral lipid components by silicic acid column chromatography[18] Figure 4 shows that polyene-induced permeability of E139-A was associated

Table 3 Mobility and percentage distribution of major sterol classes of wild type and mutant strains on thin-layer chromatography

	R_F values <0 14	0 32	0 48	0 55	0 67	0 72
E139-A	30 6	18 1		11 7	29 7	10 0
A1	38 8	8 8		18 2	22 4	11 8
A2	24 2	5 7	12 4	23 6	25 9	8 3
A3	45 2	7 4		15 5	21 2	10 8
A4	36 9	10 8		17 2	25 5	9 7
A7	24 4	13 3		22 3	27 4	12 7

Non-saponifiable sterol extracts were subject to thin-layer chromatography on $AgNO_3$-impregnated silica gel G plates The plates were developed half-way with benzene–ethyl acetate (2 1, v/v), dried under N_2 and redeveloped in the same direction the full distance with benzene–ethyl acetate (5 1, v/v) Figures given were calculated from the expression [(c p m of a given spot)/(total c p m in sterol fraction)] × 100

* As references, the R_f values of ergosterol and cholesterol are 0 32 and 0 55, respectively Sterols with polarities (as measured by their R_F values on silica gel) greater than ergosterol were not well resolved in this system

with the neutral lipid fraction (shown to be predominantly free sterol in preliminary experiments). Similarly the insensitivity of A1 and A3 to polyene-induced permeability changes was conferred on mixed liposomes by the neutral lipid fraction of these organisms. Our results clearly show that, in type 1 mutants, resistance arises from changed sterol patterns. Structural characterisation of major sterols in all strains is needed before this type of resistance can be discussed more specifically.

The existence of type 2 mutants indicates that leakage does not always result in killing. The discovery of nystatin-dependent mutants[19] suggests that this antibiotic could play a role in cell physiological function. The lethal action may involve polyene-induced malfunction of an essential physiological process or processes. When such a process is not operative, for example, at 2° C or when cells enter stationary phase or when a specific mutation occurs, its susceptibility to the fungicidal effect of polyenes may diminish. It has been reported[20] that iodoacetate and dinitrophenol reduce the fungicidal action of the polyenes on yeast.

Crystallisation of a modified fibrinogen

MOST fibrous proteins do not crystallise. An artful way to promote protein crystallisation is to modify the structure by proteolytic attack. For example, papain cleavage of γ-globulin yields the homogeneous Fc fragment which readily crystallises[1]. Following a similar approach, we have crystallised fibrinogen.

Native fibrinogen precipitated at low ionic strength forms fibrous aggregates which are aperiodic in the electron microscope. After these precipitates had been stored in the cold for several months, we observed unusual rod-shaped structures which showed microcrystalline order in the electron microscope[2]. We had previously noticed that such preparations were often contaminated with bacteria, and it seemed likely that a bacterial protease had modified the native molecule so that it formed ordered aggregates. We cultured strains of *Pseudomonas aeruginosa* from such preparations and prepared a crude protease extract. This protease cleaved fibrinogen to a form that yielded highly ordered microcrystalline arrays[3]. We summarise here our studies on the effect of the protease digestion on fibrinogen and show that more extensive controlled cleavage leads to a modified molecule which forms crystals suitable for X-ray diffraction analysis.

The protease used in these studies was isolated from the growth medium of a strain of *Pseudomonas aeruginosa* grown on trypticase soy. The crude enzyme was salted out with ammonium sulphate. The protease was incubated at 31° C with native fibrinogen (5 mg ml^{-1} in 0.3M NaCl buffered to about *p*H 7) for various times. The reaction was terminated by addition of $10^{-3}-10^{-4}$M N-α-Tosyl-L-lysine chloromethyl ketone (TLCK), and the fibrinogen was dialysed to low ionic strength (5×10^{-3}M KSCN, 0.01M 2-(N-morpholino) ethane sulphonic acid (MES), *p*H 6.2). Samples were stored in the presence of the inhibitor and chloroform.

The progressive modification of the molecule was followed by measuring the percentage of mass lost as small trichloroacetic acid (TCA)-soluble peptides, and by observing the type and amount of ordered aggregates formed at low ionic strength. Four stages of digestion were distinguished. In the very early phase, corresponding to less than about 2% mass loss, most of the material precipitated out of solution at low ionic strength and consisted chiefly of aperiodic fibres, similar to native fibrinogen. With further digestion (corresponding to a loss of 4–6% of the mass as TCA-soluble material) the modified fibrinogen was more soluble, but within about 3 d as much as 85% of the material precipitated as microcrystals with a 450 Å axial repeat[3]. In the narrow digestion range between about 6 and 8% mass loss, precipitation was even slower, and both microcrystals and large birefringent crystals appeared; the proportion of crystals could be very high. On further digestion (about 10% mass loss) some amorphous precipitate formed, but most protein remained in solution.

The extent of protease digestion could be correlated with the appearance of the sodium dodecyl sulphate (SDS) gel electrophoresis patterns run in the presence of reducing agents[4]. The native molecule has a molecular weight of about 340,000 and consists of three pairs of chains designated Aα (~70,000 daltons), Bβ (~60,000 daltons) and γ (50,000 daltons)[5,6] (Fig. 1*c*). The Aα chain was attacked first. Microcrystalline samples, digested to about 4% mass loss, gave gel patterns with most of the Aα band and part of the Bβ band missing. The gel patterns of crystals showed a single heavily staining broad band with the same mobility as the γ chain of the native molecule (Fig. 1*c*). The clotability by thrombin of the molecules from the crystals was about 50% to 80% of that of native fibrinogen.

The crystals we obtained were thin birefringent plates with the longest dimension up to 1 mm (Fig. 1*a*). They were very fragile and characteristically cleaved in a direction perpendicular to the long axis to give rod-shaped fragments.

Preliminary X-ray diffraction patterns of single crystals taken at room temperature show reflections out to about 3 Å (Fig. 1*b*). The space group is $P2_1$. The unit cell dimensions are a=134 Å, b=97.3Å, c=174Å. β=92°20′. The density of the crystals is in the range 1.135–1.140 g cm^{-3} as determined by flotation of individual crystals in xylene–bromobenzene mixtures. Assuming that the partial specific

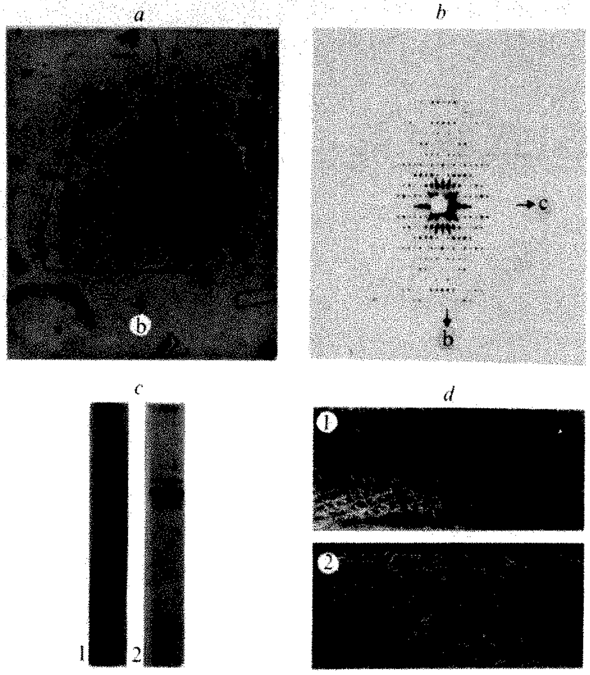

Fig. 1 *a*, Crystal of proteolytically modified fibrinogen. The b-axis is parallel to the long (vertical) axis of the crystal. Note small fragments cleaved perpendicular to this direction. (Approximately ×80.) *b*, A 4½° Precession photograph of of the Okl plane of the reciprocal lattice. The systematic absence of the OkO reflections with k odd indicates a twofold screw along the b-axis (vertical direction). *c*, SDS polyacrylamide gel electrophoresis patterns of (1) native fibrinogen; (2) modified fibrinogen from redissolved crystals. Both reduced with mercaptoethanol. *d*, Electron micrograph of crystal fragments showing (1) a net-like region: (2) fine diagonal, lateral and longitudinal striations spaced at about 45 Å, 60 Å and 35 Å, respectively. The sides of the mesh are about 105 Å by 115 Å; the acute angle is about 65°. Samples negatively contrasted with 1% uranyl acetate. (×190,000.)

volume of the protein is 0.72[7], the water content of the crystals is about 65%. The molecular weight of the protein in the asymmetric unit was therefore calculated to be 330,000, with an uncertainty of about 6%.

Crystals were washed, fragmented and negatively contrasted with 1% uranyl acetate for electron microscopy. Commonly observed images showed fine diagonal and longitudinal striations spaced at about 45 Å and 35 Å. More rarely, a net-like form was seen (Fig. 1*d*). The beaded strands of the mesh were about 30 Å in diameter, with the edges about 115 Å by 105 Å in length, defining an acute angle of about 65°. The negatively stained crystal fragments showed no direct correspondence with images of the microcrystalline forms which have a 450 Å axial repeat[3].

The unit cell dimensions and density of the crystals indicate a molecular weight for the modified protein of about 330,000 comparable with the native molecule. The estimate of mass lost from modified fibrinogen which crystallises is about 6–8% by measurement of the TCA-soluble peptides released during digestion. SDS gels of the crystals run in reducing conditions, where polypeptide chains separate by molecular weight, show material only in the γ chain region. Since no other large chain fragments are seen, the cleavage may split off relatively small fragments from the Aα and Bβ chains, reducing them to the size of the γ chain. The γ chain has a molecular weight of about 50,000; thus the weight inferred for the modified molecule from these gels is again about 300,000. Migration of the whole modified molecule on SDS gels without reducing agents present also gives a rough estimate of molecular weight close to 300,000. The chemical and crystallographic estimates of the mass of the modified molecule thus agree, within experimental uncertainties. This preliminary evidence on the modified molecule forming the crystal indicates that in spite of the cleavage it may be largely intact.

Redissolved crystals show a clotability about 50–80% of that of native fibrinogen. The fibres formed appear very similar to those of native fibrin in the electron microscope. This indicates that the modified molecule has retained the critical sites which interact to form the fibrin clot.

Some inferences about molecular shape and packing can be made at this stage, although the crystallographic data do not provide strong constraints. The modified fibrinogen crystallises in the monoclinic space group $P2_1$, and the unit cell contains two molecules of weight about 300,000. The molecule is a dimer of elongated shape, but a twofold axis is not a symmetry element of the crystal. From the symmetry of the crystal, these rod-shaped molecules must be arranged with two different orientations. Since the crystals readily cleave along the plane perpendicular to the b axis, the forces are weak between arrays of molecules related by the twofold screw. Only about 35% of the unit cell volume is occupied by protein, so that the molecules must form a fairly open meshwork of cross-connected rods.

The body diagonal of the unit cell in the crystal is about half the 450 Å length inferred for the fibrinogen molecule from studies of the microcrystals[3]. The dimensions of the unit cell in the crystal lattice need not, however, be related simply to the molecular dimensions. As in the assembly of other fibrous proteins[8–11] the rod-shaped molecules may pack with extensive side-to-side overlaps and end-to-end gaps, so that the observed periods may be only a fraction of the molecular lengths. The microcrystals of the modified fibrinogen molecule display a 450 Å axial period, and a specific staggering of arrays with this period can produce the 225 Å axial period and density distribution seen in the fibrin clot[3]. Although these large periodicities are not evident in the crystal lattice, it is likely that the modified fibrinogen in these crystals will show interactions similar to those in the microcrystals and in fibrin.

This work was supported by grants from the US Public Health Service and the National Science Foundation. We thank Dr Stephen Harrison for taking the X-ray photographs and for discussions. We thank Dr D. L. D. Caspar for discussions, Isa Bernardini for technical aid and Paul Norton for electron microscopy.

Bringing men to the Moon

'TODAY scientific technology has reached the point where man has liberated nuclear energy and sent men to the Moon". Familiar, indeed trite, words that have been repeated a hundred times and which begin the preface to the handbook of the Third International Conference on the Unity of the Sciences to be held in London next month. But in this case there is an unintentional pun in it, for Moon is also the name of the man behind it all—Rev. Sun Myung Moon. And Mr Moon is an interesting character whose organisation seems to have a magic touch at compiling international gatherings stiff with Nobel Laureates.

The conference is sponsored by the International Cultural Foundation, founded in Japan in 1968 by Mr Moon, a South Korean. Its aims are "to inspire and foster the emerging world culture and civilisation", and to achieve this it lists prospective activities which would hardly be out of place at UNESCO—except that apparently the communist half of the world is not welcome.

The first conference was in New York in 1971 and twenty attended to hear Mr Edward Haskell propound his methods for eliminating "many defects produced as a result of the fragmentation of sciences as well as the breakup of science and morals . . . by viewing the scientific disciplines from a systematic viewpoint". "We had to listen to some extraordinary ideas on unification by way of Mendeleev's periodic table", said one participant. Another was horrified that whilst the scientists thought it silly, the philosophers present all took it very seriously.

Mr Haskell's influence seems to have waned between the first conference and the second, which was held in Tokyo last year with 60 participants discussing 'Modern Science and Moral Values'. Again there was international participation and for the second time there was plenty of money to fly the "deeply concerned scholars" to Japan. There were reply paid telegrams for those who didn't go, to send greetings for later reproduction as "messages of congratulation". Nobel Prize winners were carefully cultivated and identified as such whenever possible. And Mr Moon addressed the assembled gathering in very general terms.

Amongst the hand-outs to those who attended was a book *Unification Thought*. This book, written by an unnamed Korean, is published by the Unification Thought Institute of New York and is based on the Unification Principle of Mr Moon. In the second paragraph of the Preface we are told that "communism, which is a pseudo-value system, is eroding the Free World both in public and in secret". To counter this, Mr Moon's theistic ideology is described, with emphasis on Creation by God and the action of Divine Providence. The sweep of Mr Moon's thought is enormous and on the whole harmless. The Unification Principle "disregards the theory of evolution". The Unification Principle makes logical positivism "absurd", because of the "family Four Position Base". The "purpose" of the electron is to preserve atomic structure through revolving around the proton but also to bring joy to man indirectly. And so on. On values—the forthcoming conference is on absolute values—the writer concludes "there is no other way to find the true view of value than to perceive exactly what God's purpose for creation is". And the last chapter, on "Theory of History", begins to give us some idea what this purpose is.

History is, amongst other things, the history of re-creation and is marching towards a goal. Numerology then takes over.

First it is the number three. Everything reaches completion through three stages of growth. Three sons of Adam, three sons of Noah, three temptations of Christ and so on. Recently three stages of religious Renaissance, the first, Luther and Calvin; the second 17th and 18th century Pietism, Quakerism and Methodism; the third will develop soon on a world-wide scale when all religions and thoughts will be completely unified.

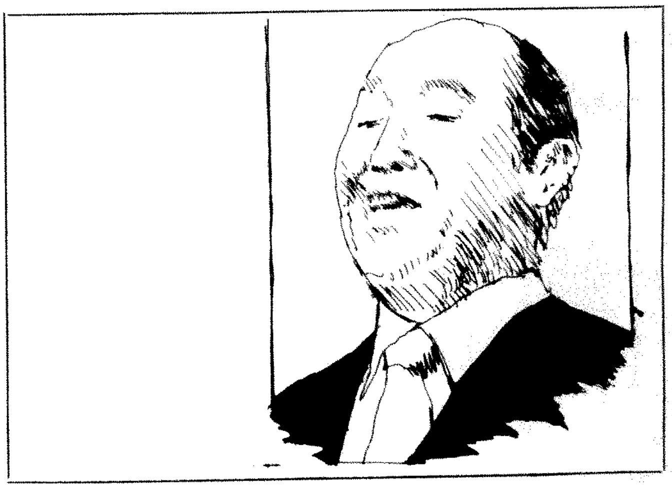
Then there is the number six. Six days of creation; six centuries of turmoil before Christ; six centuries before the appearance of the Third Adam. And the start of this last period? When the Pope became prisoner at Avignon, namely 1309. So the Third Adam should be around right now.

Next comes the number four in forty days, forty years, four hundred years.

Then, the law of false preceding true with Stalin as a false Messiah after whom we can "feel the approach of the Second Advent of the Messiah".

And finally the Law of Parallel Providence, comparing 1930 years of Old Testament development with 1930 years of development after Christ, again points clearly to an impending "Second Advent of the Messiah". So the Unification Principle exists to bring religion and science together in a unified culture and start a new cultural age under, presumably, a Third Adam or Second Messiah. Without the communists, of course.

Not that it is all theoretical. Mr Moon now has a following of a couple of million the world over and is at present crusading vigorously in the United States.



Large numbers of 'Moon children' have been imported from Japan and Korea and have affronted the American public by selling candles on street corners and showering New York and Washington with posters and pamphlets, thereby violating their visa status and breaking anti-litter laws. And large numbers of young Americans have taken it all seriously (*Time*, September 30). In the summer, Moon children were to be seen praying publicly in Washington for President Nixon. Just before a Madison Square Gardens appearance they ensured that Mr Moon had a large gathering of personal guests at a banquet at the Waldorf Astoria by camping down in United Nations missions to urge attendance on the diplomats.

The money for all this comes partly from street corner sales, but Mr Moon also owns several Korean businesses, making, amongst other things, ginseng tea and guns. The industries are given to him, it is said, by businessmen converted to the cause.

It is not clear that those invited to the Third Conference are aware of the background to the organisation. The initial brochure speaks of the purpose of the conference as discussion of the role of science in relation to problems of value and a possible way of setting up a universal standard of value for all mankind. It mentions Sun Myung Moon (without the Rev.) as the inspired founder. It lists British academic advisors, although not all on the list were very pleased to have their name used in this way. But it does not say that the fundamental philosophy is anti-communist, nor that the utterances of Mr Moon are such as to leave his followers with the impression that he himself is the Third Adam or Second Messiah.

The second round of publicity contains an extensive list of speakers—62 in all—and an even more extensive list of "commentators and discussants". No less than twenty-five of those attending have the words Nobel Laureate after their name. But none of the 150 listed comes from a communist country, nor even India, whereas three come from the Republic of China (Taiwan) and five from Korea (South Korea). A random check revealed that not everyone listed had ever had the intention of going to the conference.

The conference is being organised from an office in London. Mr Moon's book *Divine Principle* occupied pride of place on the mantelpiece. Questions were answered with charm and courtesy but generally in a rather hazy way; it could hardly be said that the philosophy of the organisation came through as anything other than the most vapid of generalisations about all sciences being one, science giving us the answers to help organise society, it not being desirable to use science for destruction and there being a spiritual dimension to science.

But have you tried to get representatives from the communist half of the world? Well it is not possible to invite people from all countries every year.

Is Mr Haskell, who played such a central role two years ago, coming this year? We aren't sure of that.

Who is this Mr Moon? (His name had modestly not been mentioned in our discussion before this point.) He is a Korean philosopher who inspired these conferences.

Is he coming? We don't know.

There is an empty slot on the packed programm for a Guest Address; who will give this? We shall b looking for someone soon.

For some, of course, the aims of this conference an its background are entirely in accord with their philosophy and they can hardly be criticised for giving it thei serious attention. And some who have been dissatisfie with the previous conferences have resolved to give i another try, in order to meet people, or in the hope tha the foundation has tightened up its academic credentials But many others seem to be in almost complete ignorance of the organisation behind it and unaware that thei presence may be used to confer some degree of respectability on something with which they would have littl sympathy.

Certainly the names of those expected to come shoul inspire some confidence that the operation will not b an entirely futile affair—provided they show up. Bu there are lingering doubts that everything is still not quit explicit, and there is an uncomfortable amount of usin of names and Nobel Prizes as a means of generatin momentum.

Never is an eminent scientist happier than when jetting around the world to conferences at which his eminence in one field permits him to lecture unchecked in another. One actually expressed the view that he would rather the conference had been elsewhere than in London to give him the chance for a trip. The foundation seems to have been successful in spotting two weak points of scientists—their Boeing complex and their propensity to amateur philosophising.

And a check with Mr Moon's Washington office reveals that he is indeed planning to be in London for the conference.

A hundred years ago

THE study of "seaweeds" is probably affected as much by the general public as that of fish; and whether or not the great mass of people who visit the Brighton Aquarium and other similar resorts really go there with any idea of becoming more intimately acquainted with the wonders of the deep, there is no doubt that the exhibition of varieties of ocean plants would be as popular as that of fish. A seaweed growing in water is very different from seaweed cast up on the shore, and a careful selection and arrangement of specimens would greatly enhance the interest of the tanks, while at the same time their presence would prove beneficial to the fish. We recommend the hint to the notice of the authorities of the Brighton, Crystal Palace, and Southport Aquariums.

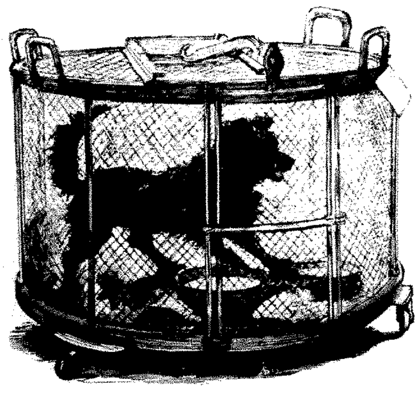
Mad dogs and Englishmen

The present epidemic of rabies in Europe is still spreading westwards and has now reached northern France; it could enter Britain. John Wilson has been looking at the risks to this country.



Caged and innoculated dog, 1884

THE most notable feature of the current outbreak of rabies in Europe is the involvement of wildlife. When the disease was eliminated from Britain and certain other European countries at the turn of the century, rabies had been maintained in the domestic dog. Now it is the fox population which acts as a reservoir of infection.

Whatever the reason, this new factor makes the present outbreak difficult to stem. As Britain's foxes are now more numerous than ever before, everything possible must be done to keep the disease away from them.

Rabies could reach Britain in two ways: a domestic animal incubating the disease might be landed illegally or an infected wild creature could make its way here under its own steam. The former is much more likely but although we can discount tales of rabid foxes attempting the channel swim, the second should not be ignored.

Bats can harbour rabies and certain species are known to arrive in Britain from the continent (the common long-eared bat, for example, migrates from Scandinavia to Yorkshire). Surprisingly, although rats are susceptible to rabies and carry other diseases from country to country on board ship, for some reason they have not yet brought rabies here. But as the distance between endemic areas of wildlife rabies and Britain diminishes, the likelihood of infection reaching us in these ways, however slight, must increase. And apart from greater vigilance against any animal stowaways, there is little that can be done to prevent it.

Illegal importation is another matter. According to a recent survey by the Ministry of Agriculture, Fisheries and Food (MAFF), 110 dogs, cats and other animals were landed illegally last year at the Kent ports alone. How many escaped detection is, of course, anyone's guess. Each of these animals might have been infected with rabies (some had been adopted only hours before the crossing) and transmitted the disease to pets and wildlife here. Although the report calls for greater deterrents against would-be smugglers, the greatest hope of keeping rabies out of Britain seems to lie in alerting the public to the dangers of the disease and in explaining why quarantine procedures are needed to prevent its entry.

And the public do need education; Britain has been free from rabies for several generations now and many people seem to think of it as a "disease of mad dogs". They have forgotten that rabies is almost always fatal in man once the symptoms appear—only two cures have ever been recorded—and so hideous are the agonies of the victim that euthanasia was once the common 'remedy'.

Nor are they aware of the regulations governing the importation of any animals they may acquire while on holiday. It is illegal to land an animal in Britain without an import licence and that is only given to owners who have made arrangements for six months' quarantine. Landing is held to have taken place before customs examination so even those people who declare their pet have committed an offence.

Official action in Kent last year prevented the entry of 33 animals but 10 evaded the port controls completely and were only detected inland (or on their way out of the country again). In all the other cases, it was the owners themselves who took action that prevented the animals from entering—and thus showed their ignorance of the law.

Customs officers reckoned that about 20 animals had been deliberately concealed. Perhaps the owners did so to avoid paying quarantine fee (about £120 for a dog) or perhaps from a misplaced sympathy of animals in quarantine. In either case, the fines handed out to the offenders (average £40) were hardly a deterrent. But under the Rabies Act (1974) fines have now been increased—£200 or more in some cases—and the local authority can have the animal summarily destroyed.

But if the worst comes to the worst how would Britain react to an outbreak? If pets or farm animals evaded quarantine there is some chance that the animal would be discovered before the disease had been transmitted to wildlife and to foxes in particular. That would be bad enough: family pets destroyed, valuable animals lost and people subjected to pain and anxiety. But if the disease did spread to the fox population things would be grave indeed. Continental workers have shown that rabies will still survive amongst foxes until their numbers are reduced to about 0.5 individuals per square kilometre. At this point the chances of a rabid fox infecting one of its fellows before it dies begin to peter out. Following the example of other European countries, the government would adopt a 'killer' policy, however unpopular it might be with some environmentalists.

With the exception of Denmark and possibly Belgium, this 'killer' policy has not met with much success. In France the disease is advancing along a front nearly 800 km long at the rate of roughly 30 km each year. To halt it would require a high degree of control over the fox numbers in a belt about 60 km deep—a prodigious effort. Britain is isolated, however, and the disease could be eliminated before it had taken a firm hold.

Plans are already prepared. Scientists from MAFF calculate that an area of about 12 miles radius around an outbreak of rabies would need to be virtually cleared of foxes. But before the hunting fraternity reach for their stirrups they should know that their activities would not be welcome for they could drive infected animals out of the area. An intensive poisoning campaign seems best.

Not everyone believes that the introduction of rabies to this country is inevitable but it is perhaps just as well that a new vaccine will soon be ready to treat any British victims of the disease. Developed at the Wistar Institute and produced at the Mérieux Institute in France the new killed virus vaccine is prepared from cultures of WI38 human tissue culture. Unlike vaccines now in use, such as the Duck Embryo Vaccine, it contains virus antigens and very little else—rather like the Salk polio vaccine. This should ensure that the incidence of side effects to vaccination will be greatly reduced.

Although trials of the WI38 vaccine are not yet complete the initial results are very promising. Even one injection quickly produces a very high titre of antibodies. The vaccine is expensive compared with conventional rabies vaccines but work is being done at the Clinical Research Centre, Harrow, to improve the dose regimen.

If the new vaccine passes its clinical trials only one painless vaccination in the arm would be necessary rather than the traditional 14 or so painful abdominal vaccinations now required. But no matter what improvements in treatment are on the way they are no excuse to take liberties with such a distressing and expensive disease. ☐

Astronomers share Nobel Prize

This year's Nobel Prize for Physics was awarded to two astronomers, Professor Sir Martin Ryle (opposite) and Professor Antony Hewish (below).

Not before time, the Nobel Prize for Physics has been awarded for work in radioastronomy. Given that at last the prize was to go in such a direction, it could hardly have been awarded to anyone other than Sir Martin Ryle, who pioneered the technique of aperture synthesis (cited by the Nobel committee) which produced a revolution in radio astronomy techniques.

The long wait for Nobel recognition for any kind of astronomy (the award to Hannes Alfvén a couple of years ago was not strictly for his work as an astronomer) has encouraged various interesting rumours. Was it true, the more irreverent young astronomers wondered, that Alfred Nobel's wife had at one time had a liaison with an astronomer, as a result of which the inventor of dynamite and benefactor had excluded astronomers from the list of those eligible for an award? Alas for those who savour such gossip it now seems that those rumours can be dashed. But never mind, the significance of Ryle's work has itself caused enough confusion among the non-scientific press to enliven many an astronomical coffee break.

Perhaps the reaction of the *Wall Street Journal* best sums up the predicament of editors called upon to explain aperture synthesis for a lay readership: "Ryle refined the use of telescopes", it said on its front page, and left it at that. But the technique, like many great advances, is not so difficult to comprehend in retrospect—it is the ability to think of it in the first place which singles Ryle out for special mention.

The synthesis implied by the name of the technique involves using an array of relatively small radio telescopes to mimic some of the properties of a much larger instrument. The latest of Ryle's brainchildren is the 5-km instrument near Cambridge; there, a set of eight telescopes placed along a railway track is used to build up a picture of radio sources as they would be 'seen' by a single antenna 5 km in diameter.

This can only be achieved by making observations of the same source over hours, days and even longer. The 5-km 'aperture' is built up by the motion of the elemental antennas as the Earth rotates, and by judicious adjustment of their positions relative to one another along the railway track. You can synthesise most of the aperture for some of the time, and some of the aperture for most of the time; you can't synthesise all of the aperture for all of the time, but the result is that with a computer it is possible to provide a map of the average intensity of the source as viewed by a non-existent 5-km dish.

So it is no surprise that Ryle's work has been recognised in this way. He already has just about every honour available to a British scientist, having been elected a Fellow of the Royal Society in 1952, appointed to the first chair of radioastronomy in the University of Cambridge in 1959 and knighted in 1966; he became Astronomer Royal in 1972. Not least among his many achievements are his teaching skills, which have probably contributed as much as his scientific ability to making the Cambridge radioastronomy group one of the best in the world.

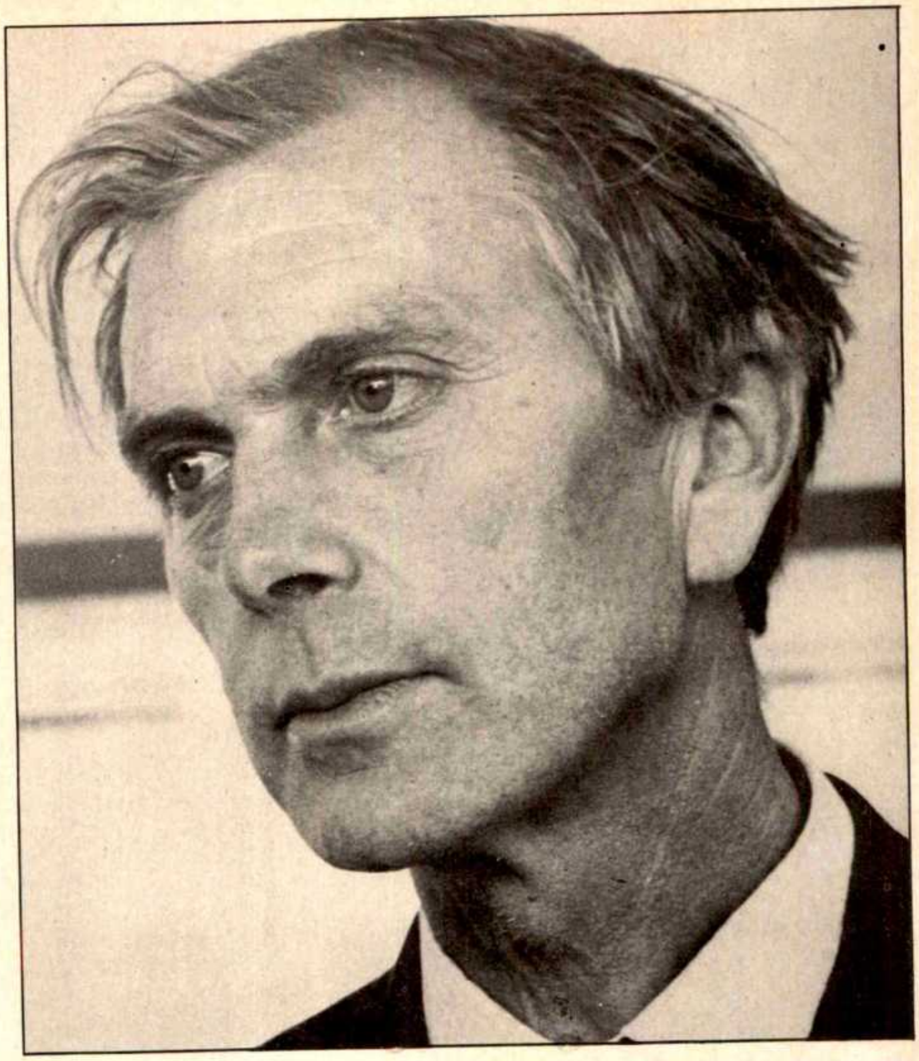
John Gribbin

The communication from Hewish and his students which reached the offices of *Nature* on February 9, 1968 will surely stand as one of the classic contributions to science in this century. Even to those of us accustomed to a succession of remarkable discoveries by radioastronomers, the news that there were objects in the Universe emitting radio waves in pulses, regularly spaced with intervals of about a second, strained credulity. A few days before this paper appeared in *Nature*, Fred Hoyle told me during a meeting in London that Hewish had discovered this new kind of radio source. My instant reaction was one of disbelief, an instinctive feeling that nothing in the Universe could behave like this and that his system must have been confused by the all too familiar problem of terrestrial interference. On the contrary the discovery was absolute and, in a sense which is rare in science today, the unique property of Hewish and his colleagues.

Why did Hewish find these signals when the rest of us with far more expensive and complicated radio telescopes missed them completely until we knew where and how to search, when they became obvious immediately? Hewish was studying the phenomenon of interplanetary scintillation. The effect, which he had discovered in 1964, occurs when the radio waves from a small diameter source such as a distant quasar are diffracted as they traverse the plasma clouds in interplanetary space. This induces a fluctuation in intensity with a period typically of about a second on otherwise steady signals. The study of this phenomenon was proving to be extremely useful both for the investigation of the solar corona and also for the measurement of the angular diameter of the distant radio sources. One of the last acts of the Department of Industrial and Scientific Research before it was disbanded in 1965 was to award Hewish a grant of about £17,000 to build a special aerial array which he had designed specifically for these investigations. There were at least three critical features of this concept which predestined that Hewish would discover objects in the Universe for which he was not searching. The aerial was very large, consisting of over 2,000 dipoles it covered 4.5 acres, and therefore had a far greater collecting area than any of the synthesis aerials at Cambridge, or of the steerable radio telescopes elsewhere. The receiver and pen recording system was designed with time constants to record fluctuating signals with periods of the order of a second. Finally, whereas radio astronomers all over the world were straining to work at shorter wavelengths in order to achieve more esolution with reasonably sized aerials, Hewish remained interested in the metre waveband where the plasma effects are more pronounced than at horter wavelengths.

In the event, the DSIR grant turned out to be one of the most cost-effective n scientific history. Less than two months after recording began, Hewish's student Miss Jocelyn Bell noted the recurrent pulses on the recording charts around local midnight when the normal scintillation phenomenon is inconspicuous. The drama of the succeeding months as Hewish established the extraterrestrial and stellar nature of the signals was hidden from the world until there could be nothing but astonishment at the final outcome. Six years later with 120 pulsars under study there seems little doubt that the signals have their origin in neutron stars, the end of a supernova explosion—a possibility suggested by Hewish in the initial publication. In these events the remains of the star have collapsed into a body with a diameter of only tens of kilometres, with densities of the order 10^{14} g cm^{-3} and possibly with magnetic fields of 10^{12} gauss.

It is this state of matter, hitherto merely a speculation of theorists, which is now observable, and the discovery must surely be acclaimed as entirely appropriate to the distinction now accorded to Hewish. BERNARD LOVELL



Royal inauguration for AAT

from Peter Pockley

As if to show that astronomical research is truly an integral part of Western civilisation, the largest optical telescope in the Southern Hemisphere was officially opened on October 16 to the strains of a string quartet playing Purcell, Dvorak and Mozart. Prince Charles came from England to say the words which set the massive 326-tonne telescope slewing and the 526-tonne dome rotating in a bravura display of engineering gymnastics which left the 400 official guests (comfortably seated on the floor of the telescope) applauding in amazement at the scale of it all.

The ceremony was nicely done. The engineers and scientists were at pains to show that they can turn on a show worthy of princes and premiers and the $A16 million of public money which it cost to build. For the people of the modest country town of Coonabarabran (population some 3,000), 29 km away, there had never been such a day. The town's five taxis had a field day ($A3 to the airport, $A8 to the telescope), the flags were out, the schoolchildren and the farmers met a real Prince, and the security men, obvious in their plainclothes, were there in force, giving rise to endless gossip.

Charter and VIP flights brought hundreds from Sydney (340 km to the south-east) and Canberra. There was a batch of 16 British scientists, too, led by Professor Sir Fred Hoyle, present Chairman of the Anglo-Australian Telescope (AAT) Board, and Professor Sam Edwards, Chairman of the Science Research Council. They will have to work hard to keep up an Anglo semi-image to the project—but there will be no trouble over control and access to the telescope which was established on a very formal intergovernmental level with 50% shares each. In the popular imagination the AAT will always be depicted in the midst of the gum tree landscape of the Warrumbungle ranges, spectacularly spread out beneath Siding Spring Mountain which is the 1,165-m-high platform for the big dome and its four smaller companions (three Australian National University reflectors and the United Kingdom's own Schmidt telescope). Despite the careful 50/50 protocol of the opening ceremony and the words of Prince Charles and Prime Minister Whitlam, the AAT will certainly become an Australian national symbol.

The description "largest in the Southern Hemisphere" is relatively easy to come by with feats of technology, for the land mass and population south of the Equator are but tiny fractions of the world totals. Yet this telescope is genuinely in the big league, and the situation of this giant eye where it can look right into the centre of the Galaxy and the Magellanic Clouds, the nearest galaxies to us outside our own, will give it an edge on its competitors (and collaborators) in the north which is sure to produce a spate of important observations. In the competitive astronomical stakes, though, the American 3.9-m telescope at Cerro Tololo in Chile will be only a few months behind the AAT.

The first calibrating photographs have already been taken before the mirror gets its first aluminising by the end of this month. Professor Ben Gascoigne, the Commissioning Astronomer, has enthusiastically pronounced the optics to be first class, better even than the specifications. He has now been joined at the AAT by the first Director, Joe Wampler, from Lick Observatory.

One European required for Spacelab

from Angela Croome

AT least one European scientist must be chosen in the next six months to accompany and tend the European experiments aboard the first Spacelab—the orbital workshop designed and built in Europe, which is to be raised into space and returned by the American Space Shuttle, the prime space effort in the United States for the 1980s.

This is a deliberate phase-shift of a size that is scarcely appreciated, so quiet has been the final transition from automated satellites to a reusable man-in-space project. Europe seems to be slipping into the manned space programme almost by the backdoor. Yet a series of papers of the recent Astronautics Congress in Amesterdam show how fast the options are closing and what a brisk pace is being set.

The subtle combination of reliability, systems compatibility, miniaturisation, ruggedness and strict programme planning and management that space operations demand are recognised as an industrial challenge compatible only with a major weapons development or a nuclear programme and a means of forcing the pace both of technology and of management. This indeed has been one of Europe's principal motives for getting into the space business in a substantial way. Added to these are the implications of man-in-space, in an international context specifically. The requirements of a manned spacecraft are at least an order of magnitude more severe than for automatic satellites. Pressurisation, life-support, toxicity and flammability restrictions must all be considered, inevitably increasing design complexity.

The first Spacelab will fly in the spring of 1980 and the final choice for this mission must be made in the spring of 1975. In fact the experiments and the man-in-space to run them are a composite package. If, for instance, a major University of Southampton experiment in atmospheric physics requiring constant supervision is selected, then a Southampton experimenter would be expected to accompany the instrument and operate it. This means, say the NASA space medicine experts who have overall responsibility for man-in-space survival and performance, that Spacelab scientists will have to be part-qualified as astronauts to complete their tasks under zero-*g* and other disagreeable and unfamiliar space conditions—in short they will have to be under 55 and obtain experience of piloting high performance jet aircraft. An interesting challenge for typical European departmental professors, one can say. The intention is that the first Spacelab payload will be shared roughly equally between Europe and the United States, with NASA having the final say in what flies and what does not.

More than 200 European proposals for the first Spacelab payload have already been received. In July the European space agency, ESRO, issued 200 invitations to appropriate industrial and academic bodies in Europe to put up ideas. Responses were due by the end of August but they are still flowing in. The German company Messerschmitt-Bölkow-Blohm is carrying out a preliminary screening, which includes tossing out proposals that are hopelessly incompatible or take insufficient advantage of Spacelab's special opportunities for bulky and relatively power-hungry experiments, and it will make its recommendations to ESRO in December. ESRO and NASA will then get together to define the first mission precisely and the final choice of experiments will follow from this.

The breakdown of the initial European proposals is interesting. By far the most numerous are technological and industrial rather than strictly scientific. (One German company has put up 20 proposals alone relating to communications.) The largest category is for space processing; 80 ideas have come in so far (more than twice as many as in any other category). There has been great interest in last year's American Skylab experiments in which pure crystals of such elements as germanium used in electronics components grew rapidly to diameters as great as 30 cm—impossible on Earth where growth is inhibited by gravity. There is speculation that space-grown crystals could actually bring down the high price of electronic components such as transistors and panels for solar heating. The production of special quality welds and of exotic alloys is also a possibility that European technologists wish to explore. Chemical separation by electrophoresis, possibly only under weightless conditions, promises greater purity in drugs and vaccines. Even an experimental space factory (requiring as it does bulky equipment, considerable power and a man in charge) has been outside the range of Europeans previously.

Earth resources and earth surveying is the second largest category of applications. It includes a novel experiment using a laser and a telescope to measure atmospheric scattering of light by gas particles; it will weigh two tons and consume one kilowat of power. Two-thirds of the Earth-monitoring proposals come from Britain. Skylab experience has shown that a man in charge is a great asset for this type of survey from space for he can react fast—for instance, refocus his instruments for detailed observation—when a special feature crops up.

The life sciences stand to benefit particularly from a supervised orbiting laboratory and there are plenty of ideas. A biological experiment is typically small and weighs little but it is expensive in human time.

The first Spacelab flight will be atypical. It will not orbit for more than a week and half the available power will be used to check out the subsystems and procedures. It will be primarily a technical flight to make sure everything works. Consequently two out of the four payload staff will be equipment technicians, presumably provided from the American side. But the timetable for the second Spacelab lags only three months behind the first and 40% of all shuttle flights are expected to carry a Spacelab. Europe is now inextricably involved in the major manned programme for the 1980s and is being paced on a sharp timetable by NASA. For the United States, the space programme has proved a forcing house in engineering and management. Manned missions raise the game more for they cannot be allowed to fail. □

Ariel-5

THE fifth in a succession of British scientific satellites which have been put up by NASA, in the absence of any suitable indigenous rocketry, was successfully launched this week from the Italian San Marco platform off the Kenyan coast. Called Ariel-5 (UK-5 before the launch) the satellite is only the second in the world to be given over entirely to X-ray astronomy, although individual X-ray experiments have been carried on other satellites.

Ariel-5 has six experiments on board, five British and one American, and information will be fed to and from the satellite by the Science Research Council's Appleton Laboratory at Slough. Four of the experiments, designed by University College, London (two), University of Leicester and Imperial College, London, will be pointed at specific X-ray sources whereas the other two (University of Leicester and Goddard Space Flight Center) will scan large areas of the sky and suggest where it might be particularly interesting for the pointing experiments to look. X-ray sources which turn on unexpectedly will be monitored in this way.

Mr J. F. Smith, Programme Manager for Ariel-5 in Britain, said this week that the satellite is functioning extremely well. All the systems are working, he said, and the only problems are minor ones which will be ironed out in a few days. One group already has interesting scientific results to hand. □

Checks and balances

SIR,—You raise the issue (*Nature*, September 6) of the role of journals in situations such as the proposed moratorium on plasmid engineering experiments You conclude for two reasons that you should not, as a policy, refuse to publish any report of experiments that might be carried out in defiance of the call for postponement—this call, or others like it Your two reasons were scientific variants of classic arguments against censorship what referee can judge papers for their ethical standing? Why drive publication underground? Yet you acknowledge implicitly the considerable power of journals such as yours to influence the standards—scientific, but perhaps ethical as well—of researchers Is there a way to use your power not through editorial censorship but instead as an important auxiliary to the checks and balances that exist or may need to be set up in the scientific community? For a model, consider the statement you will find in the instructions to contributors to *Proceedings of the National Academy of Sciences* "Manuscripts reporting experiments with humans should be accompanied by a copy of the document authorising the research by the responsible institutional committee "

American research hospitals and medical laboratories, as is generally known, have peer committees that must pass every plan for an experiment using human subjects, while there is still time—that is, before the experiment is begun But one important aspect of the open letter by the American group was that the danger was imminent, as Paul Berg, a leader of the group, has said several times, many of the experiments at issue were already planned to be completed before the international meeting in February, and their dangers if any, reside not in some future consequence or application of published results but in the experiments themselves Control must occur before the work, not merely before publication—not *imprimatur* but *laboretur* The nuclear fission or "Hahn should not have published" analogy is misplaced But many American and British biological laboratories, whose own people would be the first victims of an experiment gone wrong, are setting up biohazard or biological safety committees—scientific peer groups who will review research plans Such review is decentralised, appropriately motivated, and can be done early enough, it is done not just by peers every couple of years (as with peer review of grant applications in the American setting) but from week to week by colleagues who ought to be familiar with men, their work, and their equipment Such institutional structures seem to me to be admirably adaptable to part at least of the present problem As local safety committees begin to function, to reinforce them with an editorial requirement that reports submitted for publication be accompanied by evidence that the local review was done—like the rule at *PNAS* for human subjects—that would be a natural step with no taint of censorship

Yours faithfully,
HORACE JUDSON

Manting House,
Meldreth House, Cambridgeshire

Joke with whiskers

SIR,—Martin C Raff (Nature, 251, 184) describes nude mice which have spread through the immunological world at a remarkable pace Should they be called squeakers?

Yours faithfully,
M A PERKIN

Rochdale, UK

For the birds

SIR,—Dr W R P Bourne in his article "Egg Collector Collected" (*Nature*, **249**, 793, 1974) has done well to draw the scientific world's attention to the egg- and bird-collecting outrages regularly perpetrated by ornithologists, some of high repute, in North America I can vouch for his reference to a "conspiracy of silence", leading publications in the field have declined to publish any mention of this disturbing subject It is perhaps time that the rest of the world was made aware of the North American situation

One might imagine that the National Audubon Society (NAS) would take a stand against this After all, in the early days, were not two Audubon wardens murdered in defending egret nests in Florida? Yet when in 1969 two biologists shot 1,000 egrets in that state in the space of four weeks[1] this action was defended in a letter to me from the NAS by saying that it was all right because it was done by the "proper authorities"

What has been overlooked, however, is that experts in population dynamics (if experts they are) are not the only people with an interest in birds To a great majority of people there are ethical and aesthetic considerations involved in taking the lives of so many beautiful and harmless creatures This is perhaps an unscientific attitude, but birds do not belong to scientists and many people see no reason why, as in North America, ornithologists have some prescriptive right to kill them

One might imagine that no ornithologist would raise any serious objection to a code that asked a collector to state, when applying for a permit, the nature of the scientific research he was engaged upon, what new information and understanding about avian biology he expected to gain from a study of his specimens, what species he required and how many, whether such information could be gained from a study of pre-existing specimens, and whether his collecting was likely to harm any population The permit-issuing agency might then assess the scientific merit of the proposal and then issue a permit for a specified number of a named species for an approved purpose Yet this suggestion has been repeatedly rejected by ornithologists in North America Applicants are not obliged to state which species they wish to collect, open permits are issued without specifying which species may be shot or how many, and their holders may shoot any birds regardless of whether they are engaged in research on them or not

Yours faithfully,
J B TATUM

Blameworthy

SIR,—In my article last week ('For those in peril on the factory floor') the Royal Society was unfortunately omitted from the list of organisations taking no interest in asbestosis and similar consequences of technology In fact the Royal Society should have headed the list as the body with the greatest influence but the least inclination to do anything about it

PETER J. SMITH

news and views

In pursuit of the transforming genes of adenoviruses

ANALYSING the functional activity of any large pieces of DNA seemed a prohibitive task until the advent of bacterial restriction enzymes They have, without question, revolutionised the field of tumour virology, which was moving fast enough before their arrival, but which now produces important new facts at the drop of an enzyme This is because, although the overall function of some animal tumour viruses, particularly of the papova and adenoviruses, was quite well understood, mapping of gene function by conventional genetics was proceeding very slowly, through surely A method of selecting specific pieces of viral genomes to use as molecular probes has provided a way round this difficulty With such probes it is immediately possible to say, for instance, whether the fact that transformed cells do not show complete virus expression is because the complete viral genome is not there And it some of it is lost, then presumably that which remains contains those genes responsible for inducing or maintaining (or perhaps both) the transformed state Questions such as these are at the core of current efforts to demystify the process of transformation, which, many people hope, itself bears some resemblance to tumour induction *in vivo*

First to yield to mapping by restriction enzyme cleavage was the genome of SV40 Lagging somewhat behind, but now catching up rapidly, was analysis of the larger adenovirus genome Three new papers highlight recent developments in the adenovirus field, using specific pieces of the genome produced by restriction enzymes of *Escherichia coli* (*Eco*RI) and of *Haemophilus parainfluenzae* (*Hpa*I) Gallimore, Sharp and Sambrook (*J molec Biol*, **89**, 49, 1974) have analysed the viral DNA in lines of rat cells transformed by adenovirus 2 (Ad2) Their work, together with that described in a previous paper (Sharp, Pettersson and Sambrook, *J molec Biol*, **86**, 709, 1974), has led them to the conclusion that no Ad2-transformed rat cell contains the whole viral genome This conclusion could not have been reached without specific pieces of adenovirus DNA to use in reassociation experiments, which are conducted as follows Labelled probe DNA (whole or fragmented Ad2 DNA) is reannealed in the presence of unlabelled transformed cell DNA, and the increase in rate of reassociation produced by the viral sequences in the transformed cell DNA is measured This increase is proportional to the number of viral genomes present But using whole viral DNA as probe, there is no way of distinguishing between about one whole copy of the viral genome per cell and many copies of a small part of it—or any of the intermediate possibilities Also, the frequency of different sections of the genome may vary, giving increases in reassociation rate which are averages If restriction fragments are used as labelled probes instead, then the problem is vastly easier to disentangle *Eco*RI enzyme produces six fragments of Ad2 RNA, one of which (fragment A) represents 58 5% of the genome, and is at the left-hand or GC-rich end *Hpa*I enzyme produces seven fragments, four of which (fragments E,C,F and A) are in the *Eco*RI A fragment section of the genome This is useful since a combination of *Eco*RI and *Hpa*I treatment of adenovirus DNA allows dissection of *Eco*RI A fragment function With all these thirteen fragments as labelled probes, Gallimore *et al* measured their reassociation rates in the presence of DNA from nine different lines of transformed rat cells Six lines show essentialy the same situation they contain sequences complementary to about 14% of the viral genome, all of which are at the left end and represent all or part of *Eco*RI fragment A, and *Hpa*I fragments E and C The number of copies of these sequences apparently varies between lines though, as the authors point out, this may be due to variations in the ploidy of the cells, which would make the figure used for DNA content per diploid cell inaccurate Three other lines of transformed cells examined at the same time contain larger proportions of the adenovirus genome No line contains a complete genome, and no line lacks the sequences at the left-hand end

These findings are significant for a number of reasons First, for lack of evidence to the contrary, people have tended to assume until now that transformed cells contain at least one viral genome The only suggestion that this might not be so has come from the fact that there are transformed cell lines from which virus cannot be rescued by any of the available techniques All the lines used by Gallimore *et al* fall into this category It is interesting that rat cells are also semi-permissive for adenovirus Gallimore *et al* argue that those cells which survive and become transformed are those which, for one reason or other, contain defective viral genomes Possible reasons are either that the original infectious particle was defective, or else that part of the genome was lost after infection

If the presence of viral genes is necessary for the maintainance of the transformed state, then the work of Gallimore *et al* means that only 14% of the adenovirus genome is involved, since several of their cell lines contain only this much of it Another way of approaching this problem would be to use specific fragments of the genome to induce transformation It may be that the same left hand 14% of adenovirus DNA which is present in transformed rat cells contains all the information necessary to induce transformation in the first place A year ago, Graham and van der Eb (*Virology*, **52**, 456, 1973) described a technique for assaying infectivity of Ad5 DNA and showed that it could transform rat cells (*Virology*, **54**, 536, 1973) In this issue of *Nature* (page 687) they report some results of their efforts to localise the transforming genes by using sheared adenovirus DNA as the transforming agent The technique involves forming a co-precipitate of the DNA and calcium phosphate, which settles on to the cells, and from which DNA is taken up Graham *et al* demonstrate that whereas infectivity of adenovirus DNA is very sensitive to shearing, transformation can be induced by pieces only 1 0 $\times 10^6$ daltons in size—about 5% of the whole genome (20–25 $\times 10^6$ daltons) Separation of the two halves of the genome (which have an asymmetrical distribution of GC) reveals that it is the left or GC-rich half which has most of the transforming activity In attempting to localise this further, Graham *et al* have followed the effect of progressive enzyme digestion from the two ends of the genome inwards They conclude that because transforming activity is not affected

A sketch of Tasmanian Aboriginals done from memory by Annie Benbow in 1900 The last member of the race died in 1876, they had been moved from Tasmania to Flinders Island in the Bass Strait and the last 44 returned to a former convict probation station in Tasmania in 1847 Most of them died of influenza (Records of the Queen Victoria Museum No 49, 1974)

by digestion of the terminal 1% of the left end, but then decreases rapidly on further digestion, a segment extending from 1% in to about 6% of the genome comprises the transforming or 'T' segment The results do not, however, really justify this degree of precision in defining the T segment Its function could, for instance, be affected by destruction of sequences adjacent to it, and its actual position may not be so close to the left end as it seems A much more convincing approach would be to use restriction fragments of adenovirus RNA as transforming agents For instance, the *Hpa*I E fragment makes up 4 1% of the left end of the genome and it, together with some of the adjacent fragment C, should contain the T segment In the discussion at the end of the paper, such studies with restriction fragments are said to have been done, I hope their outcome will soon be published

The work of Graham *et al* reinforces the conclusions of Gallimore *et al* that it is the left end, and probably the left 14%, of the adenovirus genome which is concerned with cell transformation The experiments of Graham *et al* provide a way of studying the induction of transformation by pieces of DNA which cannot code for more than two proteins, and may only code for one The transcription of these sections of adenovirus DNA in transformed cells is now of even greater interest Previous work has already shown that only a small percentage of the viral genome is transcribed in some adenovirus-transformed cells—a phenomenon also well documented for other DNA tumour viruses The possibility that this is because most of the genome is actually missing as opposed to being repressed is an exciting one

Another technique which has been essential to recent experiments on SV40 transcription is the separation of the two complementary strands of SV40 DNA (Westphal, *J molec Biol*, **50**, 407, 1970) The technique depends on the asymmetrical transcription of twisted circular SV40 DNA by *E coli* RNA polymerase Using separated strands, it has been shown that sections of both strands of the DNA are transcribed during the lytic cycle (Khoury, Martin, Lee, Danna and Nathans, *J molec Biol*, **78**, 377, 1973) It is not possible to separate the two strands of adenovirus DNA in the same way Whole strands can be separated by differential binding of poly(U,G) to denatured Ad2 DNA followed by density gradient centrifugation Tibbetts and Pettersson (*J molec Biol*, **88**, 767 1974) have now published a combination of this technique plus some kinetic trickery which produces labelled single strands of all the six *Eco*RI restriction fragments of adenovirus DNA The technique is as follows Large amounts of unlabelled whole complementary strands of Ad2 DNA are prepared as described above A large excess of one whole complementary strand, for instance the heavy strand, is then mixed with labelled Ad2 DNA (whole or a specific restriction fragment), denatured and exhaustively renatured What happens is that in the presence of a large excess of unlabelled heavy strands the amount of labelled complementary light strands becomes limiting, and at the end of the reaction up to 50% of the DNA remains single stranded This residual single stranded DNA can be isolated by hydroxyapatite chromatography and corresponds to the heavy strands present in excess during the reaction The important point is that it includes both labelled and unlabelled strands, because the unlabelled heavy strands, being present in large excess, will preferentially renature, so effectively excluding their labelled counterparts from re-forming double-stranded molecules with their original partners, the labelled light strands The technique of Tibbetts and Pettersson produces very pure single-stranded preparations, and much of their paper is concerned with establishing this and with analysing the kinetics involved They then go on to use their preparations to show that in HeLa cells productively infected with Ad2, early cytoplasmic mRNA is complementary to 15% of the heavy strand and 30% of the light strand Late mRNA is complementary to 22% and 66% respectively Of this late mRNA, most is transcribed from both strands of *Eco*RI fragments A,B and C, and from the light strand of fragments D,E and F They discuss the implication that these areas of the genome may represent groups of genetic functions Now the use of single-stranded restriction fragments should be extended to analyse transcription in adenovirus-transformed cells

The three papers discussed in this review illustrate the application of three important techniques, namely, the use of restriction enzymes to produce specific fragments of viral genomes, the use of fragmented viral DNA to induce cell transformation, and the separation of complementary strands of viral DNA to study viral transcription They also herald what could be the final campaign in the battle to analyse transformation from the viral point of view Unfortunately, of course, transformation involves cells as well Whether, when the viral DNA that is present in transformed cells is fully understood structurally and functionally, we shall also understand how transformation is induced and maintained remains to be seen Tumour viruses should perhaps be considered as particularly useful triggers—because they can be analysed—for inducing cells to lose control of their division and growth What we shall have when we understand their function is a model for studying essential cellular control mechanisms The implications of this are immense

Elizabeth Rogers

Fighting foot-and-mouth

from a Correspondent

THE Animal Virus Research Institute celebrated the completion of 50 years of research on foot-and-mouth disease at Pirbright by holding a symposium on September 26 and 27

The changes in the world situation were reviewed by three speakers Dr J G van Bekkum (State Veterinary Institute, Lelystad, Netherlands) presented the tables of prevalence of the disease in European countries in the last 50 years During the major waves of disease—for example, in 1937/8 and in 1951/2—there were as many as 370,000 outbreaks in countries such as France and Germany The development of the tongue tissue vaccine by Frenkel had made possible the introduction of prophylactic vaccination and campaigns were begun in Holland in 1952 and, within the next ten years, in France and Belgium In each country the number of outbreaks fell dramatically, to under 10 yr^{-1} There had been problems in relation to immunisation of pigs but these were being overcome and, in the recent outbreak in France, vaccine had played an important part in control Europe still remained at risk through importation and through possible spread of the disease from Eastern Mediterranean countries but prospects for the control of ultimate eradication from Western European countries were good

Dr J H Graves (Plum Island Animal Disease Research Laboratory, New York) dealt with current problems in the control of the disease in the Americas In spite of the great efforts which have been made in extensive vaccination campaigns, results have not been as good as would have been expected on the basis of the European experience A particularly difficult problem was the control of potency of vaccines used in the field and it was here that the work of the Pan American Foot-and-Mouth Disease Centre in Rio de Janeiro might be expected to influence the situation This centre had already run many courses for laboratory workers in various countries in South America and, as a result, diagnostic methods had been improved and standardised Similar action is now being taken on vaccine potency control Dr Graves also referred to the new risks which were posed by the planned Pan-American Highway Plans were being discussed for quarantine zones to prevent spread of the disease northwards

Dr J B Brooksby (Pirbright) drew attention to the very uneven progress in control of the disease in countries in Asia and Africa Extensive campaigns have been carried out in the Soviet Union but the statistical information available is slight In many other regions limited campaigns have begun Perhaps the most encouraging of these were in relation to disease-free zones A good example was in Kenya, where a start had been made with a limited number (fewer than 400,000) of animals and gradually extended as the campaign was shown to be a success The zone in which the disease was not controlled included nearly two million animals Though the total number of animals so far involved in Asia and Africa was trivial in comparison to the population, it was in such schemes that lay the greatest hope for ultimate control of the disease and the development of useful programmes for livestock improvement

In another session, the biosynthesis of the virus and the structure of the virus particle in relation to its antigenic properties were reviewed by members of the biochemistry department of the institute A paper by Dr K M Cowan (Plum Island Animal Disease Research Laboratory, New York) carried the studies of virus properties into the field of vaccines The properties of two plaque variants isolated from cultures of virus of type Asia 1 in BHK cells were described Selection occurred during routine passage, the large plaque variant being predominant in monolayer culture, where as the small plaque variant was favoured by growth in suspended cells The small plaque variant was antigenically deficient in serological tests and also in its capacity to immunise cattle This finding emphasised the practical importance of the method of culture of the virus for vaccine production

The arithmetic of destruction

by David Davies

RARELY does the arithmetic of strategic nuclear weaponry surface for public discussion words such as superiority, sufficiency and imbalance are reckoned to be all that a layman, or for that matter a politician, should require All the more welcome then, is a recent pamphlet *Offensive Missiles* by Kosta Tsipis of the Stockholm International Peace Research Institute (Stockholm Paper 5) The author tries to form numerical estimates of destruction capabilities of the US and Soviet land-based missiles and concludes that the United States has been, is and will continue to remain well ahead

As long as the accuracy of missiles was inadequate to guarantee that the opposition's missile silos would be wiped out by a pre-emptive strike, it was foolish for a potential aggressor to target missile bases extensively, since the counterpunch aimed at cities could be so massive Thus for many years targetting doctrine was centred on the destruction by both sides of cities Gradually, however, the acquisition of missiles with higher accuracies capable of splitting in flight into several re-entry vehicles (MIRVs) each with its own target has enabled the possibility to be reconsidered of taking out all silos at each 'farm' and all farms simultaneously But this operation depends crucially on accuracies and reliabilities being sufficient to ensure that few, if any, opposing missiles remain serviceable That this is now on the cards is clear from, among other things, the declaration of the US Secretary of Defence, Mr Schlesinger, of the US government's intention to go for a counterforce capability

Warheads can destroy missiles in their silos by a variety of methods the overpressure from a blast is perhaps the most damaging effect and consequently silos are often hardened to withstand pressures up to several hundred pounds per square inch Let H be the hardening pressure In dealing with destruction probabilities the yield in megatons (y) and the circular error probability (CEP) in nautical miles appear in the ratios $y^{\frac{2}{3}}/(CEP)^2$ which call K, the lethality

Then if n warheads are aimed at the same target, the probability of demolishing it with at least one warhead is

$$P=1-\exp\left\{\frac{Kn}{2H^{\frac{2}{3}}\{fH\}^{\frac{2}{3}}}\right\}$$

The function $f(H)$ is slow varying and for H in the range 100–1,000 pound per square inch is roughly 0 15 Thus, for example, to have a probability of 90% of destroying a silo hardened to 1,000 p s i a value of Kn of 71 is needed

Tsipis makes the important point that countersilo capability of a strategic nuclear force is thus dependent on the product Kn summed over all missiles This should allow us to calculate the relative abilities of the United States and Soviet Union to annihilate each other's missile forces The figure shows how the two sides stand in 1974

The weakest element in all this is knowledge of the accuracy of the re-entry vehicle as reflected quadratically in the CEP The US values are fairly easily inferred from the open literature, but can the Soviet values—in all cases inferior to those of the US—be relied upon? Tsipis follows a policy of minimising the difference between Soviet and US accuracies the Soviet value is the most optimistic, the US value the most pessimistic supportable by published figures This may be sound policy, but it will raise a few eyebrows that Soviet missiles are so inferior to

American ones Our only knowledge of Russian missile capability comes from US intelligence sources and this must surely be a suspect channel since there may be political reasons at any time to exaggerate or underplay opposition strength (only three years ago the same sources were erring by a factor of five in the relatively simple business of estimating the yield of Soviet nuclear tests) Since the value of *K* is so strongly dependent on *CEP* and since Tsipis is strangely unprepared either to substantiate his figures or to point out publicly the weakest link in the chain, it should be said that the figures consequent on *CEP* are one man's estimate

If however they are to be trusted the inference is fairly clearly that whether by number of missiles (though not launchers) or by *Kn*, the United States is at present in a comfortably superior position, although Tsipis goes on to show that the value of *Kn* required to destroy all silos of either country with 90% probability is still larger than present values (see figure), so there is not yet a counterforce capability on either side

Even if in the course of continuous improvement (including terminal guidance on to targets) either side gets the theoretical capability to demolish all the missile bases of the other side, there are reasons to believe that this could not be converted into an assured practical capability Tsipis points out that there are at least two unknowns, one technical and one strategic

The effect of one nuclear weapon detonating in the vicinity of a missile site is to make the delivery of a second a highly uncertain process in the period during which the fireball effects persist On the other hand this makes the launch of missiles also a speculative process An attacking nation must aim for a simultaneous attack on all silos in the farm with such precision that a second volley is unnecessary

In all these calculations the submarine fleet, which may have saved some of its missiles, remains inviolate, as the location and destruction of submarines is still a highly chancy process Thus either or both sides could then launch a salvo against cities from submarines, and bombers would also come into their own

Do we know that either side would be caught flat-footed by a first strike? It seems unlikely that the attacked would fail to launch his missiles immediately the intention became clear—and these would be aimed at cities Thus counterforce is a strategy that without extraordinary assurances would be extremely perilous, and (as Tsipis points out) only guarantees an ever-increasing expenditure on nuclear arms

One point must be made in conclusion SIPRI has been trusted over the past decade for its immensely impressive output of objective figures It has recently, in my opinion, started to use the figures to pass value judgements on various governments The trend is clear in the conclusion to the present booklet which contains gratuitous comments and guesses on the superpowers and their intentions This diminishes the value of the report I have already noted that the figures on accuracy are inevitably subjective once views are expressed in a paper on the "unjustified and unnecessary" nature of US requests and on the doubtfulness that the Soviet Union will display "rational restraint" it is difficult to know whether these views have, even unconsciously, fed back into the subjective estimates

Immunisation with steroids

from our
Steroid Biochemistry Correspondent

Much has been learnt about the biological role of hormones by surgical removal of the endocrine glands responsible for their secretion and administration of components of glandular secretions to determine the reversibility of the changes produced But many glands secrete more than one hormone and it is desirable to selectively prevent or neutralise the secretion of a single hormone Antibodies against specific secretions are now making this approach possible For example, immunising an animal to its own steroid hormones reduces the concentration of circulating non-protein-bound steroid, the biologically active fraction, and prevents its interaction with tissue receptors

Some studies with antibodies to the female sex hormones have already been reported in rats This approach has been extended by Nieschlag *et al* (*Acta endocr*, *Copenh*, **76**, 556–569, 1974) to study the role of various steroids in the control of testicular and adrenocortical function As might be expected immunisation of rabbits with an antiserum to testosterone induced hypertrophy and hyperfunction of the testis as determined by histometry and measurement of serum testosterone levels But the weight of the accessory reproductive glands of the testosterone-immunised rabbits was lower than that of control animals, the prostatic epithelium was atrophied and the diameter of the alveoli reduced showing neutralisation of the biological action of testosterone Elevated concentrations of luteinising hormone and follicle-stimulating hormone were detected in blood and the changes produced were similar to those induced by administration of these gonadotrophins This increased secretion of gonadotrophins from the pituitary seems to result from binding of the testosterone to the circulating antibody making it unavailable to the hypothalamic receptors

In animals immunised against cortisol but not those receiving testosterone, androstenedione or oestradiol there was evidence for hyperfunction of the adrenal cortex In rabbits immunised against oestradiol there was an increased secretion of luteinising hormone and Leydig cell hyperplasia of the testes similar to that observed after testosterone administration but in contrast there was no change in follicle-stimulating hormone levels, testicular weight or in accessory reproductive glands The findings suggest therefore that oestradiol may have a differential effect on gonadotrophin secretion in the rabbit The results of immunisation against other related steroids were more difficult to interpret because of some degree of cross reaction of the antibody with other hormones

This way of investigating the role of various steroids in feedback control systems and their interaction seems very promising It will no doubt be developed further in the future if more specific antibodies to a wide range of steroids can be developed

Plants which survived glaciation

from Peter D Moore

THE explanation of present day, disjunct distribution of plants and animals by reference to climatic changes during the Pleistocene is a process fraught with difficulties European biogeographers have continually been at loggerheads with their geological colleagues concerning the likelihood of certain species surviving in isolated pockets or on solitary peaks during periods of major glacial advance In Norway a number of species show a bicentric distribution having stations on the northern and on the southern ends of the Scandinavian mountain chain, but being absent in the central area (for example, *Campanula uniflora*) Per-glacial survival in these two areas has been invoked as an explanation (Nordhagen in *North Atlantic Biota and their History*, edit by A Love and D Love, 241, Macmillan, Toronto, 1963) Similar suggestions were put forward in the explanation of disjunct groups of arctic alpine plants in Britain, such as the Teesdale assemblage (see *Nature*, **249**, 798, 1974) In both British and Norwegian situations, however, the problem may well be one of post-glacial disjunction owing to the extent of forest cover during the climatic optimum The survival sites may be post-glacial rather than per-glacial refugia and may represent relict fragments of plant communities which were widespread at the close of the last glaciation

In North America, a similar problem exists in the Gulf of St Lawrence area, where the disjunct distribution of some plants has been explained as the product of survival through the Wisconsin glaciation, but once again post-glacial forest spread could have been the agent of disjunction In the west, parts of the Yukon have never been glaciated and are thus undisputed potential refugia for those species capable of survival under periglacial conditions (see Lindroth, *Endeavour*, **29**, 129, 1970) Packer and Vitt (*Can J Bot*, **52**, 1393, 1974) have now proposed that the Mountain Park area of the Canadian Rocky Mountains in Alberta may have served as a glacial refugium

Their argument is based mainly upon the collection of disjunct arctic-alpine and alpine plant species which are found together in this area, though they claim that geological evidence also supports the idea of an ice-free area existing throughout Wisconsin times The ice-free regions would have included some foothill areas as well as protruding mountain peaks (nunataks) The disjunct species involved include some, such as *Eriophorum callitrix*, with a mainly arctic distribution, some, such as the bryophyte *Orthotrichum pylaisii*, which occur in both arctic and alpine situations, and some, such as *Telesonix jamesii*, which are essentially alpines and occur in isolated mountain sites mainly to the south of Mountain Park A collection of disjunct species (the authors name sixteen), however, does not in itself prove per-glacial survival There are two alternative explanations which must be examined first, namely long-distance immigration from a distant centre of dispersal, and disjunction by forest invasion of territory once occupied by the relicts

Long-distance dispersal is unlikely to account for all the species, since most have very poor dispersal mechanisms If forest spread had caused the disjunction, then one would expect survival of at least some of the species at various sites between their now isolated stations, since at no time in the post-glacial period has the tree line been high enough to eliminate them from all geographically intermediate sites They are, however, absent from these The authors' hypothesis of *in situ* survival of the Wisconsin glaciation is thus the simplest available to explain the distribution

One must still ask why the plants did not spread from this centre during the conducive climatic conditions of late-Wisconsin times, prior to forest invasion It is difficult to conceive of severe genetic impoverishment occurring in populations isolated for a period (frequently interrupted) of at most 100,000 yr One must hope that future palaeoecological studies of those species will supply more information on their glacial histories Meanwhile, it is a matter for concern that this area is not included in any Canadian or provincial conservation programme and is currently threatened by mining

Plumbing at the North Pole

from Peter J Smith

ALTHOUGH the original soundings taken by Nansen (recorded in *Norwegian North Polar Expedition, 1893–96*, vol 4, Jacob Dybwad, 1904) left no doubt that the Arctic Ocean is a deep water basin, the full complexity of the region has only become evident since modern surveys and traverses began in the later 1950s Few would now disagree with Dawes (in *Implications of Continental Drift to the Earth Sciences*, Academic Press, 1973) when he says that "the basin is not a simple deep structure with uniform character but is made up of individual basins separated by submarine ridges of contrasting morphology", although there would perhaps be less agreement on how the ridges were formed and hence on what they represent in terms of plate tectonics

There are three ridges in the Arctic Ocean The Lomonosov ridge is flat-topped and relatively narrow, rises to within 954 m of sea level, extends 2,000 km from the vicinity of northern Greenland and Ellesmere Island to the New Siberian Islands off the coast of Russia, and splits the total basin unequally into the Amerasian (larger) and Eurasian (smaller) basins The Amerasian basin, in turn, is divided unequally by the Alpha ridge, a broad fractured structure with rugged topography and complex morphology, and the Eurasian basin is cut roughly in half by the Nansen ridge, a seismically active offset extension of the mid-Atlantic ridge Significantly, the three ridges are almost parallel to each other Less significantly, the Lomonosov ridge is unique in that its edge lies beneath the north geographical pole

All the evidence suggests that the Nansen ridge began spreading about 40 million years ago and continues to do so at a rate of about 1 0 cm a year, it has a clear geographical relationship with the mid-Atlantic ridge, is associated with a well defined pattern of earthquake epicentres, and gives rise to typical linear magnetic anomalies (albeit with smaller than usual amplitudes) The Alpha ridge, on the other hand, is evidently inactive in terms of both seismicity and spreading, although it is associated with linear magnetic anomalies of high amplitude This last observation led Vogt and Ostenso (*J Geophys Res*, **70**, 4925, 1970) to propose that the Alpha ridge, though now dormant, is the site of ancient seafloor spreading According to this plausible interpretation, spreading would have begun about 200 million years ago (possibly simultaneously with the opening of the North Atlantic) and ended about 40 million years ago when the activity transferred to the Nansen ridge Dawes tends to be more cautious about this, drawing attention to Vogt and Ostenso's own admission that the Alpha ridge may represent "something entirely different"

But if the Alpha and Nansen ridges are essentially oceanic features, the Lomonosov ridge is thought to be of continental origin, although it lies in an anomalous geographical position It is aseismic, has no linear magnetic anomalies associated with it and it is generally quiet magnetically—all of which suggests a scarcity of igneous rock But this is negative evidence, and positive evidence in favour of a continental composition is more sparse It is true that a seismic profile obtained by Ostenso (in *Implications of Continental Drift to the Earth Sciences,* Academic Press, 1973) indicates a smooth topography and a deep sedimentary structure, but again this relies for much of its effect on a comparison with known oceanic ridge structures It is also true that positive, if indirect, evidence for the Lomonosov ridge's continental nature may be adduced from structures on the land adjacent to the Arctic Ocean, although, as Dawes points out with respect to the alignment of the ridge with geological features on Ellesmere Island, this support could prove to be ambiguous in the face of data suggesting that the ridge, although continental, originates elsewhere

More positive evidence is thus urgently required—and has now been provided, within limits, by Lillestrand and Weber (*J Geophys Res*, **79**, 3347, 1974) During the Second Canadian North Pole Expedition (1969) these workers measured the plumb line deflection in the vicinity of the Lomonosov ridge near the North Pole by comparing the paths of a drifting ice island station as measured astronomically and as determined by means of a Transit Satellite receiver (The displacement between the two independently determined paths gives the plumb line deflection almost directly) The mean deflection at 89° 40′ N, 77° W was found to be 9 arc s towards 34° E, and the estimated deflection at the rotational north pole is 4–8 arc s in the direction 20–40° E

This is apparently the first time that the plumb line deflection at the North Pole has been determined, and so the result is of interest in itself But it is also important in connection with the nature of the Lomonosov ridge, for Lillestrand and Weber go on to show that the measured deflection is in good agreement with the value predicted from a model constructed on the assumption that the ridge is a sedimentary structure underlain by a lower density continental crustal block Moreover, several gravity measurements made in the area are consistent with the free air gravity anomaly computed from the same model. Of course, all gravity-based interpretations are ambiguous in that any data set can be accounted for by a large number of different structures Within this limitation, however, the new result from the North Pole cannot but strengthen support for the view, first put forward by Heezen and Ewing (in *Geology of the Arctic,* University of Toronto Press, 1961) and later expanded by Wilson (*Nature,* **198**, 929, 1963), that the Lomonosov ridge represents a section of the Siberian continental margin split off when the Nansen ridge became active beneath the edge of Eurasia

Democratic science

THE multiauthor paper has become a commonplace and the multinational project has come into its own But authors usually achieve a consensus before publishing and present a united if sometimes cautious front The latest multinational attempt to resolve some of the thorny problems of mycobacterial taxomy (Meissner *et al*, *J gen Microbiol*, **83**, 207, 1974), however, has resulted in a published majority report with six out of the twenty-two authors presenting their own dissident statement on one of the proposals Perhaps this approach could be encouraged, it would certainly make for more interesting reading in most scientific papers

Diseases of skeletal muscle

from a Correspondent

MUCH of the work of the Third International Congress on Muscle Diseases (Newcastle upon Tyne, September 15 to 20) dealt with the interaction between nerve and muscle Dr L Guth (National Institutes of Health, Bethesda) opened the meeting with a review of trophic interactions, dealing especially with cross innervation studies Other workers discussed experiments utilising chronic stimulation of nerve or muscle both in animals and man to alter the histochemical, biochemical and physiological characteristics of muscle

In a session on myasthenia gravis Dr E Heilbronn (Stockholm) described the production of experimental myasthenia gravis in rabbits immunised with a purified preparation of acetylcholine receptor from the electric organ of *Torpedo,* and the effect of antibodies against this receptor This will probably prove a fruitful model for the investigation of abnormalities of neuromuscular transmission Various other immunological aspects of myasthenia gravis were considered, including the significance of HL-A antigens and various skeletal muscle and other antibodies Dr G H Oosterhuis (Amsterdam) reported no correlation between thymic histology and the prognosis for myasthenia gravis

A session was devoted to the neural theory of muscular dystrophy Several workers, including Drs C P Panayiotopoulos (Athens National University), J P Ballantyne (University of Glasgow) and Professor W G Bradley (University of Newcastle upon Tyne) questioned the evidence upon which the theory was originally based They considered both technical aspects and questions of logic, Professor A J McComas (McMaster University) defended the theory Both Panayiotopoulos and Ballantyne reported studies using different techniques of motor unit counting in human muscle, finding no fall in the number of motor units in dystrophic patients compared with their own controls The estimated number by their two different techniques was however not identical Bradley reported that changes in the nerves of mice with muscular dystrophy were not found in patients with Duchenne muscular dystrophy, though Dr Mukoyama (Nagoya) described some changes of the myelin sheaths in the spinal roots of such patients Bradley's studies repeating the transplantation experiments originally taken to support the neural theory gave reason to suspect that the contraction of the host muscle might be recorded from the transplanted regenerate Dr Neerunjun (Royal Postgraduate Medical School) however reported studies which supported the neural theory Dr A C Peterson (University of British Columbia) described chimera experiments indicating that a skeletal muscle fibre might be morphologically normal though it had 96% dystrophic nuclei From these experiments he concluded that the cause of murine muscular dystrophy lay outside the skeletal muscle In discussion, the question was raised whether one or two per cent of normal nuclei might provide sufficient of a putative deficient substance to cure the disease Dr M Rathbone (McMaster University) showed that transplantation of foetal spinal cord from dystrophic chicks could produce biochemical enzyme changes indicative of dystrophy in otherwise normal chicks

A session was devoted to papers bearing on the vascular theory of muscular dystrophy Neither Drs O B Paulson and F Jerusalem (Mayo Clinic, Rochester) nor Dr M D O'Brien (University of Newcastle upon Tyne) found decreases in muscle blood flow or capillary abnormalities in Duchenne muscular dystrophy Professor K Kunze commented that denervated human skeletal muscle shows similar or even lower P_{O_2} values when locally measured and compared with those in Duchenne and other muscular dystrophies No defence of the vascular theory came in discussion from Dr W King Engel (National Institutes of Health, Bethesda), though he restated his theory in a later review session dealing with aetiological theories

In sessions on the clinical management of human muscular dystrophy Dr I M Siegel (University of Chicago) reviewed the results of his enthusiastic and effective treatment of muscular dystrophy with surgery and surgical appliances Dr R H T Edwards (Royal Postgraduate Medical School) described a simple dynamometer for use in clinical studies of patients with muscle weakness Dr J B Peter (University of California, Los Angeles) described a controlled trial of long-term high dose corticosteroid therapy in Duchenne muscular dystrophy Initial results indicated a fall in the serum enzyme activities, but no certain clinical improvement to date

Other sessions dealt with normal muscle, with various forms of myopathy, malignant hyperpyrexia, and myositis, as well as the various animal models of muscular dystrophy Biochemical studies of membrane abnormalities in myotonic conditions proved stimulating Drs A D Roses and S H Appel (Duke University) reported various membrane abnormalities, including that of membrane protein phosphorylation in dystrophia myotonica Dr R M Andiman (University of California, Los Angeles) found an increase of desmosterol in the membranes of animals rendered myotonic by various drugs, but no increase in human myotonic membranes

Peripheral nerve studies in health and disease were fully considered in the congress A session and a workshop were devoted to axoplasmic flow Dr S Ochs (University of Indianapolis) reviewed the evidence for fast and slow rates of axoplasmic flow and Dr G W Gross (Munich) described his experiments on the garfish olfactory nerve, which led him to propound a theoretical model of the many features making up axoplasmic flow Dr B G Livett (Monash University) (for Professor L Austin) described experiments showing marked abnormalities of axoplasmic flow of proteins and lipids in the nerves of dystrophic mice In a fruitful workshop on motor unit function, Professor E Henneman (Harvard) described evidence that motor units have a regular and repeatable order of activation This gave rise to considerable discussion, not all speakers being convinced by the evidence

Mad March hares

from our Animal Ecology Correspondent

THE springtime behaviour of hares, normally peaceful and retiring creatures, is proverbial During February, March and April they gang together, becoming bellicose, vocal and extrovert The 'madness' lasts only a few weeks, beginning at the start of the breeding season but ending long before the breeding season is finished

In a thorough study on the breeding biology of the European hare, G A Lincoln has brought to light some intriguing questions (*J Zool, Lond*, **174**, 1, 1974) The period of sexual quiescence in does lasts from September to January, and in bucks viable sperm occurs in the epididymides from mid-December to early September The number of sperms present reaches a high level from February to June with the maximum testosterone content in April Pregnancies were recorded every month from January to August with the maximum number of females pregnant and the highest mean number of foetuses per pregnancy occurring in April, May and June

Lincoln found spermatozoa in cervical smears taken from does during November and December, well before the first ovulation of the season (In this mammal ovulation is initiated by coitus Stieve, *Zool Anz*, **148**, 101, 1952) The hormonal complexion of the hare does not allow ovulation to occur until early January, so matings earlier than this fail to result in pregnancy Perhaps such matings have a social function providing necessary courtship and mating experience for young animals

'March madness' is thought by Lincoln to be a rut having the function of stimulating the resumption of breeding activity among the does Wynne-Edwards, however, believes it to be a form of self advertisement (*Animal Dispersion in Relation to Social Behaviour*, Oliver and Boyd, Edinburgh, 1962) The complex chasing and boxing of the 'madness' is a social means of establishing a breeding hierarchy amongst the males, possibly identifying socially inexperienced individuals from the rest He argues that this must happen right at the start of the breeding season so that the year's "quota" of reproduction can be assessed Both interpretations can be correct and verification must await further study Certainly the behaviour has little immediate physiological effect as only 16% of March madness conceptions result in hares the following spring compared with between 39% and 45% from later conceptions

The suggestion that a mechanism exists whereby young hares gain sexual experience before actually breeding has a parallel in at least one other species of mammal Young male baboons mate with females at the very start of their oestrus cycles when the females' receptivity and chance of pregnancy is low Towards the end of their cycles, females mate with older and more experienced males when their receptivity is high Most pregnancies result from these late matings (Washburn and DeVore, *Scient Am*, June 1961) Perhaps even hares have a society with complex rules of conduct which offers to instruct young initiates in its mysteries

Chemical uniformity of airborne particulate material, and a maritime effect

D. H. Peirson, P. A. Cawse & R. S. Cambray

Atomic Energy Research Establishment, Harwell, Oxfordshire, UK

Airborne particulate material has a uniform elemental composition, in which the industrial elements are enriched relative to soil In the surface of the North Sea the trace element content seems to be massively enhanced relative to bulk seawater

DURING 1972–3 measurements of the trace element content of airborne dust, rainwater and the dry deposit, sampled at various places in Britain, following exploratory work at a single location[1,2], has yielded much basic information on the annual deposition inventory, the "washout factor", and the "dry deposition velocity" which will be described in detail elsewhere[3,4] Meanwhile it is opportune to report observations that, first, demonstrate a remarkable uniformity in the elemental composition of the general aerosol and, second, suggest a considerable enhancement of the trace element content of the ocean surface

The methods of sampling and analysis have been published previously[2] and will be restated only briefly Samples of airborne dust have been collected by drawing air through a filter paper (Whatman 40) held in a polypropylene duct, which is capable in still air of collecting particles (specific gravity 1) of diameter up to about 150 μm Rainwater is sampled by polythene funnel and bottle Because the funnel is exposed continuously, both wet and dry deposition are collected The dry deposition is collected separately on a horizontal sheet of filter paper (Whatman 541) sheltered from direct rain Samplers are mounted at 1 5 m above ground, are run continuously and are changed each month The location of the sampling stations is shown in Fig 1

Samples are analysed mainly by neutron activation followed by gamma-ray spectrometry but also by X-ray fluorescence, atomic absorption and chemical methods

Chemical uniformity

The average concentrations in air during 1972 of about 30 trace and other elements at seven sites in Britain are tabulated in Table 1 The sites were chosen to represent rural and more industrial cases, although all are non-urban The range of the values for an (non-maritime) element seem to span an order of magnitude or more Now if the results from each site in Table 1 are referred to a single element, say scandium, then the ratios so obtained show much less variation from place to place (except for Na, Cl and Br) If in addition the concentration ratio of an element relative to scandium is normalised to the same ratio given by Bowen[5] in average soil then this "enrichment factor" shown in Fig 2 demonstrates the reduction in variation from place to place It also separates the elements into two classes, those that are "soil-derived" like scandium having factors about unity and those of "industrial" origin that are enriched relative to soil by a few to many times There are two anomalies in Fig 2—the large excesses of cobalt and nickel at Trebanos are probably due to nearby industrial sources Obviously it is not difficult to seek excessive and anomalous values, for example, in a busy street in London during July 1972 the enrichment factor for lead was nearly 8,000 whereas the general rule from Fig 2 is that the ratio of lead to scandium is sensibly constant over all the sites at a value somewhat more than 1,000 times that in nominally average soil Enrichment factors may be derived from observations at more distant sites in the northern hemisphere For example, elemental

* February–December 1972
No adjustments have been made for filter efficiency[2]

analysis of air samples from the Osaka district of Japan[6] can be summarised to give factors close to those reported in Fig 2 for V, Co, Ni, Zn, As, Se, Sb and Pb Another comparison using aerosol analyses by Rahn *et al*[7] from a remote site in northern Norway again illustrates the uniformity of enrichment factors for V, Cr, Zn, As, Se and Sb In fact Rahn (private communication) by considering the distribution of enrichment factors worldwide, from remote to industrialised areas, has also demonstrated a general uniformity but with a sharp rise of enrichment factor at the highest elemental concentrations, that is, in the vicinity of a source

The division of elements in Fig 2 into soil-derived of low enrichment and industrial of higher enrichment conforms very well to the classification performed previously[1,2] according to dry deposition velocity[8], that seems to be correlated with particle size The decrease of enrichment factor with increasing dry deposition velocity (rate of dry deposition/concentration in air) is shown in Fig 3 for trace elements determined at Chilton There is as yet no direct comparison at this site of particle size against deposition velocity However preliminary measurements[3] of the mass-median diameter at Chilton, using an Andersen sampler, confirm that deposition velocity increases with particle size and suggest that, at this site, a deposition velocity of 0 5 cm s^{-1} corresponds to a mass median diameter of about 1 μm (specific gravity 1) This suggests that those trace elements that are enriched above the

No adjustments have been made for filter efficiency[2]

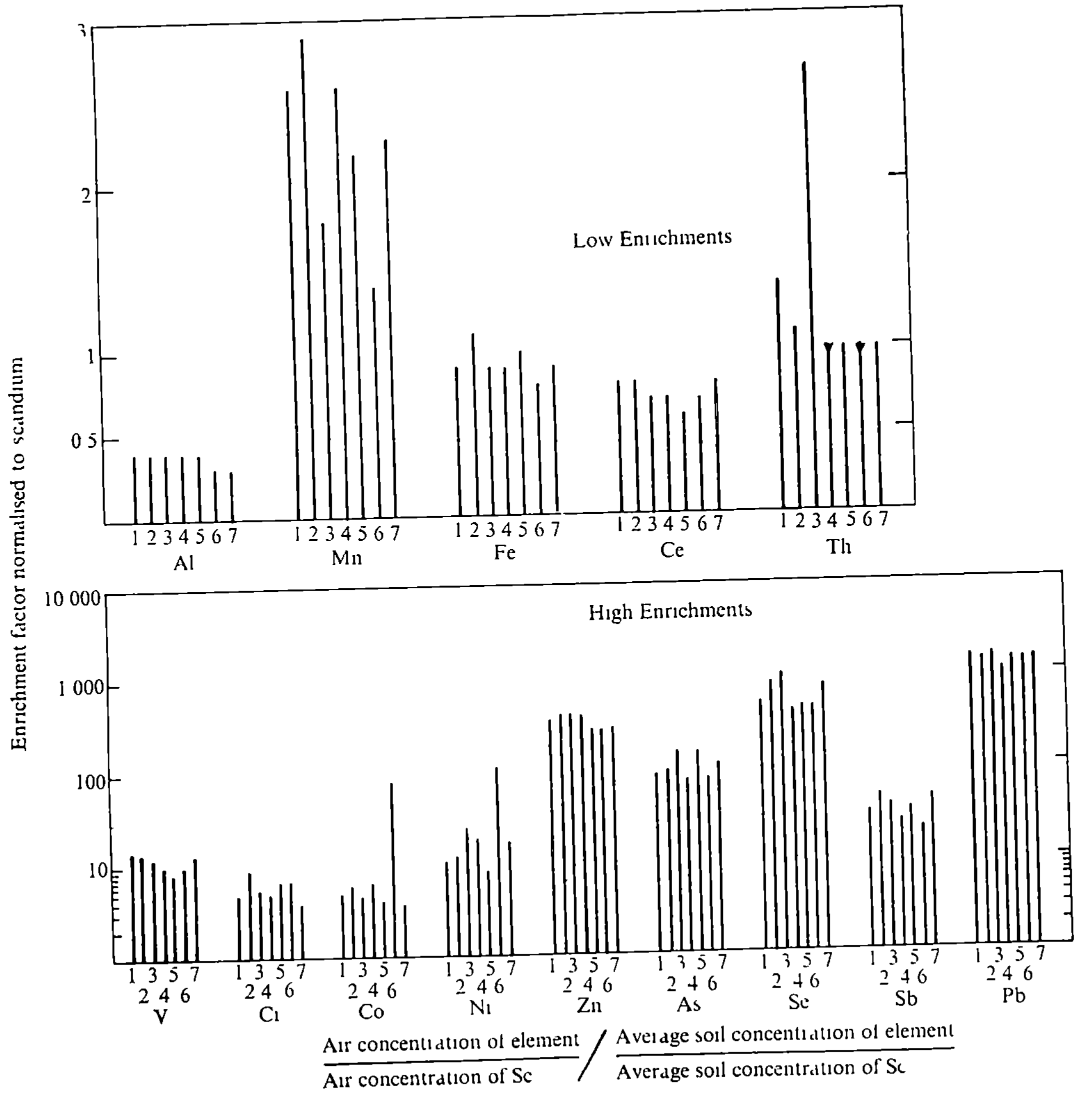

Fig. 2 Air particulate enrichment factors (1972) Sites 1 Chilton, Berks, 2 Leiston, Suffolk, 3 Lerwick, Shetland Is, 4 Plynlimon, Montgomery, 5 Styrrup, Notts, 6 Trebanos, Glamorgan, 7 Wraymires, Lancs

natural levels in soil appear as small particles, presumably formed by condensation after industrial combustion whereas natural particles formed by grinding and wind erosion are larger But it is not impossible that the combustion of fossil fuels for example can produce both large and small particles

If the results of the measurements presented above are representative not only of Britain but also of foreign sites in the same latitudes, then it is necessary to imagine and explain a general aerosol pervading this zone of latitude having a varying concentration but essentially the same elemental composition (except for the maritime elements Na, Cl and Br and also for regions in the vicinity of pollution sources, for example Trebanos, Fig 2) It is difficult to postulate a mixture of such sustained uniformity from separate natural and industrial sources that generate particles of differing characteristic sizes Material, that may be raised from the Earth's surface either by wind causing the suspension of soil and dust or by industrial processes, will probably lose particles of size greater than about 10 μm to gravitation It is possible that enough of the particulate material below this limit will diffuse vertically upwards and join the westerly airstreams in the middle and upper troposphere at altitudes up to about 15 km These air streams have been invoked to explain the passage of radioactive debris from nuclear explosions[9,10] Scavenging by rain will occur at and below cloud level (up to 3 km) and there will be continuous exchange by vertical diffusion throughout the troposphere There is supporting evidence in the long range transport of soils[11,12] Delany *et al*[13] measured vertical profiles up to an altitude of 9 km over continents and oceans, and found that over both, the component of the aerosol derived from the continents was dominant above about 2 km It is reasonable to relate the aerosol behaviour described above to the "tropospheric background aerosol" proposed by Junge[14]

There is thus a plausible explanation of the transfer of particulates from the surface and subsequent transport within the atmosphere, but not of the initial formation and subsequent maintenance of the mixture of elements It is suggested, but cannot yet be proved, that the natural and artificial aerosols are produced by the separate processes, are mixed in the atmosphere, are circulated zonally and eventually reappear at the Earth's surface Alternatively the aerosol mixture, or the part of it that is available for transport on a zonal or global scale, might be produced by a common process, not yet identified After deposition the dust is available for resuspension, more so from the paved surfaces of urban areas which are thereby exposed to higher concentrations of airborne dust than are rural areas

Provided that the observed effect of chemical uniformity is real and is not caused by some undetected artefact of the sampling equipment, then two points of significance emerge First, a scientific explanation of the formation of the aerosol mixture is required and could be pursued by a microscopic examination of the physical and chemical characteristics of the particles Second, in relation to the monitoring of dust-laden environments, it should

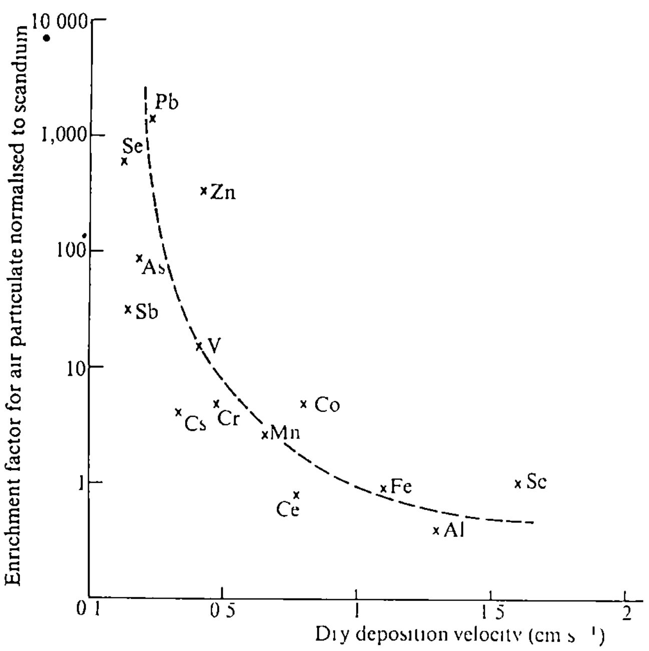

Fig. 3 Enrichment factor and dry deposition velocity at Chilton (Berks) 1972

be possible by comparison with the "normal" elemental mixture to identify and define the presence of elemental "pollution"

Maritime effect

The observations of the effect of the ocean upon the atmospheric aerosol are less direct and comprehensive than in the case given above The observations were made as part of a preliminary attempt to estimate the input of trace elements from the atmosphere into the North Sea[4]

The average concentrations of trace elements in air and rain for a 12-month period during 1972–3 are shown in Tables 2 and 3 The sampling stations were sited at or near the east coast of Britain except for Arran in the west of Scotland, a platform at 25 m above the North Sea about 55 km from the Norfolk coast and Petten in north Holland The only noticeable trends in the air concentration results of Table 2 are that the values at Lerwick and Collafirth, being clean and rural, are generally lower than elsewhere except for the maritime elements Na and Cl On the other hand the rain concentrations in Table 3 are higher by up to an order of magnitude at the platform in the North Sea than at the other sites, not only in the maritime elements but also in the other elements considered above to have soil and industrial origins Such an enhancement would complicate any attempt to calculate the deposition of trace elements by rain into the North Sea

There is no ready explanation of this effect The high values of elemental concentration in rain obtained at the platform are general it is unlikely that local contamination would elevate the values for all elements Only Zn appears in excessive amounts and is a possible contaminant from the platform itself Generally rain collectors situated on or near the sea would receive an amount of sea-spray that is significant compared with the actual rain that is collected As has been demonstrated by Freudenthal[15] for Sr-90, it is unlikely that this spray will scavenge trace elements from the atmosphere so much more efficiently than rain

The most plausible explanation is that the excess of trace elements in rain has arrived with the sea-spray, driven by wind from the ocean surface The air samplers do not register this excess presumably because the size of the spray particles is beyond the upper limit of collection of the sampling duct The limit calculated for the downward-facing duct would be reduced in winds having large horizontal velocities

The enhancement of the rain content by this maritime effect may be demonstrated by considering the concentration of an element in rain relative to that in air from Tables 2 and 3 This ratio ($\mu g\ l^{-1}$ of rain $\mu g\ kg^{-1}$ of air), which takes account of the differences from place to place in the concentration in air, is equivalent to the washout factor used previously[1,2,8] The relation between this rain air ratio and the seawater content of rain from site to site is demonstrated in Fig 4 for several elements With increasing seawater content, as indicated by the concentration of Na, the value of the ratio increases, typically by five times in the samples taken on the platform This

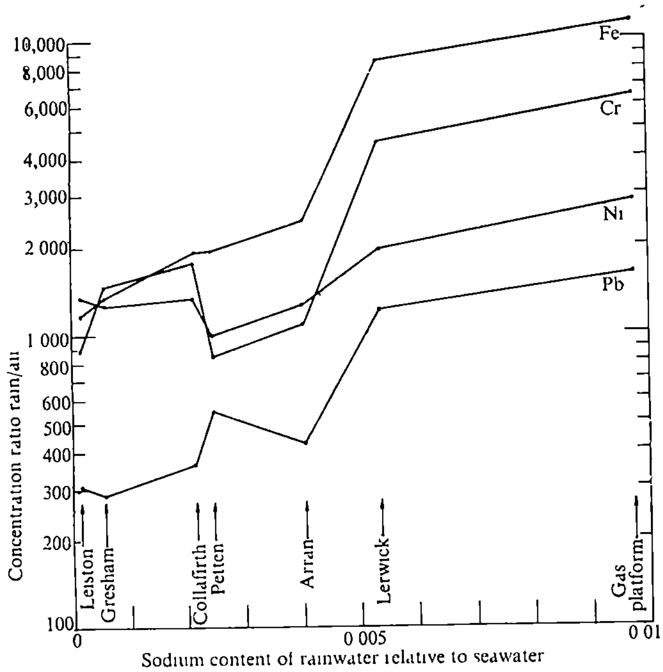

Fig 4 Elemental concentration ratio, rain/air and seawater content of rain (1972–1973)

implies that most of the elemental material measured in the platform samples has been collected as spray from the surface of the sea If the trace element content of these samples is compared with that in bulk seawater[16,17] (Table 3) relative to Na, then it can be seen that the concentration of these trace elements, derived from the sea surface, is enhanced by several orders of magnitude compared with that in bulk seawater

Duce *et al*[18] and Piotrowicz *et al*[19] have measured enrichments of up to 50 times in surface layers The present observation is consistent with their results extrapolated to the surface microlayer and also with the results of Szekielda[20]

An excess of material on the ocean surface can arise in two ways, either by deposition from the atmosphere or by concentration of material from within the sea The present work requires extension and elaboration to confirm these results, but if the enrichment of the sea surface is a real effect then it would be logical to investigate the mechanism of enrichment and also the role of the ocean as a source of material for transport in the atmosphere, locally and on a much larger scale

This work was supported by the Natural Environment Research Council and, for the maritime measurements, by the Ministry of Agriculture, Fisheries and Food (Lowestoft) and the Department of Agriculture and Fisheries, Scotland (Aberdeen) The authors are indebted to the individuals and organisations, who managed the sampling stations, and to N J Pattenden and L Salmon for advice and collaboration

Pitcairn Island—another Pacific hot spot?

R. A. Duncan & I. McDougall

Research School of Earth Sciences, Australian National University, Canberra 2600, Australia

R. M. Carter & D. S. Coombs

Geology Department, University of Otago, Dunedin, New Zealand

The volcanic Pitcairn Island, which has surface lavas with apparent ages between 0 45 and 0 93 Myr, may be the youngest member of another NW–SE trending volcanic lineament in the Pacific Ocean

PITCAIRN Island, in the south-eastern Pacific Ocean (24°04′S, 130°06′W), is built entirely of volcanic rock[1] Unlike the majority of volcanic islands in the Pacific basin, which are grouped in distinctive linear chains (see Fig 1), Pitcairn is isolated from its nearest neighbours, Oeno, Ducie and Henderson (all coralline islands) by 160 km, and it is 600 km from its closest volcanic neighbour, Mangareva in the Gambier Islands Easter Island lies approximately 2,100 km to the east, near the summit of the East Pacific Rise The position and youth of Pitcairn Island beg explanation by one or another of the rapidly proliferating theories of nonorogenic volcanism.

Pitcairn Island is built up from the seafloor, a depth of at least 3,500 m (ref 2) The age of the oceanic crust on which

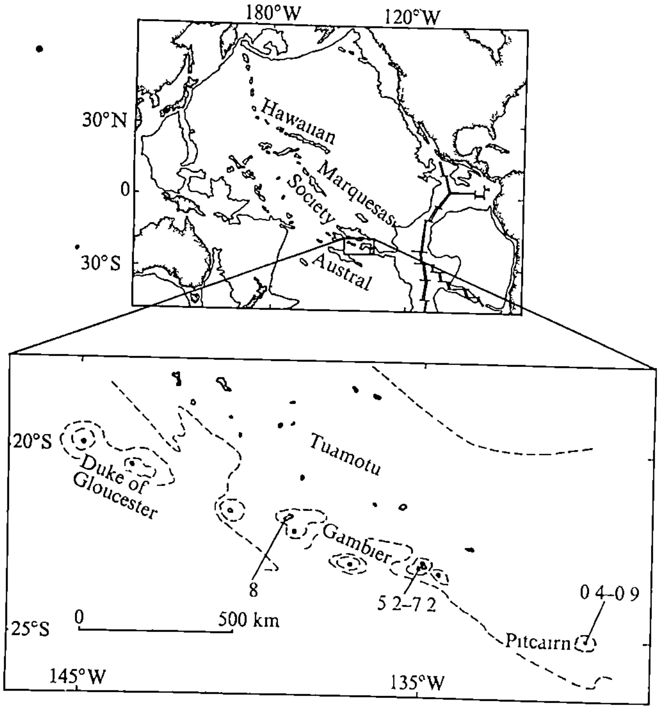

Fig. 1 Pitcairn Island is situated in the Pacific Basin, possibly the SE end of the Duke of Gloucester–Gambier Islands volcanic lineament which is parallel to other well known Pacific Island chains (Hawaiian, Marquesan, Society and Austral) The Duke of Gloucester Islands are all coral atolls at sealevel Numbers indicate K–Ar ages × 10^6 yr Bathymetry in the Pacific Basin denoted by the 4,000 m contour, in the inset by the 4,000 m and 2,000 m contours (dotted lines)

the island is constructed is not known with any great precision but magnetic anomaly studies[3] predict an age close to 30 Myr (anomalies 7–9) Basal sediments from Deep Sea Drilling Project (DSDP) site 75, 1,200 km NNW of Pitcairn (and roughly the same distance from the East Pacific Rise), have been assigned a lower Oligocene age (35–40 Myr)[4]

The island is approximately elliptical, measuring 4 km by 2 km and is cliffed on all sides, rising to an altitude of 347 m (Fig 2) Volcanic rocks of two types—lavas and pyroclastics—predominate Structurally, the island seems to be the remna of a single shield volcano, its dissected caldera rim forming prominent annular ridge which opens to the north Four uni have been discriminated the Tedside Volcanics—gentl dipping flows exposed near the west coast, the Christians Ca Formation—an agglomeratic tuff generally overlaying th Tedside Volcanics with erosional unconformity, the overlyin Adamstown Volcanics—horizontal flows which fill the centr basin, and the Pulawana Volcanics—a sequence of lava flow at the western extremity of the island, which may be coeva with the Adamstown Volcanics, as their lithology suggests There are also some dykes, mainly within the Tedsid Volcanics

Petrologically, the lavas range from alkali olivine basalt through hawaiites and mugearites to minor trachytes Th basalts contain phenocrysts of plagioclase feldspar, olivine an augite The hawaiites and mugearites exhibit trachytic textur and contain fewer phenocrysts than the basalts A commo additional groundmass phase in these samples is biotite The alkaline character of the trachytes is evident in phenocrysts o alkali feldspar, aegirine augite and fayalitic olivine Almost all of the rocks contain interstitial alkali feldspar, the amount increasing in the sequence olivine basalt to trachyte Chemical analyses of hawaiites, mugearites and trachytes from Pitcairn Island have been presented by Lacroix[5] who finds them comparable to the petrological association in the Marquesas Islands[5,6] New analyses from this Pitcairn collection will be published elsewhere

Geochronology

The samples selected for dating in this study are primarily hawaiites and mugearites All four lithological units are represented in the age determinations

Of the 17 selected samples, 12 were chosen for K–Ar age determination, on the basis of thin section examination Only those specimens which were devoid of any alteration of the K-bearing phases were selected Generally, they were holocrystalline and nonvesicular

Measurements were taken following the techniques previously described by McDougall[7–9] Constants used in the calculations are $\lambda_e = 0\ 585 \times 10^{-10}$ yr^{-1}, $\lambda_\beta = 4\ 72 \times 10^{-10}$ yr^{-1}, ^{40}K/K $= 1\ 19 \times 10^{-2}$ atom %

Table 1 presents the analytical data for 20 K–Ar age determinations on the 12 whole rock samples Generally, the duplicate analyses on 8 of the samples show agreement to within experimental error The samples are grouped according to the formations defined by Carter[1] Localities and ages are shown in Fig 2

The calculated ages fall into at least two groups Ages for four samples from the Tedside Volcanics, stratigraphically the oldest unit exposed on Pitcairn, form a group distinctly older than the rest, averaging 0 85 Myr and spanning the period 0 76–0 93 Myr The oldest apparent age was obtained on sample 74–1 from the north-west coast (near sealevel), about 1 km from the other three Tedside collecting localities which were in Jinser Valley The three Jinser Valley samples are from nearly horizontal lavas Samples 74–2 and 73–645 are from approximately the same stratigraphical horizon and give nearly identical ages, averaging 0 86 Myr The third sample (73–643), stratigraphically lower in the sequence, yields a significantly younger age of 0 76 ± 0 01 Myr (Because minor intersertal glass occurs in this sample it is possible that some radiogenic argon has been lost from it, resulting in a younger apparent age) These data suggest that much of the exposed Tedside Volcanics were erupted over a short interval of time between about 0 85 Myr and 0 93 Myr ago

The samples from the Christians Cave Formation, and the Adamstown and Pulawana Volcanics all yield younger K–Ar ages—from 0 46–0 63 Myr—consistent with their stratigraphically younger age A block from an agglomerate of the Christians Cave Formation yields an age of 0 60 Myr, indistinguishable from the apparent age of 0 62 Myr for sample 73–650 from the overlying Adamstown Volcanics The Christians Cave formation can thus be interpreted as contemporaneous with an early phase of the Adamstown Volcanics Sample 73–640 gives a similar age (0 63 ± 0 01 Myr) and was collected from the south coast The radiometric age supports its inclusion in the Adamstown Volcanics as tentatively suggested by Carter[1] The two remaining samples from the Adamstown Volcanics have measured ages that are significantly younger (0 53 Myr and 0 45 Myr) Sample 73–654 is from a biotite mugearite flow, from which samples were taken by early Polynesians to manufacture artefacts The Pulawana Volcanics, which overlie stratigraphically the Tedside Volcanics, near to the west coast, give concordant K–Ar ages of 0 62–0 63 Myr on two samples A trachyte dyke (73–648) cutting the Pulawana Volcanics near the western tip of the island gives a slightly older age of 0 67 ± 0 01 Myr These ages are indistinguishable from the older ages found for the Adamstown Volcanics, which supports the suggestion[1] that the two formations are in part equivalent

We interpret these data as indicating that the Tedside volcanics, regarded as a relic of a dome building phase, were erupted between about 0 8 Myr and 0 9 Myr ago Following a hiatus of about 0 2 Myr, during which time caldera subsidence occurred, the Christians Cave Formation, the Adamstown Volcanics (which filled the caldera), and the extracaldera flows of the Pulawana Volcanics, were erupted about 0 62 Myr ago, with volcanism continuing until at least about 0 45 Myr ago The volcano was therefore active for a period of 0 5 Myr during the younger part of the Pleistocene

The Adamstown Volcanics and Christians Cave Formation are normally magnetised[1], which is consistent with their geochronological placing in the Brunhes normal magnetic epoch This study suggests that the Pulawana Volcanics also should have normal polarity Field compass texts indicated that the Tedside Volcanics may be normally magnetised This suggests that Tedside Volcanics were erupted during the short Jaramillo normal polarity event (about 0 90 Myr BP) during the Matuyama reversed polarity epoch

Migration of volcanism

Potassium–argon age determinations indicate that the exposed lavas on Pitcairn Island were erupted between 0 45 Myr and 0 93 Myr ago, and the island is therefore a relatively young feature in the south-eastern Pacific Ocean Its young age is incompatible with the estimated age of the surrounding sea floor and we conclude that Pitcairn Island could not have been formed at the East Pacific Ridge and then drifted northwest Its relationship to other areas of recent volcanism within the Pacific Ocean basin—the islands at the south-eastern end of the conspicuously linear and almost parallel Pacific island chains (the Hawaiian Islands, the Marquesas Islands, the Austral Islands and the Society Islands, Fig 1)—is not immediately clear, because of the absence of a neighbouring chain of volcanic islands The possibility that a nearby seamount chain exists, cannot be dismissed until more detailed bathymetry has been undertaken Pitcairn Island lies, however, very near to the south-eastern extension of the Duke of Gloucester Islands–Gambier Islands lineament, which is also approximately parallel to the Pacific island chains Potassium-argon age determinations on volcanic samples from the Gambier Islands[10] suggest that the tholeiitic and alkali olivine basalt lavas which form the islands of Mangareva, Aukena and Makapu, cooled between 5 2 Myr and 7 2 Myr ago Winterer[11] has reported an age of 8 Myr (D Krummenacher, personal communication) for basalt from a drill hole at Mururoa Atoll at the north-western end of the Gambier Islands Thus, there is the suggestion of a NW–SE migration of volcanism, which supports other geochronological studies of linear Pacific island chains[12–15]

If Pitcairn Island is a more recent manifestation of the source which produced volcanism in the Gambier Islands (and earlier, presumably, in the Duke of Gloucester Islands), then that source has migrated relative to the Pacific plate at a rate of approximately 11 cm yr^{-1} This value falls within previously determined migration rates of Pacific island chains, which range from 15 cm yr^{-1} in the Hawaiian Islands[15], through 10 cm yr^{-1} in the Marquesas Islands[12], to 9 cm yr^{-1} in the Austral Islands[13,14]

William A. Held*
Institute for Enzyme Research, University of Wisconsin, Madison, Wisconsin 53706

Methyl deficient 16S RNA from kasugamycin resistant Escherichia coli *has been used to study methylation of RNA during ribosome assembly* in vitro *Methylation occurs at an intermediate stage and is inhibited at a late stage of assembly 30S ribosomal proteins required for methylation, and inhibition, have been identified*

RIBOSOMAL RNA is synthesised *in vivo* as a large precursor which is reduced in length and methylated during ribosome assembly[1–6] Sequential addition of ribosomal proteins and conformational changes occur during maturation, resulting in the formation of mature ribosomes[6] Nomura and coworkers have studied the *in vitro* assembly of ribosomes using fully methylated mature 16S RNA Little is known, however, about the role of ribosomal proteins in the processing of precursor 16S RNA[7] Recent experiments which demonstrated that 16S RNA from kasugamycin-resistant *E coli* is undermethylated, provide an approach to an understanding of methylation and the sequence of events that occur during assembly of 30S ribosomes

Mutations at the *ksgA* locus in *E coli* result in kasugamycin resistance due to the lack of a methylase activity[8–10] Helser *et al* demonstrated that resistance or sensitivity to the antibiotic kasugamycin is determined by the nature of 16S RNA, 16S RNA from the resistant strain differs from the sensitive strain in that it lacks dimethylation of two adjacent adenines in a sequence of $m_2^6A\ m_2^6ACCUG$ near the 3′-OH end of the molecule[8] Helser *et al* have also demonstrated a direct cause and effect relationship between adenine dimethylation and sensitivity to the drug by first methylating the resistant 16S RNA *in vitro* followed by reconstitution of 30S subunits with this RNA[9]

Isolated 'kasugamycin-resistant' 16S RNA could not be methylated *in vitro* in these studies, but the ribonucleoprotein particles prepared by CsCl density gradient centrifugation (CsCl cores) were active substrates This is consistent with the notion that methylation occurs during ribosome assembly We report here our studies on methylation of 16S RNA from a kasugamycin-resistant strain during 30S ribosome assembly *in vitro*

Purification and properties of methylase

The methylase was purified from *E coli* A19 (RNase I^-, General Biochemicals) Cells were disrupted in a French press in TMAI buffer (10mM Tris-HCl, *p*H 7 6, 30 mM NH_4Cl, 10 mM $MgCl_2$ and 6 mM 2-mercaptoethanol), the ribosomes separated by centrifugation and washed overnight in IF buffer (20 mM Tris-HCl, *p*H 7 8, 30 mM $MgCl_2$, 1 M NH_4Cl, 6 mM 2-mercaptoethanol) The salt-washed ribosomes were pelleted and the high speed supernatant was used for purification of the enzyme The supernatant was dialysed first against TMAI buffer overnight and then against phosphate buffer (50 mM NaH_2PO_4, *p*H 5 8, 1 5 mM 2-mercaptoethanol) containing 10% glycerol and adsorbed on to a phosphocellulose column equilibrated with the same buffer The column was washed with phosphate buffer containing 0 25 M NaCl and the enzyme was eluted with a linear salt and *p*H gradient (0 25–0 65 M NaCl), *p*H 5 8–6 5) The methylating activity eluted as a major peak near 0 55 M NaCl with a small shoulder The major peak fractions were pooled and dialysed against TMAI buffer (containing 10% glycerol) and used as a source of methylase The conditions for assay of column fractions for methylase activity were as reported previously[8] The methylase obtained by this procedure is 60–80-fold purified over crude extracts and remains stable when frozen at –70° C in TMAI buffer containing 10% glycerol Further purification of the enzyme resulted in loss of activity, hence the phosphocellulose enzyme was used in all experiments 30S ribosomes, CsCl core particles and 16S RNA were prepared from kasugamycin-resistant *E coli* strain TPR 201 according to methods described by Traub *et al*[9,11]

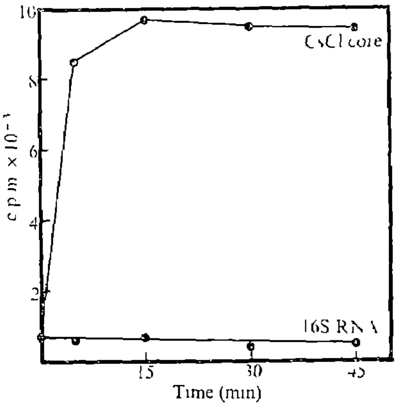

Fig 1 Time course of methylation of CsCl core particles obtained from kasugamycin-resistant 30S ribosomal subunits 0 25 A_{260} units of CsCl core particles (16 6 pmol) or 16S RNA (20 pmol) were incubated in 30 µl of reconstitution buffer (30 mM Tris-HCl, *p*H 7 4 20 mM $MgCl_2$, 6 mM 2-mercaptoethanol and 330 mM KCl) for 30 min at 40° C These conditions are referred to as 'reconstitution conditions'[12] The tubes were then chilled on ice and 5 µl of partially purified methylase (~1 µg) and 1 µl of ^3H-methyl-labelled S-adenosyl L-methionine specific activity 500 µCi µmol^{-1}) were added The reaction mixtures were diluted to 100 µl with methylase buffer (50 mM Tris-HCl, *p*H 7 8, 45 mM NH_4Cl, 4 mM $Mg(OAc)_2$) and assayed for the indicated times at 37° C The reaction was stopped by adding 1 ml of 10% trichloroacetic acid (TCA) and 0 2 ml of 0 2 mg ml^{-1} bovine serum albumin The precipitates were collected, washed with 5% TCA and counted Under these conditions, 10,000 c p m correspond to 68 pmol of methyl groups incorporated (About 5–10% background radioactivity was usually observed in RNase treated controls These background counts were not subtracted from the data presented The RNase sensitive maximum methylation corresponds to 3 3 methyl groups per core particle)

Figure 1 shows the kinetics of methylation with kasugamycin-resistant core particles as a substrate, 16S RNA is not a substrate for methylation The extent of methylation of core particles is comparable with that reported by Helser *et al*[8] Subsequently, 30S ribosomes were reconstituted from CsCl core particles and split proteins (SP30) under the conditions used for total reconstitution of 30S ribosomes[11,12] The resulting particles were assayed for methylation without isolation As Fig 2 shows, addition of split proteins to produce 30S ribosomes resulted in an inhibition of methylation

These results indicate that 16S RNA is not a substrate for methylation and that binding of some ribosomal proteins is essential for methylation to occur Completion of assembly of 30S ribosomes must result in a structure in which the AACCUG sequence is in an unreactive state for methylation

To determine which proteins are involved in conferring substrate specificity to 16S RNA, we studied the methylation of 16S RNA in ribonucleoprotein complexes with different protein compositions Purified 30S proteins were mixed in three groups as described in the legend to Table 1 These three groups included all the proteins present in the core particles as well as S5 (according to the accepted nomenclature of Wittmann *et al*[13] S5 was included in the mixture to ensure efficient binding of S21 (Fig 4)[14]

16S RNA was incubated with groups of proteins under reconstitution conditions and the mixture was assayed for methylation of the resulting ribonucleoprotein complexes as described previously Table 1 shows that all three groups of proteins (*A*, *B*, and *C*) were required for methylation of 16S RNA (Table 1*a*, line 8) Omission of any group gave a non-methylatable complex (Table 1*a*) In addition, the results indicate that the formation of an RNA–protein complex which can be methylated is temperature-dependent Incubation at 0° C and assay for methylation at 37° C resulted in reduced methylation (Table 1*b*) The observed low level of methylation was presumably due to some reconstitution during the assay at 37° C

Several single-component omission experiments were done to determine whether all proteins in each group were essential for methylation (Table 2) Omission of S13 and S20 from group *A* did not affect methylation but the omission of any one of the proteins S4, S8, or S15 caused a reduction in methylation (Table 2*a*) Addition of S4, S8, and S15 in combinations of two to groups *B* and *C* did not bring about methylation (Table 2*d*) Thus, three of the proteins (S4, S8 and S15) in group *A* are needed for methylation (Table 2*d*, line 4) Single-omission experiments (Table 2*b*) suggest that only S16 of group *B* is required for methylation In the presence of groups *A* and *C*, however, addition of S16 only was not sufficient for maximum stimu-

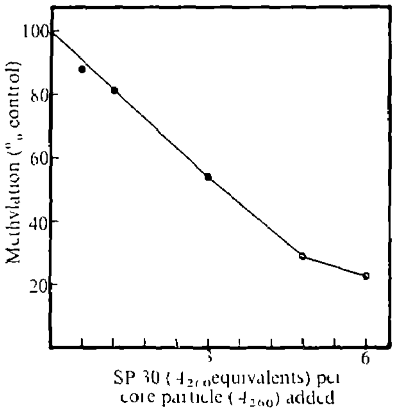

Fig 2 Inhibition of methylation after reconstitution of 30S ribosomes from core particles and split proteins CsCl core particles and split proteins (SP30) were prepared as described by Traub *et al*[11] The split proteins (SP30) were dialysed against TRI buffer (30 mM Tris-HCl, *p*H 7 4, 20 mM $MgCl_2$, 6 mM 2-mercaptoethanol and 1 M KCl) 30S ribosomes were reconstituted under 'reconstitution conditions' as described in Fig 1 and the resulting particles were methylated essentially as described in the legend to Fig 1 One A_{260} equivalent of SP30 corresponds to the split proteins obtained from 1 A_{260} unit of 30S ribosomes[11] 100% methylation corresponds to 3 3 methyl groups per core particle

Table 1 Reconstitution of core structure for methylation

			c.p.m.	%
(a)	(1)	16S	1,047	15
	(2)	16S + Gp *A*	1,406	21
	(3)	16S + Gp *B*	1,046	15
	(4)	16S + Gp *C*	918	14
	(5)	16S + Gp *A* + Gp *B*	1,916	29
	(6)	16S + Gp *A* + Gp *C*	2,073	31
	(7)	16S + Gp *B* + Gp *C*	1,340	20
	(8)	16S + Gp *A* + Gp *B* + Gp *C*	6,641	100
	(9)	Core particle	8,100	122
(b)		16S + Gp *A* + Gp *B* + Gp *C* $\xrightarrow[30']{0°}$	2,563	39

Proteins in various groups are *A*, S4, S8, S20, S15 and S13, *B*, S7, S16, S17, S19, and S5, *C*, S6, S18, S11, S21 and S12 30S ribosomal proteins were purified from *E. coli* Q13 as described by Held *et al.*[12] Purified ribosomal proteins were dialysed against reconstitution buffer containing 0.5 M KCl. Particles of indicated protein composition were reconstituted by incubating 0.25 A_{260} units of kasugamycin-resistant 16S RNA with a 2 molar excess of pure proteins. Reconstitution and methylation assays were as described previously. In the experiment in (*b*), 16S RNA was incubated in the reconstitution buffer with the indicated proteins at 0° C for 30 min and assayed for methylation at 37° C. 100% methylation (6,641 c.p.m.) corresponds to 2.3 methyl groups per 16S RNA. The extent of methylation (100% values) varied from 2.0 to 3.5 methyl groups per 16S RNA in different experiments. This variation may reflect differences between batches of 16S RNA and proteins used for reconstitution as well as variability of the components of the methylase reaction.

lation of methylation. Both S16 and S17 were required (data not shown, see also below). Thus S16 and S17 are the only proteins needed from group *B*, S5, S7, and S19 are dispensable.

Single omission of proteins in group C indicate that S6, S11, and S18 are needed for methylation of 16S RNA together with the proteins in groups *A* and *B* (Table 2*c*).

(d)		Effect of addition of single proteins to protein mixtures on methylation	
	(1)	16S + Gp *B* + Gp *C* + S4 + S8	74
	(2)	+ S4 + S15	10
	(3)	+ S8 + S15	15
	(4)	+ S4 + S8 + S15	108

Particles were reconstituted as described previously. The protein composition of groups *A*, *B* and *C* is given in Table 1. In single-omission experiments shown in (*a*), (*b*) and (*c*) the indicated purified proteins were omitted from the reaction mixtures. In (*d*) the indicated proteins were added to mixtures of group *B* and group *C* proteins. 100% methylation corresponds to 2.7 (7,956 c.p.m.), 2.0 (5,976 c.p.m.) and 2.7 (6,596 c.p.m.) methyl groups per 16S RNA for (*a*), (*b*) and (*c*), respectively.

Addition of S6, S11 and S18 individually, or in combinations of two, to groups *A* and *B* does not lead to significant methylation (data not presented here). Thus three proteins (S6, S11, and S18) of group *C* are required for methylation.

These results indicate that at least eight of the 14 proteins present in the core particle (S4, S8, S15, S16, S17, S18, S11 and S6) are necessary for methylation of 16S RNA. Table 3 shows that a methylatable substrate can be formed by addition of this set of eight proteins to 16S RNA. The extent of methylation is almost the same as that observed with particles reconstituted with a mixture of all the core proteins (Table 3, line 5). Thus, the interaction of 16S RNA with eight proteins is needed to form a minimum structure required for methylation. Omission of any one of the proteins in the minimum structure leads to reduced methylation. Omission of S4, S8, S16 or S17 leads to a more drastic reduction in methylation than other proteins.

Inhibition of methylation

As pointed out earlier, Fig. 2 shows that reconstitution of 30S ribosomes from CsCl core particles and split proteins results in inhibition of methylation. To determine whether one or more of the 'split' proteins may be involved in the inhibition, we performed several single component omission experiments in which each one of the 'split' proteins (S1, S2, S3, S5, S9, S10 and S14) was omitted from reconstitution mixtures[7,11].

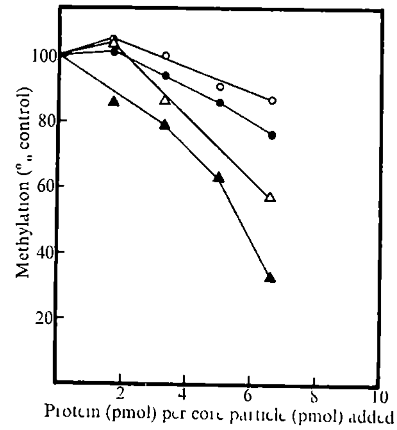

Fig. 3 Effect of single protein omission on methylation of reconstituted 30S ribosomes. *E. coli* A19 salt-washed ribosomes prepared as described in the text were dissolved in TMAI and sedimented through 30% sucrose in TMAI. The ribosomal subunits were separated by zonal ultracentrifugation in a Ti 15 rotor (5–30% sucrose gradient in 10 mM Tris-HCl, *p*H 7.4, containing 0.3 mM $MgCl_2$, 30 mM NH_4Cl and 6 mM 2-mercaptoethanol). 30S ribosomal proteins were extracted and purified essentially as described by Hardy *et al.*[24] The purified split proteins were dialysed against reconstitution buffer containing 0.5 M KCl before reconstitution. Ribosomes were reconstituted from CsCl core particles and purified split proteins. Proteins omitted from reconstitution mixtures are indicated in the figure. Reconstitution and assay conditions are as previously described. 100% methylation corresponds to 3.3 methyl groups per core particle. ○, minus S3; ●, minus S14(S9); △, minus S10; ▲, minus S2 (S1, S5).

Figure 3 shows that omission of S1, S2 or S5 did not affect inhibition of methylation by the rest of the split proteins. Omission of S3, S9 or S14 resulted in a considerable reduction in the inhibition of methylation and omission of S10 partially reduced the inhibition. Addition of any one of the purified split proteins to the core particles does not inhibit methylation (data not shown here) It should be noted that the extent of inhibition observed in experiments with purified split proteins was somewhat less than with unpurified split proteins (data in Fig 2)

We next asked if the inhibitory proteins S3, S9, S10 and S14 are sufficient to inhibit methylation of the minimum methylatable structure established above (Table 3) Three proteins (S7, S19 and S5), not required for methylation, were also added since they are necessary for the binding of proteins S3, S9, S10 and S14 (Fig 4)[14] Methylation was not inhibited when the inhibitory protein were added together with S7, S19 and S5 (Table 4, line 3) The presence of the additional proteins may have stabilised the minimum structure and thus stimulated the reaction

Table 3 Establishment of minimum core structure for methylation

		% Methylation
(1)	16S	9
(2)	16S + Gp *A* + Gp *B* + Gp *C*	100
(3)	16S + Gp I	15
(4)	16S + Gp II	11
(5)	16S + Gp I + Gp II	89
(6)	– S4	13
(7)	– S8	14
(8)	– S16	17
(9)	– S17	19
(10)	– S15	33
(11)	– S18	42
(12)	– S11	42
(13)	– S6	44

Proteins present in group I are S4, S8, S16 and S17, and Group II, S15, S18, S11 and S6 100% methylation corresponds to 2 2 (6,576 c p m) methyl groups per 16S RNA

Thus, in the experiment shown in Table 4 (line 3) methylation was not inhibited by the inhibitory proteins even though all the proteins present in core particles were present with the exception of S20, S21, S13 and S12 Addition of each one of these four proteins to the mixtures did not result in inhibition (Table 4, lines 4–7), but addition of S20 and S21 together resulted in a significant inhibition of methylation (Table 4, line 9) S12 slightly enhanced the inhibition observed with S20 and S21 (Table 4, line 13)

Our results can be summarised as follows (1) 16S RNA is not methylated but CsCl core particles are active substrates (2) Interaction of eight proteins (S4, S6, S8, S11, S15, S16, S17 and S18) with 16S RNA results in the formation of a minimum structure which can be methylated (3) Addition of split proteins to core particles leads to an inhibition of methylation Proteins S3, S9, S10 and S14 are the split proteins responsible for inhibition S1, S2 and S5 are not involved in inhibition (4) In addition to the inhibitory split proteins, the inhibition of methylation of 16S RNA is observed only in the presence of most of the core proteins, several of which are not essential for methylation (that is S7, S19, S20 and S21)

Methylation and assembly of 30S ribosomes

In the experiments reported here, the 30S ribosomal proteins required for *in vitro* methylation of 16S RNA, as well as those involved in inhibition of this reaction, have been identified Table 3 shows that eight 30S protein (S4, S8, S15, S16, S17, S18, S11 and S6) are required for methylation of the AACCUG sequence in 16S RNA *in vitro*

Six 30S proteins (S4, S7, S8, S15, S20 and S17) have been shown to interact with 16S RNA directly in the absence of other proteins in a site-specific manner[14–19] Four of these proteins, S4, S8, S15 and S17, are necessary for *in vitro* methylation of 16S RNA Zimmermann *et al* reported that S4, S8 and S15 (as well as S20 and possibly S13) interact specifically with an RNA fragment toward the 5′ half of the 16S RNA[20] The m$_2^6$A m$_2^6$A CCUG sequence is about 25 nucleotides from the 3′–OH end of 16S RNA[21] Thus, several proteins (S4, S8 and S15) which are known to bind some distance from the site of methylation are nonetheless necessary to establish an RNA–protein structure which can be methylated This suggests that these proteins are required for a structural change which affects the substrate specificity of the 3′–OH end of the RNA for methylation It is interesting that S7, which is the only protein known to bind directly near the 3′–OH end of 16S RNA[20], and hence close to the methylation site, is not required for methylation (data described in Table 3)

A comparison of the proteins required for methylation of 16S RNA and the assembly map (Fig 4)[14 16] indicates these proteins are strongly interrelated and occupy an early part of the map In addition to S4, S8, S16, and S17, the group of interrelated proteins shown on the left side of the assembly map (S15, S18, S6 and S11) are required for methylation while all of the proteins on the right side of the map whose binding strongly depends on the prior binding of S7, are not required This latter group of proteins, however, inhibits methylation (that is S9, S14, S10 and S3) It is probable that *in vivo* the methylating enzyme acts on intermediate particles which contain the essential eight proteins and perhaps other proteins, but lack some or all of the inhibitory proteins

Analysis of the protein composition of ribosomal precursor particles is consistent with the early incorporation of the eight proteins required for methylation during *in vivo* assembly 21S particles accumulated at low temperatures by a cold-sensitive mutant of *E coli* contain all the proteins found to be required for methylation with the exception of S11[22] In addition to the set of seven proteins, these particles also contain proteins which are not required for methylation (S7, S19, S20, S13 and possibly S9) It should be pointed out that these *in vivo* particles contain precursor 16S RNA which is not methylated Five of the eight proteins required for methylation (S4, S8, S15, S16 and S17) are also present in the *in vivo* 22S particles studied by Nierhaus *et al*[23]

Table 4 Inhibition of methylation of minimum core structure

		% Methylation
(1)	16S	19
(2)	16S + Gp I + Gp II	100
(3)	16S + Gp I + Gp II + Gp III	125
(4)	+ S20	113
(5)	+ S12	129
(6)	+ S21	116
(7)	+ S13	132
(8)	+ S20 + S12	100
(9)	+ S20 + S21	65
(10)	+ S20 + S13	104
(11)	+ S20 + S12 + S13	97
(12)	+ S20 + S13 + S21	68
(13)	+ S20 + S12 + S21	54
(14)	+ S12 + S13	120
(15)	+ S12 + S21	99

The protein composition of groups I and II are the same as that given in Table 3 Proteins present in group III are S7, S19, S3, S5, S9, S10 and S14 100% methylation corresponds to 3 5 (10,287 c p m) methyl groups per 16S RNA

Our results indicate that the eight proteins required for RNA methylation *in vitro* should be present during an intermediate step of ribosome assembly *in vivo* (that is, before the methylation of the m$_2^6$A m$_2^6$A sequence) Such an intermediate may contain some proteins which are not required for the methylation reaction we studied In addition, some of the proteins found to be required for methylation of the m$_2^6$A m$_2^6$A sequence may also be necessary for methylation of other RNA sequences during ribosome assembly It is also possible that other 30S proteins are specifically required for some of the methylations other than the dimethylation of adenines It is probable that the methylation of both adenines in the AACCUG sequence occurs even when partial methylation is observed[9] It is possible, however, that methylation is a sequential process in which the degree and type of methylation is determined by the composition and structure of the intermediate ribonucleoprotein particle

Methylation of the AACCUG sequence in 16S RNA is inhibited by 30S proteins which are incorporated during the final stages of 30S ribosome assembly (Table 4 and Fig 4) Four split proteins S3, S9, S10 and S14 are responsible for the inhibition of methylation of core particles (Fig 3 In addition to the inhibitory split proteins, we have found that several core proteins also contribute to inhibition of methylation (data in Table 4)

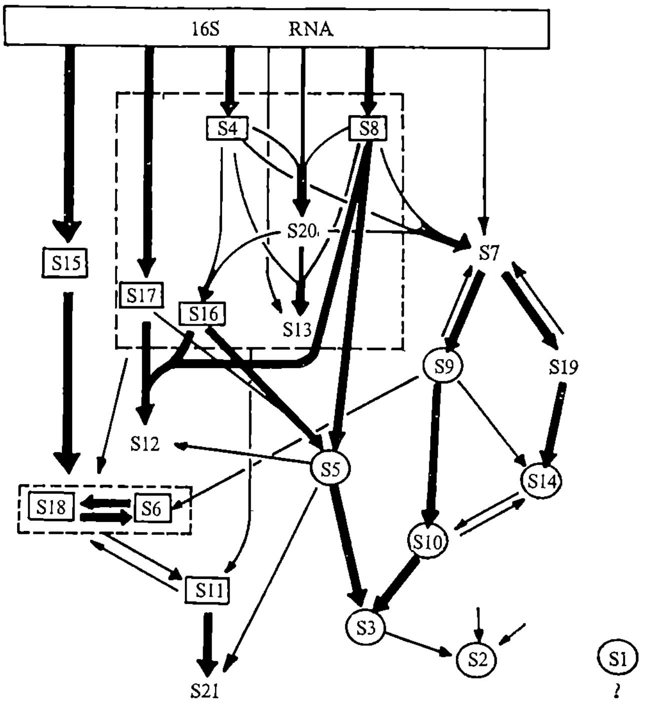

Fig 4 The 30S ribosome assembly map and the proteins required for methylation of 16S RNA The assembly map is from the work of Mizushima and Nomura[14] and Held *et al*[16] An arrow from 16S RNA to a protein indicates that the protein binds directly to 16S RNA in the absence of other proteins Arrows between proteins indicate the facilitating effect of one protein on the binding of another A thick arrow indicates a strong facilitating effect and a thin arrow, a weak facilitating effect The 30S proteins required for methylation of *ksg* 16S RNA are boxed CsCl split proteins are circled

In earlier experiments, occasional methylation of 30S ribosome preparations were observed This was thought to be due to partial unfolding of particles in such preparations[9] Subsequently, it was observed that methylation of 30S particles could be inhibited by the addition of split proteins, but with about one-quarter the amount needed for core particles (our unpublished observation) Thus we believe that the occasional methylation of 30S particles is due to a deficiency of one or more of the inhibitory proteins in the isolated 30S ribosomes This interpretation is consistent with the observation that the inhibitory proteins S3, S10 and S14 are present in amounts of less than one copy per isolated 30S particle[15]

The inhibition of methylation is a complex phenomenon Some of the proteins involved in the inhibition of methylation might make the site of methylation inaccessible to the methylase as a result of blocking the sequence to be methylated, while other proteins may facilitate the binding of inhibitory proteins In addition, specific changes in RNA conformation near the 3′-OH end might also be responsible for the observed inhibition

By using an approach similar to that used here, it should be possible to study the various steps in the maturation of precursor RNA and methylation of sequences other than the m$_2^6$A m$_2^6$A sequence Such studies would give information regarding the role of 30S proteins during maturation and assembly of the ribosome

We thank Dr Julian Davies and Masayasu Nomura for interest, encouragement and critical reading of the manuscript This work was funded by grants to Dr Davies from the National Institutes of Health and to Dr Nomura from the National Institute of General Medical Sciences and the US National Science Foundation

Size and location of the transforming region in human adenovirus type 5 DNA

Laboratory for Physiological Chemistry,

H. L. Heijneker
Laboratory of Molecular Genetics, State University of Leiden, Leiden, The Netherlands

Fragments of human adenovirus type 5 DNA as small as one million daltons can transform cells in vitro. The DNA segment which induces transformation is located between 1 and 6% from the left end of the Ad 5 DNA molecule.

HUMAN adenoviruses contain linear double stranded DNA of molecular weight 20 × 10^6 to 25 × 10^6 (refs 1, 2). They can be classified into three subgroups A, B, and C which vary in their degree of oncogenicity[3]. Viruses of subgroup C (to which adeno 5 belongs) are nononcogenic in that they do not give rise to tumours after injection into newborn hamsters[4], they can, however, transform cells *in vitro*[5,6] and in certain conditions the transformed cells can induce tumours in animals[7,8].

We have recently shown that Ad 5 DNA is infectious for human KB cells[9] and that it can transform rat cells *in vitro*[10]. Although DNA from simian adenovirus 7 had previously been reported to be oncogenic in newborn hamsters[11] our observations provided the first demonstration of transformation *in vitro* by adenovirus DNA. The development of an *in vitro* assay[10] afforded the opportunity for quantitative studies of transformation by adenovirus DNA.

While examining the effects of various treatments on the biological activity of Ad 5 DNA we observed that transforming activity was much more resistant to shearing than was infectivity. DNA preparations which were rendered noninfectious by shearing still retained undiminished transforming activity. We concluded that we might be observing transformation by DNA fragments. The studies presented here were undertaken to prove that Ad 5 DNA fragments of less than genome size have transforming activity, to determine the minimum size of fragments which retain the ability to transform cells, and to map the location of the transforming (T) segment within the viral DNA molecule.

The assays for biological activity were carried out using a modification of what we now call the calcium technique[9]. This method is based on the formation of a coprecipitate of DNA and calcium phosphate (formed by adding $CaCl_2$ to solutions of DNA in phosphate-containing buffer) which on addition to cell cultures becomes associated with the cells. DNA uptake then takes place at 37° C by a process which again requires calcium ions. The most important modification which we have introduced in the technique is the addition of a carrier DNA to all assays. This was shown to improve the efficiency of the assay[9] and has the important advantage of producing a linear dose response (ref 12 and Fig 1), thus simplifying quantitative calculations of specific activities.

Transformation by sheared Ad 5 DNA

Ad 5 DNA which was sheared to fragments having a sedimentation coefficient ($S_{20,w}$) of 22S (molecular weight 8 × 10^6) had the same transforming activity as unsheared DNA (Fig 1) yet infectivity of the sheared DNA could not be detected when

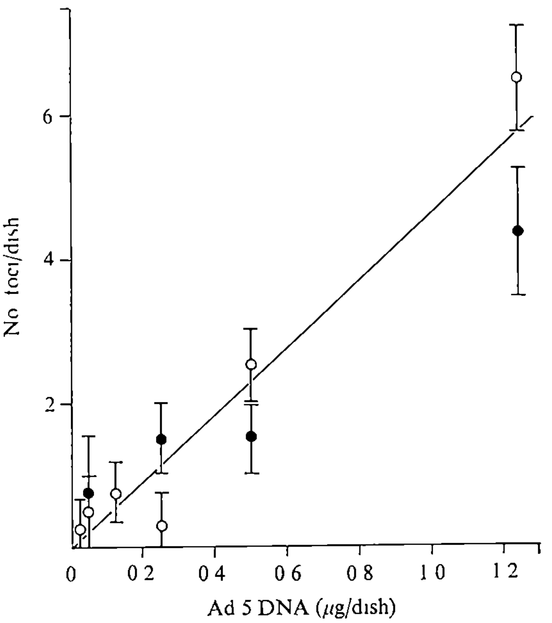

Fig 1 Dose response for transformation of primary rat kidney cells by intact (○) and sheared (●) Ad 5 DNA. The DNA was extracted from purified Ad 5 as described previously[1]. Shearing was carried out by passing 200 μg ml^{-1} solutions of Ad 5 DNA in 0.1×SSC (15 mM NaCl, 1.5 mM sodium citrate) 10 times through a needle (0.72 mm inside diameter×30 mm long) using maximum hand pressure on a syringe with a 15 mm diameter plunger. All sedimentation coefficients were determined by band sedimentation in 1 M NaCl at 20° C at an initial DNA concentration of approximately 25 μg ml^{-1} in an analytical ultracentrifuge equipped with ultraviolet optics and a photoelectric scanner. Coefficients have been corrected for viscosity but not for concentration dependence. Intact Ad 5 DNA sedimented at 30S and DNA sheared as described above sedimented at 22S. The assays for transforming activity were based on previous studies on infectivity[9] and transforming activity[10] of Ad 5 DNA and were carried out on subconfluent cultures of primary rat kidney cells prepared by trypsin dispersion of kidneys from week old Wistar rats. Viral DNA was diluted into HEPES buffered saline (HeBS: 8.0 g l^{-1} NaCl, 0.37 g l^{-1} KCl, 0.125 g l^{-1} $Na_2HPO_4 \cdot 2H_2O$, 1.0 g l^{-1} dextrose, 5.0 g l^{-1} N-2-hydroxyethylpiperazine-N′-2-ethanesulphonic acid, final *p*H 7.05) containing salmon sperm DNA at 10 μg ml^{-1}. $CaCl_2$ was added to 125 mM and the mixture was incubated at room temperature for 10–20 min during which time a precipitate formed. Aliquots (0.5 ml per dish) of the resulting suspension (consisting of a co-precipitate of DNA and calcium phosphate) were then added to rat kidney cells growing in 60 mm plastic Petri dishes containing 5 ml Eagle's minimum essential medium supplemented with 10% calf serum (MEM+10% CS) and the dishes were placed in a 37° C, 5% CO_2 incubator. After 3–4 h at 37° C the medium was removed and replaced with fresh MEM +10% CS and the incubation at 37° C continued. After 3–4 d the medium was replaced with low calcium medium[6] (MEM for suspension cultures+0.1 mM $CaCl_2$+5% CS) and this was refreshed at 3–4 d intervals. At 3 weeks, by which time few normal cells remained attached to the dishes, the cultures were fixed, stained with Giemsa, and transformed colonies were counted. Each point represents the average of 4 dishes and the error bars represent ±1 s.d.

assayed in conditions which resulted in 20–30 PFU μg^{-1} for intact DNA Furthermore, permissive cells (hamster and human) which could not be transformed by intact DNA (due to the resulting productive infection which spread to all the cells in the culture) could be transformed by noninfectious sheared DNA These observations showed that transformation did not require infectious DNA molecules and suggested that DNA fragments smaller than a viral genome had the ability to transform They did not, however, eliminate the possibility that transforming activity was associated with a shear-resistant (for example, circular) molecular form of Ad 5 DNA To rule out this possibility intact and sheared DNA preparations were fractionated through sucrose gradients and fractions were assayed for transforming activity

Activity should sediment at the same rate before and after shearing if it were associated with a shear resistant form of Ad 5 DNA The results shown in Fig 2 clearly demonstrate that this was not the case Transforming activity of unsheared preparations sedimented with the same velocity as intact DNA and shearing reduced the sedimentation velocity and transforming activity of the DNA to the same extent (Fig 2*a* and *b*) The results shown in Fig 2*c* indicate that even DNA fragments smaller than 15S (3 × 10^6 daltons) could transform with an efficiency as high as that of intact DNA Thus transforming activity appeared to be retained even after breaking the DNA to fragments as small as 1/8 of the viral genome It was now of considerable interest to determine more precisely the degree to which Ad 5 DNA could be fragmented before all transforming activity was lost

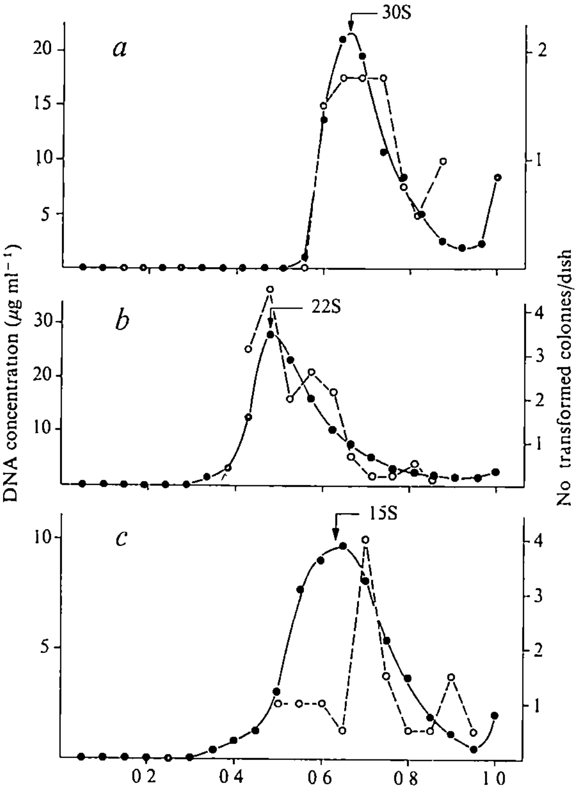

Fig 2 Transformation by intact and sheared Ad 5 DNA fractionated by velocity sedimentation Aliquots of ^{3}H-Ad 5 DNA (2,000 c p m μg^{-1}) were layered on to 5–22% exponential sucrose gradients containing 1 M NaCl, 0 01 M Tris, *p*H 8.1, and 0 5 mM disodium ethylenediaminetetraacetate which had been prepared by pumping sucrose solutions from a 70 ml mixing chamber connected to a reservoir containing 50% sucrose Gradients were centrifuged at 4° C for 22 h (*a* and *b*) or 34 h (*c*) at 25,000 r p m in a SW 27 rotor and fractionated from the top DNA concentrations were determined by counting 25 μl and transforming activity was measured as described in the legend to Fig 1 (50 μl DNA was assayed per dish) Recovery of radioactivity was 60–70% The sedimentation coefficients given in the figure were determined by band sedimentation in the analytical ultracentrifuge before the DNA was fractionated through sucrose gradients *a*, Intact DNA Transforming activity was measured in two separate experiments, two dishes/fraction The points therefore represent the mean of four dishes *b*, DNA sheared to 22S according to the legend to Fig 1 Each point represents the mean of two separate assays on two dishes each *c*, DNA sheared by passage 20 times through a 0 42 mm × 22 mm long needle using maximum hand pressure on a syringe with a 9 mm plunger Fractions were assayed once for transformation, 2 dishes per assay ●, DNA concentration, ○, Transforming activity

Minimum size of transforming fragments

If transformation by Ad 5 DNA required the integrity of some segment (the T segment) of length L then transforming activity of randomly fragmented DNA should decrease as the fragment size approached L and should be zero for fragments less than or equal to L in molecular weight To obtain an estimate of L, Ad 5 DNA was extensively fragmented by shearing or sonication (resulting in modal sedimentation coefficients of 11 5S and 12S, respectively), fractionated by velocity sedimentation, and assayed for transforming activity

The results, plotted in Fig 3*a* and *b*, showed that for both sheared and sonicated preparations, transforming activity was found only in fractions containing DNA fragments sedimenting faster than 10S To ensure that the molecular weight of the DNA fragments had not changed between the time they were prepared and the time they were assayed for transforming activity, and to determine as accurately as possible the molecular weight of DNA fragments in the region where transforming activity approached zero, peak fractions from the gradients in Fig 3*a* and *b* were concentrated after transforming activity had been measured and sedimentation coefficients were redetermined in the Model E ultracentrifuge The resulting values (shown in Fig 3*a* and *b*, and differing only slightly from the modal values obtained before fractionation) were then used to calibrate the gradients to determine molecular weights from the equations in the legend to Fig 3

The graph of specific transforming activity plotted versus molecular weight in Fig 3*c* shows that fragmentation of Ad 5 DNA, whether by shearing or sonication, began to reduce transforming activity when the fragment size fell below about 2 × 10^6 daltons and activity was completely abolished at slightly below 1 × 10^6 daltons If loss of activity at this point was due to the introduction of breaks into the T segment then the size of the T segment must be approximately 10^6 daltons But since there may be other explanations for absence of transforming activity below 10^6 daltons (for example, DNA fragments smaller than 10^6 daltons may be inherently lacking in any biological activity in our assay system) we can only conclude that the T segment is not greater than about 10^6 daltons in length

The possibility that transformation by small fragments required the interaction of two or more DNA segments can be ruled out since such a mechanism would result in a dose response of 2nd or higher order Yet we observed no significant departure from a first order dose response with decreasing fragment size It would appear, therefore, that only one small segment of the Ad 5 DNA molecule is required for transformation and that the molecular weight of this segment is not more than about 10^6 daltons

The properties of cells transformed by small DNA fragments are now under investigation We can only say that such transformed cells do not appear to differ morphologically from those transformed by intact DNA One line of rat kidney cells transformed by fragments of molecular weight 1 5 × 10^6 is now at the 27th passage in culture, several transformed hamster lines (transformed by DNA fragments of molecular weight about 8 × 10^6) have been maintained in culture for 5–23 passages and one transformed human cell line is now at passage 51 Furthermore, of five transformed hamster cell lines tested for tumorigenicity, all induced tumours when injected into newborn hamsters Thus DNA fragments seem to be capable of inducing not only stable, but also oncogenic transformation By indirect immunofluorescence using serum from tumour-bearing hamsters, we have demonstrated T antigen in all of several DNA-transformed cell lines tested, including one transformed by fragments of molecular weight 1 5 × 10^6 (The serum was obtained from hamsters bearing tumours induced by Ad 5 transformed cells and was pretested against transformed rat cells which had previously been shown positive for T antigen[10])

Location of the T segment

The finding that fragments of Ad 5 DNA had the ability to transform cells suggested the feasibility of mapping the T segment within the viral DNA molecule and of purifying this segment The first step which we took in this direction was to determine which half of the molecule contained transforming activity Since the DNA of Ad 5 (like that of Ad 2 (refs 14, 15)) has an asymmetric distribution of GC, it was possible to separate the two halves of Ad 5 DNA by equilibrium buoyant density centrifugation of half molecules in a Hg(II)-Cs$_2$SO$_4$ gradient according to the method of Nandi, Wang and Davidson[16] DNA was sheared, fractionated on sucrose gradients to purify the halves which were then separated in a Cs$_2$SO$_4$ gradient in the presence of Hg(II) Fractions corresponding to AT or GC-rich halves were pooled, dialysed against HeBS, and aliquots were analysed by buoyant density centrifugation in CsCl in a Model E analytical ultracentrifuge The results indicated that a single fractionation on a Hg(II)-Cs$_2$SO$_4$ gradient was sufficient to provide relatively pure preparations of AT-rich and GC-rich halves (the cross contamination was less than about 10%) When these preparations were assayed for transforming activity it was found that the AT-rich halves had less than 5% of the transforming activity observed for the GC-rich fractions (0 7 colonies per μg AT-rich

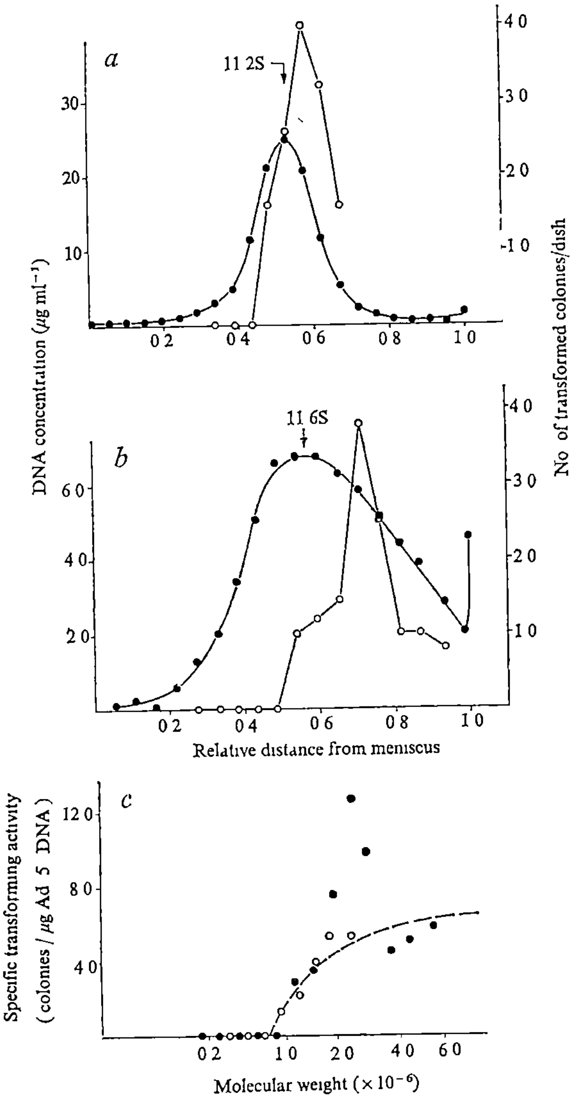

Fig 3 Transformation by extensively fragmented Ad 5 DNA *a*, DNA at 200 μg ml^{-1} was sheared for 3 min in a Sorvall omnimixer micro attachment by a stainless steel blade rotating at 40,000 r p m A sedimentation coefficient of 11 5S was determined for this DNA before it was fractionated on sucrose gradients DNA was sedimented by centrifugation at 23,000 r p m for 44 h on gradients prepared according to the legend to Fig 2 After fractionating and assaying aliquots for transforming activity (50 μl per dish) the peak fraction was concentrated and the sedimentation coefficient again measured to give the value shown in the figure *b*, DNA at 100 μg ml^{-1} was sonicated in a MSE sonicator for 15 s, at 20,000 c p s, amplitude 2 μm This resulted in a DNA preparation which sedimented in the analytical ultracentrifuge as a rather broad band having a modal sedimentation coefficient of approximately 12S (The coefficient shown in the figure was determined for the combined fractions 10 and 11 after assaying for transformation) ●, DNA concentration, ○, transforming activity, mean of 5 dishes per point *c*, Specific transforming activity of Ad 5 DNA fragments calculated from panels A (○) and B (●) as a function of molecular weight Molecular weights were calculated from the equations D=kS and S=0 0882 M$^{0\ 346}$ (ref 13) where D is distance sedimented and k was determined from the sedimentation coefficients shown in panels A and B

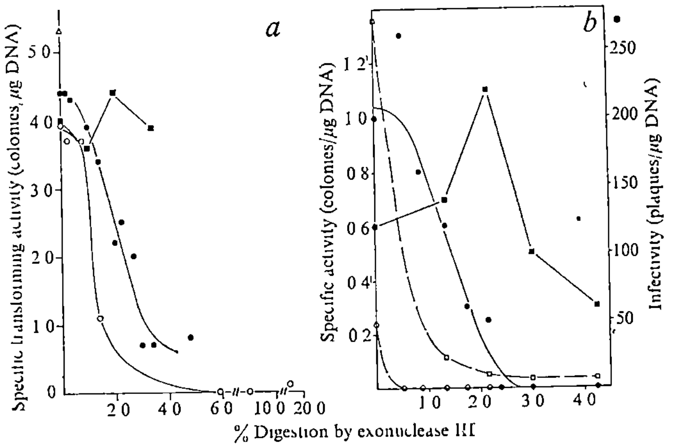

Fig 4 *a*, Transforming activity of Ad 5 DNA after treatment by exo III or exo III+S1 Enzymatic digestions were carried out in the following way. To 1 ml ^{3}H-Ad 5 DNA (10^4 c p m μg^{-1}, 300-500 μg ml^{-1} in 0 1×SSC) was added 0 1 ml of a buffer containing 33 mM each of Tris, *p*H 8 0, MgCl$_2$, and 2-mercaptoethanol Digestion was initiated by the addition of 0 1 ml exonuclease III (2000 U ml^{-1}, 1 5×10^5 U mg^{-1} in 40 mM potassium phosphate buffer, *p*H 6 5, containing 1 mM 2-mercaptoethanol and 0 4 M KCl) and incubation at 20° C Exonuclease III was prepared as described[23] with additional purification by phosphocellulose chromatography and Sephadex G100 gel filtration[24] The extent of digestion was monitored by removing 10 μl aliquots and determining the fraction of acid soluble radioactivity At various times 80 μl aliquots were removed and exonucleolytic digestion was stopped by adding 20 μl 0 15 M sodium acetate buffer, *p*H 4 2, containing 5 mM ZnSO$_4$ and 1 5 M NaCl Single-stranded ends were subsequently degraded by adding 20 μl single-strand specific nuclease S1 from *Aspergillus oryzae* (300 U ml^{-1}, 1 5×10^5 U mg^{-1}, in 20 mM sodium acetate buffer, *p*H 4 6, containing 0 1 mM ZnSO$_4$, 0 3 M NaCl, and 5% glycerol) S1 purification was essentially as described by Vogt[25] The reaction was carried out at 37° C for 30 min and was terminated by the addition of 10 μl 0 1 M EDTA, *p*H 8 0 (The % digestion by S1 equalled the amount of DNA made acid soluble by exo III) Finally, HeBS containing 0 5 mM EDTA was added to give a final DNA concentration of 50 μg ml^{-1} and the samples were dialysed against HeBS+0 5 mM EDTA Assays for transforming activity were carried out according to the legend to Fig 1, 2 μg DNA per dish, 5 dishes per point (△) Untreated DNA, (■) exo III treated DNA, (○, ●), exo III-S1 treated DNA *b*, Infectivity and transforming activity of Ad 5 DNA treated with exo III or exo III+S1 Enzyme digestions were carried out as in *a* except that unlabelled Ad 5 DNA was used and the extent of digestion by exo III was determined by measuring the amount of deoxynucleotides incorporated into the treated DNA by DNA polymerase I (purified from an *E coli* pol A mutant deficient in 5′-3′ exonucleolytic activity[23]) Transforming activity (■, ●) and infectivity (□, ○) were assayed as described in the legend to Fig 1 except that infectivity assays were carried out on primary human embryonic kidney (HEK) cells or on a line of HEK cells transformed by Ad 5 DNA ■, □, exo III treated DNA, ●, ○, exo III+S1 treated DNA

Table 1 Calculation of the location of the T segment

Experiment	Fraction of intact single strands	Average no. nicks/strand	Effective no. nicks/strand introduced by exo III*	No. 3′ ends per molecule†	% exo III digestion resulting in 50% reduction in transforming activity	Total % digestion by exo III followed by S1 at 50% reduction	Total % digestion per 3′end (distance from left end of Ad 5 genome to T segment)‡
1	70%	0.36	0.1	2.92	1.3	2.6	0.89
2	32%	1.14	0.1	4.48	2.2	4.4	0.98
3	100%	0	0.1	2.2	1.4	2.8	1.27

The fraction of intact single strands was determined by band sedimentation in alkali in the analytical ultracentrifuge. The average number of nicks per strand was calculated from this fraction assuming a Poisson distribution. The % digestion by exo III followed by S1 was double that by exo III alone.

* The exonuclease preparation had a low level of contaminating endonuclease activity introducing nicks which could then serve as substrates for exonuclease digestion.

† The number of 3′ends per molecule is 2 + the number of nicks per molecule.

‡ Calculated from the total % digestion divided by the number of 3′ ends per molecule.

DNA compared to 18 colonies µg^{-1} for the GC-rich halves.) Thus the T segment appeared to be located in the GC-rich or left half of the Ad 5 DNA molecule, a finding which has been recently confirmed by studies on the transforming activity of DNA fragments obtained by treatment with the R1 restriction endonuclease from *E. coli*.

A more precise localisation of the T segment was obtained by assaying transforming activity of Ad 5 DNA treated with *E. coli* exonuclease III (exo III) (which removes mononucleotides from the 3′ end of polynucleotides in duplex molecules[17]) followed by single strand specific nuclease S1 from *Aspergillus oryzae*. The combination of these two enzymatic treatments has the effect of digesting the Ad 5 DNA molecule inward from the two ends and should result in a decrease in transforming activity when the digestion reaches the region required for transformation.

The results of two experiments are illustrated in Fig. 4*a*. Treatment of Ad 5 DNA with either exo III or S1 separately did not significantly affect transforming activity. The combination of exo III and S1 treatment initially had no effect on transforming activity but after an exo III digestion of about 1% (that is, a total digestion of 2% by the two enzymes), transforming activity dropped rapidly. In contrast, infectivity of Ad 5 DNA was immediately eliminated by exo III–S1 digestion (Fig. 4*b*); digestion of as little as 0.2% (data not shown) resulted in a complete loss of infectivity (> 200-fold decrease) indicating that all molecules were digested by the enzymatic treatment. Figure 4*b* shows also that infectivity was reduced by exo III alone, an effect which is presently being investigated in more detail to determine if, for example, it is related to the inverted terminal repetition contained in adenovirus DNAs[18,19]. The fact that transformation was not immediately affected by exo III–S1 treatment clearly shows that the extreme ends of the Ad 5 DNA molecule are not required for transformation.

We interpret the eventual loss of transforming activity after treatment of Ad 5 DNA with exo III and S1 as being the result of digestion into the T segment and in Table 1 have used the data of Fig. 4 to calculate the distance from the end of the Ad 5 DNA molecule to the beginning of the T segment. When account has been taken for single strand nicks (which are starting points for exonucleolytic digestion) the results from three experiments are in good agreement and give a mean value of 1.1%. From the fact that transforming activity was located on the GC-rich half of the Ad 5 DNA molecule, and from the results of Fig. 3 we conclude that the T segment begins at 1% from the left end of the Ad 5 genome and terminates at about 5–6%.

Implications

Transformation by DNA tumour viruses is often considered to be analogous to lysogenisation of bacteria by bacteriophage, a process thought to involve the integration of the phage genome into the host chromosome by a reciprocal recombination between the host DNA and a circular form of the phage DNA[20]. The results presented in Figs 2 and 3 provide clear evidence that Ad 5 DNA fragments of considerably less than genome size have the ability to transform cells. As it is rather unlikely that such randomly generated fragments can circularise, these results suggest that transformation does not require a circular viral DNA molecule. That fragments as small as 10^6 daltons can transform cells also implies that the proportion of the viral genome which is required to initiate and maintain transformation is less than about 5%. This is in reasonable agreement with results of attempts to determine the size of the transforming region by radiation studies[21], and is consistent with the fact that only about 4–10% of the viral genome is transcribed in rat cells transformed by Ad 2 (ref. 22). Thus, the T segment is large enough to code only for 1–2 average-sized proteins so that presumably not more than about two viral genes are involved in transformation by Ad 5 and these must be contiguous.

We have localised the T segment between 1 and 6% from the left end of the Ad 5 genome. Several lines of evidence are in agreement with this finding. First, Gallimore (P. H. Gallimore, personal communication) has shown that the left end of the Ad 2 genome from 0–14% was always present in several lines of Ad 2 transformed cells. Second, preliminary results indicate that treatment of Ad 5 DNA with two restriction enzymes which cleave in the region between 1 and 6% from the left end results in loss of transforming activity while treatment with a third enzyme which cleaves just to the right of this region leaves transforming activity undiminished and activity appears to be associated with the fragment originating from the left end of the Ad 5 DNA molecule (A. J. van der E., C. Mulder and F. L. G., unpublished).

As in the case of transformation by intact viruses, the mechanism by which the T segment induces cell transformation remains to be elucidated. However, the purification of the T segment, which now appears to be a possibility, should provide a simpler system with which to study the genes and gene products involved in oncogenic transformation.

We thank Miss R. H. Tjeerde and Mrs K. B. Postel for technical assistance and Drs S. O. Warnaar, S. Bacchetti, and J. Sussenbach for reading the manuscript. This work was supported in part by funds from Euratom and the Foundation for Medical Research of the Netherlands Organization for the Advancement of Pure Research (ZWO).

Photoelectric photometry of OH471 and OQ172, and other optical objects near radio sources

IDENTIFICATION of the optical objects associated with radio sources is usually made by using the blue and red photographs of the National Geographic Society–Palomar Observatory Sky Survey (PSS) Objects lying near the radio positions are generally counted as possible identifications if they appear diffuse and are therefore galaxies, or appear stellar and blue, and are therefore quasi-stellar object (QSO) candidates Only if radio positions of $\lesssim 1''$ accuracy are available can identifications be made with red or neutral stellar objects without gross contamination of the true identifications by foreground galactic stars, most of which appear neutral or red on the PSS prints

Among radio source identifications hitherto made using accurate (1″) positions there are few red or neutral stellar objects compared with the number of blue ones[1], but they include some of the most interesting of the identifications They include *a* QSOs with redshifts $z \gtrsim 3$, where Lα emission is redshifted to $\lambda \gtrsim 5{,}000$ Å and there are numerous absorption lines blueward of Lα, both effects combining to make the object appear redder than QSOs with lower redshifts, *b* galaxies, which are so compact as to appear stellar on the PSS plates, and *c*, objects like OJ287 which have featureless spectra, often with a redder continuum than those of most QSOs Objects in classes *a* and *b* are usually recognised once their spectra are obtained since those known in these categories have strong Lα emission (class *a*) or strong sharp emission lines of, say, [O II] and [O III] (class *b*) Those in class *c* can only be distinguished from stars on the basis of their featureless spectra which, when the objects are faint, may be a difficult observational task since not all stars show strong absorption lines In this case, *UBV* photometry can confirm the identification through the particular colours of these objects

Radio positions with accuracy ~ 1″ are routinely measured at the University of Texas Radio Astronomy Observatory (UTRAO) and a small percentage of the sources have been identified with red or neutral stellar objects[1] Here, I report on measurements of broadband colours for a small group of the Texas identifications (together with OH471, identified using the same techniques[2]), comparing these with colours of previous radio source identifications I discuss the increased reddening of QSOs with increasing redshift All the identifications are within 3″ of the accurate radio positions, except for one which is within 5″ (Table 1)

U, *B* and *V* magnitudes were measured with two photometer systems on the 82-inch (2 1-m) Struve reflector of McDonald Observatory One system employed a selected RCA 1P21 and the other a RCA 4516 (S20 photocathode) phototube The *U*, *B*, *V* measurements were referred to that system defined by the measurements by Crawford, Golson and Landolt[3] and by Landolt[4] The results of the measurements, and other data, are given in Table 1 Errors given there comprise r m s (random) counting statistical errors added in quadrature to estimated systematic calibration uncertainties The forms of the spectral energy distributions for these objects are shown by their positions in the $U-B$, $B-V$ diagram (Fig 1), where the new data are compared with previous photometry for QSOs, N-galaxies, objects of the OJ287 type, and radio galaxies Here, no corrections have been applied for galactic reddening

It is of interest to compare QSOs in different redshift ranges $z \leqslant 2\ 5$, $2\ 5 < z < 3\ 0$ and $z \sim 3\ 5$ The QSOs having $2\ 5 < z < 3\ 0$ have $U-B > -0\ 4$ compared with $U-B < -0\ 4$ for the lower redshift ones, since for $2\ 5 < z < 3\ 0$ Lα emission occurs predominantly in the *B* filter and absorption shortward of Lα causes a relative decrease of power received in the *U* band The QSO of largest redshift among these objects, 4C05 34 ($z = 2\ 88$, ref 5) has the least negative $U-B$ and can barely be distinguished from an F star on the basis of broadband colours alone[6] Although all the radio-emitting QSOs would have been suggested as QSOs from their blue appearance on the PSS prints, a common criterion employed in suggesting QSO candidates[7–9] has been that $U-B < -0\ 4$ On this basis, all the objects having $2\ 5 \leqslant z < 3\ 0$ would have been missed The two QSOs, OQ172 and OH471, having $z \sim 3\ 5$ (refs 10, 11) have rather larger $B-V$ values than do QSOs of smaller redshift—because of the further redshift of Lα into the *V* passband Note also the large difference (~ 2 mag) in $U-B$ for these two objects at nearly the same *z*—attributable to the much greater absorption below the Lyman limit for OH471 (Spectrophotometry by Oke[12] is in quantitative agreement with these results) OQ172 does appear slightly blue on the PSS prints, whereas OH471 is quite red Thus, on the basis of *UBV* colours or apparent colours from the PSS, QSOs of $z > 3\ 0$ will frequently be indistinguishable from main sequence stars, and objects with greater absorption below the Lyman limit will

lie even further below the main sequence and to the right, in the $U-B$, $B-V$ diagram Objects of higher redshift will have an even greater proportion of their light output in the V filter A useful criterion for the selection of candidates for QSOs having $z > 3$ may be broadband colours extending to longer effective wavelength, say U, V, R and I, or by comparison of images on ultraviolet, red and infrared plates, analogous to the technique used by Braccesi *et al*[13] to discover lower redshift QSOs

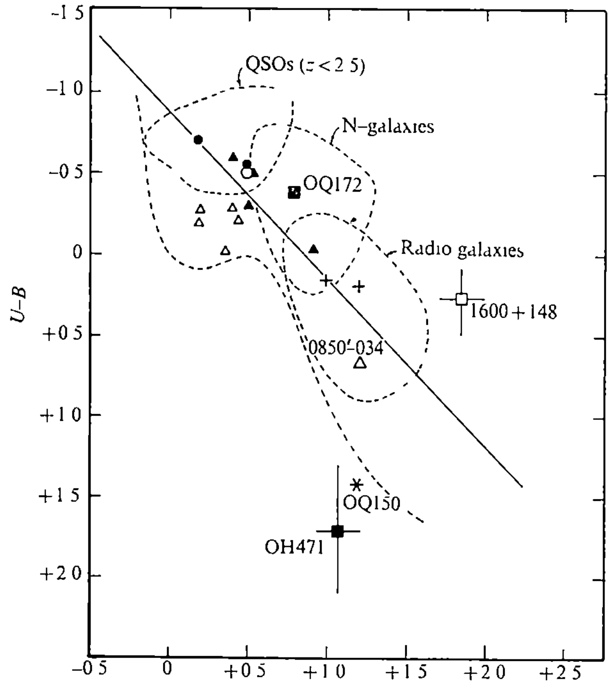

Fig. 1 New colours for some radio source identifications compared with typical colours for QSOs ($z < 2$ 5), N-type galaxies, OJ287-type objects and radio galaxies Error bars shown for OH471 and 1600+148 indicate the dominant contributions from counting statistics The average main sequence and blackbody curves are shown Data for the QSOs PHL957 and 4C05 34 have been taken from Sandage[18], and unpublished data for three other QSOs having $z \sim 2$ 5 have been supplied by R Lynds and D Wills For OJ287-like objects, data are from ref 19 The symbols refer to colours for new QSOs (●), OJ287-type objects (▲), QSOs having redshifts 2 5 < z < 3 0 (△), galaxies (+), and 3C66A (○)

Two of the objects observed (3C66A and 1147+245 (OM 280)) lie in the region of the class *c* objects, above The results for 3C66A have already been discussed[14] No lines have been found yet in the optical spectrum of 1147+245 (refs 15, 16)

Among the red stellar objects, the candidate identification for 1430+095 (OQ050) lies close to the main-sequence curve in Fig 1 and a spectrogram later confirmed that the object is a late type star and therefore probably not associated with the radio source Another red object, within 3″ of 0850−034 (4C−04 17), lies fairly near the main sequence curve, in the region also occupied by radio galaxies Only weak spectra of this object have been obtained by Derek Wills and me, there are certainly no strong emission lines, but the possibility of stellar absorption lines is not excluded The remaining red object, associated with 1600+148 (4C14 61), should probably be classified as a galaxy on the basis of the present photometry Image-tube photographs (scale 25″ mm^{-1}) confirm the stellar nature of the image seen on the PSS, again, however, only weak spectrograms have been obtained ($B \simeq 20$ 5) sufficient only to rule out the presence of very strong emission lines The remaining stellar object in Table 1, 1049+616 (4C61 20), has a redshift[16] $z = 0$ 422 Wills and Wills[16] remarked that the spectrum was somewhat more like that of a galaxy than of a QSO, but the present results show that its colours are quite typical of those of the majority of QSOs

Two galaxies were also observed, they each appear compact (but definitely non-stellar) in the PSS Of these, 0456−043 is the more compact and shows emission lines in the spectrum ($z \simeq 0$ 118), the other, 1037+302 (4C30 19), shows no emission lines The colours of these two objects are quite similar

The present photometry has been valuable in attempting to classify objects on the basis of their continuum colours, especially for the apparently stellar candidate radio source identifications where no lines have been seen in the optical spectrum The colours of the high redshift QSOs, OH471 and OQ172, lead me to suggest that broadband photographic or electrographic photometry at a few effective wavelengths over a wide wavelength range (extending into the infrared) may be a practical alternative to using the properties of radio emission and good radio-optical position agreement in selecting high redshift ($z \geqslant 3$) QSOs, it may therefore be a useful way to test whether or not radio-emitting QSOs are a representative sample of QSOs as a whole

I thank Gerry Grupsmith for observing help and colleagues in the radio group for radio source positions. Unpublished photometry of three QSOs having $z \simeq 2.5$ was supplied by R. Lynds and D. Wills. This work was supported by the National Science Foundation.

Rapid variations in the spectrum of the magnetic variable star HD215441

THE star HD215441 has the largest magnetic field ever recorded, about 34 Kgauss (ref. 1), varying without change of polarity. There are some indications of smooth brightness variations of this star with amplitude $\Delta m \approx 0.2$ mag as well as of small smooth variations of linear polarisation correlated with the brightness variation[2-4].

Rapid fluctuations (during several minutes) of brightness (W. Schoreich and R. Panov, unpublished) and polarisation in a wide spectral interval as well as polarisation in the wing of the H_β line[6], were also observed. Photoelectric measurements with narrow and wide passband filters showed variations of equivalent width of H_β by 30% within 90 s. Similar variations have not been detected for other Balmer lines[7].

Some efforts to detect rapid spectral variations of the star HD215441 are described below.

Our observations were carried out with a spectrograph and three-stage image tube (with a multi-alkali photocathode) at the Nasmyth focus of the 2.6 m telescope of the Crimean observatory. The dispersion was about 37 Å mm^{-1} at H_α and 46 Å mm^{-1} at H_β, the resolution being about 3 Å. In favourable observing conditions exposure times were 60 s for H_α and 25 s for H_β. During observations on August 25, 26, 28, and September 7, 1973, and January 2, 1974 (when the star was observed during a time interval of more than an hour) more than 300 spectrograms were obtained.

The spectrograms and registrograms show the complicated character of the spectrum with emission (as well as absorption) features. Some successive registrograms of spectra of H_α and H_β regions obtained with a one-minute interval and spectra obtained on different nights are shown in Figs 1 and 2 (the field size of the spectrograph camera does not permit one to obtain H_α and H_β lines on the same spectrogram). The differences in spectra are easily seen. Many details are repeated, but sometimes (for instance on August 26) the emission features in the region of H_α are absent (Fig. 2). Some absorption features of this spectrum correspond to emissions in the spectra of August 28 and September 7. Inspection of the spectra shows that there are continuous intensity variations of many emission features and absorption lines (and probably of the H_α and H_β lines) with the shortest time scale of the order of several minutes.

The complicated character of the spectrum, its variability and low resolution do not permit one to identify emission details with certainty as yet.

Approximate wavelengths of the strongest emissions (determined with an accuracy of 2–3 Å) correspond to FeII, VII, CrII, HfII, TiII, ArII, ClII as frequently as to GdII, LaII, CeII, NdII, SmII. (According to Preston[8], lines of neutral atoms in the spectra, apart from H and HeI, are probably

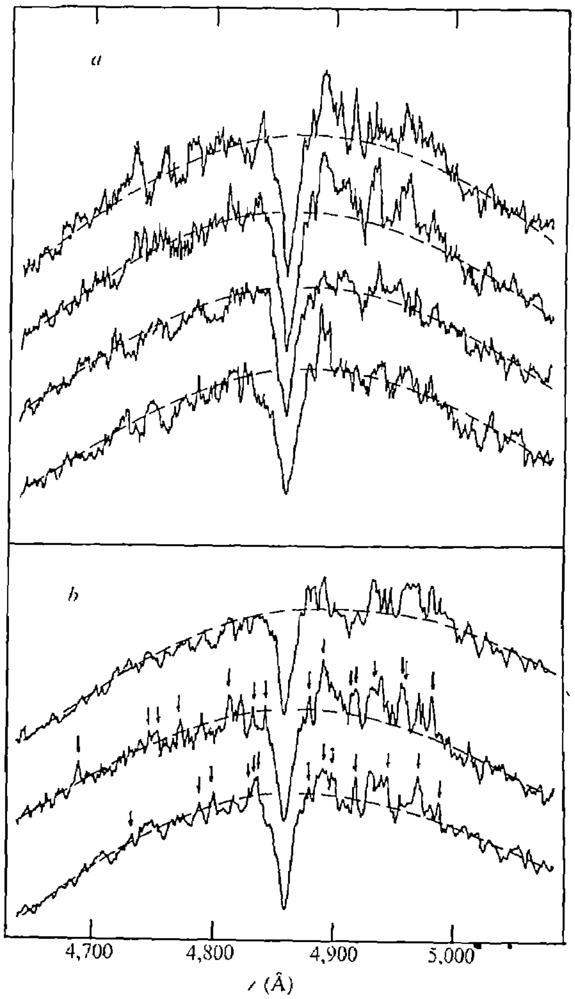

Fig. 1 *a*, Example of registrograms of successive spectra of HD215441, obtained on September 7, 1973, with a one-minute interval in the region of H_β. *b*, Registrograms of spectra, obtained on different nights. Dashed curves show conventional continuum. Top, August 26, 1973, centre, August 28, 1973, bottom September 7, 1973.

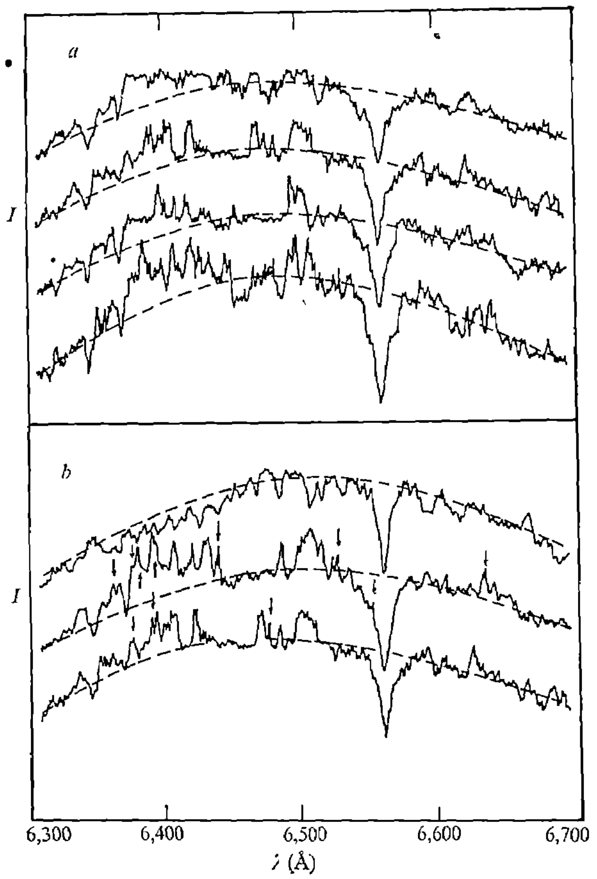

Fig 2 As Fig 1 but for H_α

absent) Positions of some rare earth lines are denoted by arrows on Figs 1*b* and 2*b*

The appearance of rare earth lines in the spectrum of HD215441 is not improbable Extremely variable emission features point to rapid non-stationary processes on the surface of the star, and it is not ruled out that these processes are similar to solar flares In flares the lines of rare earths are sometimes very prominent[9,10] On the other hand, an abnormally high abundance of rare earths is a peculiar feature of some magnetic stars

As some emission details can appear in the wings of hydrogen lines their equivalent widths can change due to blending Thus the equivalent width variations of the H_β line found by Wood[7] might be, more or less, caused by this effect or by a variable emission close to the line

We thank Dr A B Severny for discussions

Photometry of the zodiacal light in the near infrared

During our investigation[1] of comet Kohoutek (1973f) we had occasion to take many photographs of the zodiacal light through various filters In particular we photographed it in infrared light with filters to isolate regions from 610 to 920 nm Later we calibrated the emulsions and camera lenses together by photographing suitably dilute sunlight scattered by a fresh MgO surface

After making allowance for airglow emission it was clear that the albedo of the zodiacal dust cloud is greater, by a factor of two or more, in the region 750 to 920 nm than in the visible This is in contrast to the results of Matsumoto[2] Attempts to observe a reddening of the visible light have been rather inconclusive[3]

Our result is interesting for several reasons We might expect reddening for a very narrow size range of scatters with radii of about 10^{-6}m (ref 4) but this would be disguised if the usually assumed size distributions are correct

The work of Johnson and Fanale[5] on crushed meteorite fragments provides some evidence for a high infrared albedo for asteroidal material (especially for particles of radius $<10^{-4}$ m) but not to the extent that the present observations showed It is difficult to account for this infrared excess without introducing further hypotheses

High concentrations of ice particles in a layer cloud

Concentrations of ice particles in clouds, greatly in excess of those expected from ice nucleus measurements have been reported[1,2] Most of these observations have been made, however, in cumulus or other complex cloud systems, which increases difficulties in interpretation Here I describe measurements of high concentrations of ice crystals in a simple, nonconvective cloud layer

The measurements were made in very light snowfall (which never exceeded a 'trace' in equivalent precipitation rate) at Snoqualmie Pass, Washington State, between 1045h and 1300h LT on November 28, 1972 The distribution of cloud, winds and temperatures measured with a rawinsonde, and the locations at which airborne and ground measurements were made is shown in Fig 1 The cloud top, as observed from the aircraft, was very smooth and uniform and located at 1,830 m (all altitudes are above mean sealevel) where the temperature was −5° C Cloud base was at 1,220 m, where the temperature was

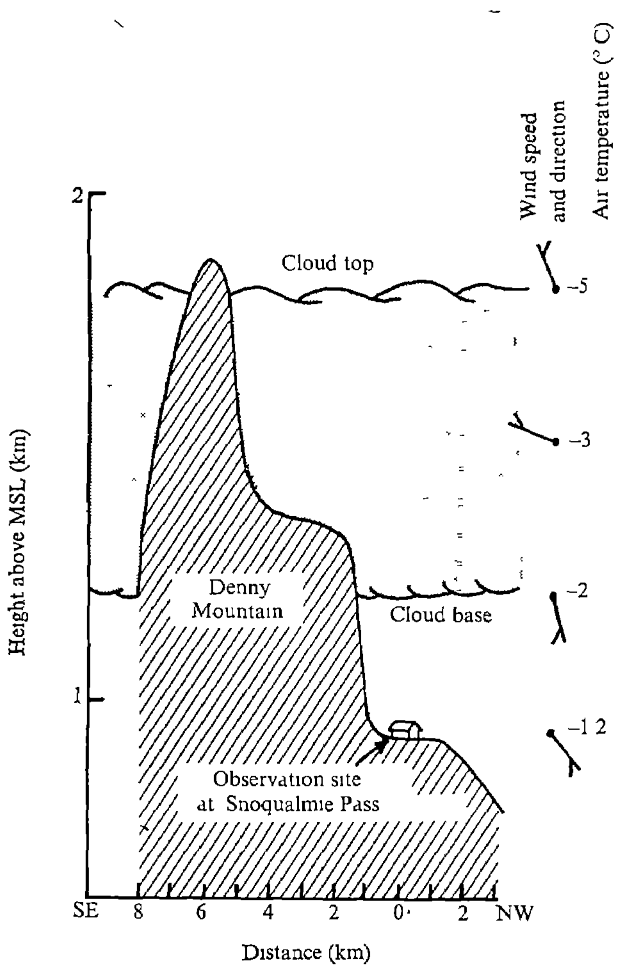

Fig 1 Observation site and atmospheric conditions

−2° C. A spectrum of cloud droplet sizes was obtained near the cloud top with a Formvar cloud particle sampler attached to the aircraft (Fig 2). Also shown in this diagram is the contribution to the liquid water content from droplets of various sizes, droplets with diameters up to 75 μm were present.

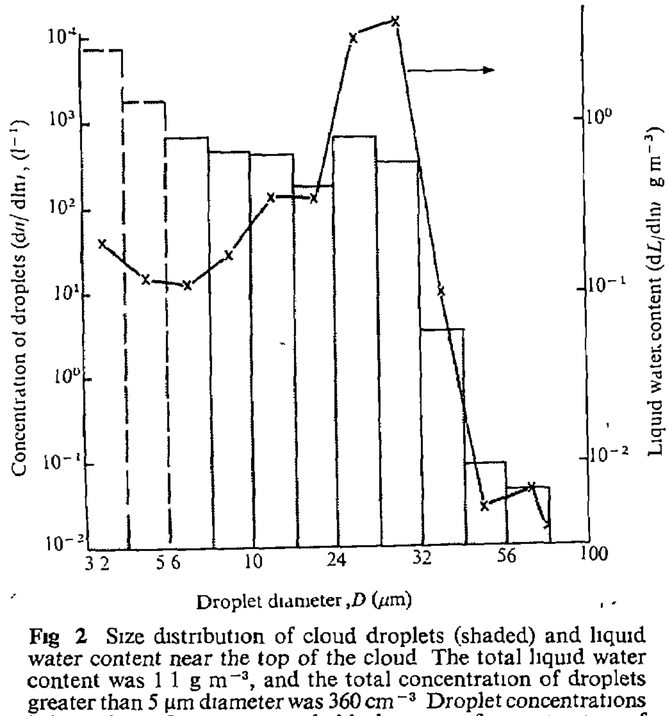

Fig 2 Size distribution of cloud droplets (shaded) and liquid water content near the top of the cloud. The total liquid water content was 1.1 g m^{-3}, and the total concentration of droplets greater than 5 μm diameter was 360 cm^{-3}. Droplet concentrations below about 5 μm are unreliable because of uncertainties of collection

Some isolated ice needles and irregular crystals were also collected from the aircraft flying near the cloud top.

The crystals reaching the ground site (elevation 915 m) initially consisted of single needles and sheaths, but as the snowfall rate increased they formed aggregates. As the number of crystals in an aggregate is difficult to estimate, the results described here are confined to the period when single crystals only were collected. The concentrations of single crystals in the air were deduced from measurements of the number of crystals which fell on to glass slides exposed horizontally for measured time intervals, by considering the speeds of fall of needles and sheaths ($\simeq 1$ m s^{-1})[3]. The concentrations of crystals in the air was about 1 l^{-1}. Measurements of atmospheric ice nuclei indicated that at the minimum temperature in the cloud (−5° C), the concentration of ice nuclei should be about 10^{-4} to 10^{-3} l^{-1}. Therefore, the concentrations of the crystals in this simple layer cloud exceeded, by at least a factor of 10^3, those expected from measurements of ice nuclei.

The size distributions of the crystals collected on the ground are shown in Fig 3. The crystals tended to be either completely unrimed or moderately to densely rimed. The droplets frozen on to rimed crystals were up to 100 μm in diameter and were concentrated on the leading edges of the crystals. The rimed crystals tended to be fewer in number but larger in size than the unrimed crystals, indicating that the unrimed crystals had shorter growth times. The unrimed crystals possibly originated on ice splinters produced during riming in the lower regions of the cloud. In this connection, we note that the conditions under which riming occurred in this cloud encompass the critical combination of conditions for temperature, droplet sizes and impact speeds under which large numbers of splinters have been observed in laboratory experiments[4]. As unusually high concentrations of ice crystals, however, have been observed in clouds where there was no riming (G. Vali, personal communication) and, in some situations, do not occur in clouds where riming does take place[5], there is still no completely satisfactory theory to explain the phenomenon.

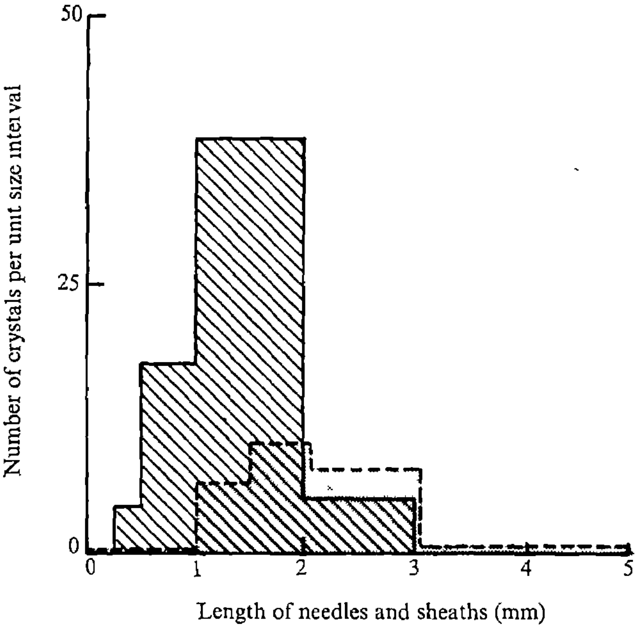

Fig. 3 Size distribution of rimed (shaded) and unrimed (hatched) needles and sheaths collected at the observation site

The high concentrations of ice crystals which occurred in the cloud described here could not have been produced by the mechanism postulated by Mason[6] because that requires convective towers. Indeed, contrary to Mason's contention, there are several sets of independent field observations which show high concentrations of ice crystals in non-convective clouds (refs 2 and 7, and G Vali, personal communication)

Because there are natural limits to the masses and speeds of fall which ice crystals can achieve in the atmosphere, ice crystal concentrations of the order of 1 l^{-1} are needed to produce even light snowfalls Such concentrations must, therefore, be quite common in shallow layer clouds For example, a needle crystal of 5 μg mass has a speed of fall of about 1 m s^{-1} To produce an equivalent water precipitation rate as small as 0 02 mm h^{-1}, these crystals have to exist in the air in concentrations of about 1 l^{-1}

Mercury in the sediments of the Pallanza Basin

SURFACE sediment samples (0–3 cm) taken from the Pallanza Basin of Lago Maggiore, Italy, in 1970 have been analysed for mercury, using flameless atomic absorption spectrophotometry The concentration of mercury in the Maggiore sediments proved to be extremely high when compared with other reported lake sediments (Table 1, and ref 1) They were checked by another laboratory and both sets of results were in extremely good agreement Mercury concentrations ranged from 0 2 to 20 1 p p m, with a mean of 7 7 p p m and a standard deviation of 4 9 p p m

The highest concentrations of mercury in the Pallanza Basin occur to the south of Pallanza, with additional elevated regions occurring in the nearshore area to the north of Stresa and off Feriolo (Fig 1*a*) Thomas[2] has demonstrated the use of a quartz correction for total mercury in assessing the variable adsorption of mercury by sediment fines and in locating point source inputs A similar correction has been applied for the Pallanza Basin sediments, in which total observed mercury has been corrected for the percentage of material of sand size (Fig 1*b*) Mercury enriched sediment occurs predominantly along the north shore of the basin, in water which is up to approximately 125 m deep, with the Toce River as the indicated primary source The areas of higher concentration at Feriolo and Stresa are again apparent from the distribution given in Fig 1*b*

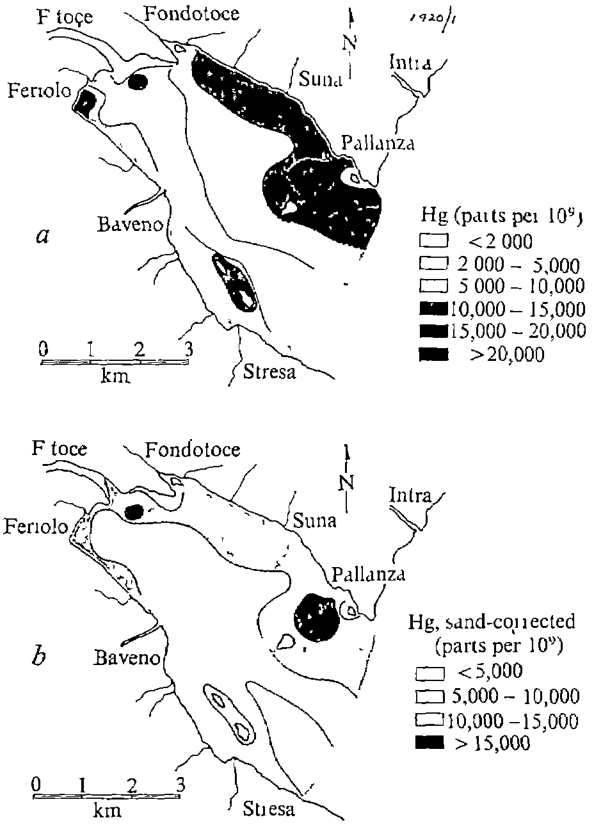

Fig 1 *a*, Distribution of total observed mercury in the surface sediments of the Pallanza Basin, *b*, distribution of sand corrected mercury in the sediments of the Pallanza Basin

After the start of summer stratification, in late March, suspended materials associated with Toce River waters occur predominantly to a maximum depth of 50 m in the Pallanza Basin[3,4] Thus, through the bulk of the basin, turbid Toce River water flows over the hypolimnion and is transported to the open waters of Lago Maggiore In the shallow water areas, suspended solids, associated predominantly with the epilimnion, are deposited and retained The maximum input of solids from the Toce River takes place with the spring runoff which occurs in late April and May, postdating the start of lake stratification[4]

Table 1 Mercury concentrations in some lacustrine, surface sediments*

Lake	No of samples	Depth of sample (cm)	Concentration (parts per 10^9) Minimum	Maximum	Mean	Standard deviation
Superior	405	0–3	4	584	83	56
South Michigan	31	Variable	30	380	146	
North Channel	55	0–3	8	1,112	151	231
Huron Georgian Bay	117	0–3	12	9,500	257	1,013
Huron	163	0–3	54	805	222	162
St Clair	55	0–2	70	2,565	632	628
Erie	243	0–3	13	7,488	609	703
Ontario	248	0–3	32	2,100	651	507
Pallanza Basin, Lago Maggiore	34	0–3	240	20,100	7,649	4,882

* Data from ref 1

The relationship of total mercury to other sedimentary parameters has been examined by means of a linear correlation matrix Significant relationships were observed with the clay size fraction ($r = 0\ 722$) and with iron ($r = 0\ 553$), suggesting that the mercury is associated with iron rich, detrital clay particles (see ref 5) No significant relationship with organic carbon ($r = 0\ 367$) was observed

The impact of the high mercury concentrations on the aquatic biota, has not been examined Damiani[6] discussed the variation of the C/N ratio in the sediments of the basin and noted that lower ratios, attributable to autochthonous organic matter, occurred in the shallow water areas along the north shore from Fondotoce to Pallanza, north of Stresa and off Feriolo Higher C/N ratios, indicative of allochthonous organic matter, were observed in the deeper central waters of the Pallanza Basin and were attributed to direct derivation from the Toce River Figure 2 shows the relationship of mercury to the C/N ratio, the relationship is significant, with a correlation coefficient of $-0\ 656$ Even though the gross statistical relationships show that the mercury is associated predominantly with the clays, the relationship of mercury with the C/N ratio implies that the mercury may in part, be associated with autochthonous organic matter This is in distinct contrast to the lower mercury levels in allochthonous organic matter with a high C/N ratio, derived from the Toce River It is possible that this relationship is coincidental in that the deposition of clay and associated mercury from the Toce River occurs predominantly in the shallow water regions which in turn receive the highest input of deposited autochthonous organic matter We feel, however, that the degree of the relationship between mercury and autochthonous organic matter, as inferred from the C/N ratio, implies uptake of mercury by the primary producers in the shallow water zones, which indicates that mercury transfer processes are taking place Confirmation may follow from an examination of the levels of mercury concentration in the biota of the lake

Drag reduction in polymer mixtures and the effect of molecular weight distribution

Small amounts of certain high molecular weight polymers can reduce the frictional drag in turbulent flow through pipes[1,2] Although the phenomenon—the so-called drag reduction effect—has been studied extensively, very little information is available about the effects of molecular weight distribution in polydisperse samples All common drag reducing agents are characterised by a broad distribution of molecular weights, which changes during shear degradation[3,4] Consequently, any molecular theory of drag reduction must include some means of handling these complications The equations presented here represent a possible first step in this direction

For many materials the percentage of frictional drag reduction at a fixed Reynolds number, DR, can be related to a reduced polymer concentration, r, by the empirical equation[5,6]

$$DR/DR_{\max} = r/(1+r) \qquad (1)$$

where

$$r = c/[c] \qquad (2)$$

The polymer concentration, in weight parts per million (w p p m), is represented by c, and $[c]$ and $DR_{\max}$ are empirical constants called the intrinsic concentration and the maximum drag reduction, respectively These equations are valid at flow rates significantly above the onset of drag reduction and at relatively low concentrations, where DR is substantially less than $DR_{\max}$ At higher concentrations the measured drag reduction is often less than that predicted by equation (1) and thus $DR_{\max}$ is seldom obtained in experiments This is parti-

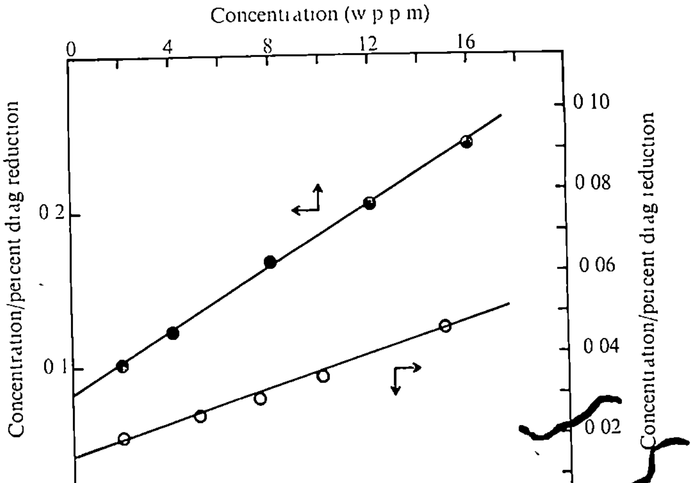

Fig 1 Graph of concentration over percent drag reduction against concentration ●, WSR-205 data, ○, WSR-301 data Slope equals ($1/DR_{\max}$), intercept on the ordinate equals ($[c]/DR_{\max}$)

Table 1 Properties of polymer samples

Compound	[c]	DR_{max}
WSR-205	8 0	98
WSR-301	1 5	98

cularly noticeable in capillary tube measurements where DR_{max} can be quite large The intrinsic concentration is a measure of the polymer's effectiveness as a drag reducing additive, that is, materials with the lowest values for [c] are the most effective

Little, Ting and Kim have studied the drag reducing ability of polyethylene oxide[6] and polyacrylamide (unpublished work) They found that equations (1) and (2) are obeyed at low concentrations and that [c] can be related to the weight average molecular weight, $\bar{M}$

$$[c] = A/(\bar{M}-M_0) \qquad (3)$$

where A is a constant characteristic of the polymer family and M_0 is the molecular weight below which no drag reduction is observed in that family The weight average molecular weight can be defined as

$$\bar{M} = \sum_i c_i M_i / c \qquad (4)$$

where c_i is the concentration (w p p m) of molecules with molecular weight M_i Equations (1) and (2) may now be written as

$$\frac{DR}{DR_{max}} = \frac{\sum_i r_i}{(1 + \sum_i r_i)}$$

where r_i is the reduced concentration of the ith component

$$r_i = c_i/[c_i] \qquad (6)$$

and $[c_i]$ is the intrinsic concentration of the ith component

$$[c_i] = \frac{A}{(M_i - M_0)} \quad \text{when } M_i > M_0 \qquad (7)$$

$$[c_i] \rightarrow \infty \text{ when } M_i \leqslant M_0$$

Experimental results[6] also indicate that DR_{max} varies with molecular weight but only for molecules where M_i is close to M_0 If $\bar{M}$ is significantly greater than M_0, the effects of these lower molecular weight molecules is small and so DR_{max} can be treated as a constant

These results suggest that reduced concentrations should be additive when the sample is considered to be a mixture of many different components, each with a single molecular weight The best way to test these equations would be to study mixtures of several different monodisperse polymers from the same polymer family Unfortunately, such samples are very difficult to obtain An alternate but less satisfactory procedure is to test mixtures of polydisperse samples Expressions for drag reduction with mixtures of polydisperse samples from the same polymer family can also be derived using equations (2–4) The results are similar to equations (6) and (7) except that M_i is replaced by $\bar{M}_i$, the weight average molecular weight of the ith component This means that the reduced concentrations should be additive for mixtures of polydisperse samples as well as for mixtures of monodisperse samples

Table 2 Measured and predicted* drag reduction in mixtures

WSR-205 concentration (w p p m)	Drag reduction at indicated concentration (w p p m) of WSR-301						
	0	0 25	0 5	1 0	1 5	2	3
0			24(25)	40(39)	52(49)	59(56)	65(65)
0 5		19(18)	27(26)	41(41)	51(51)		
1 0		22(22)	30(31)	43(43)	54(52)		
2 0	20(20)	29(29)	34(36)	47(47)	55(54)		
4 0	33(33)	36(39)	44(45)	53(53)			
8 0	48(49)	52(53)	57(56)				
12 0	59(59)						
16 0	66(65)						

*Values predicted from equations (6) and (7) are in parentheses

To test this, two high molecular weight polyethylene oxide samples were obtained (Union Carbide Corp) An automated capillary rheometer[7] was used to measure the concentration dependence of drag reduction for aqueous solutions of both samples at a Reynolds number of 9,000 The capillary tube has an inside diameter of 0 1575 cm The intrinsic concentrations and maximum drag reductions were then determined[6] from the slopes and intercepts in graphical plots of c/DR against c Figure 1 shows graphs for the two samples, and in both cases the linearity is excellent The values of [c] and DR_{max} are listed in Table 1 Various mixtures of these two samples were then prepared and their drag reduction measured at a Reynolds number of 9,000 The results are listed in Table 2

In each case the predicted and experimental results are in agreement in spite of the fact that these mixtures represent a variety of distinctly different average molecular weights and molecular weight distributions This suggests that equations (5–7) may represent a meaningful first step towards understanding the behaviour of mixtures and, therefore, the effects of molecular weight distribution It is hoped that, as monodisperse drag reducing polymers become available, these relationships can be more rigorously tested

Role of upper-layer interactions in electron diffraction symmetries

STEEDS *et al* have published pictures showing effects of upper-layer interactions in molybdenite[1,2] Because of its use in structure analysis it seems worthwhile to set down rules from the literature which relate electron diffraction symmetries to three-dimensional crystal symmetries As distinct from problems which can be solved by considering only zero-layer interactions, such as the determination of a polar axis in the plane of projection[3,4], the total crystal symmetry, including the boundaries, must be considered when upper-layer interactions are important As a simple example some results obtained from a highly tilted crystal are given, and I also comment on the conclusions of Steeds *et al*[1,2]

There are two rules pertaining to the symmetry of the zone-

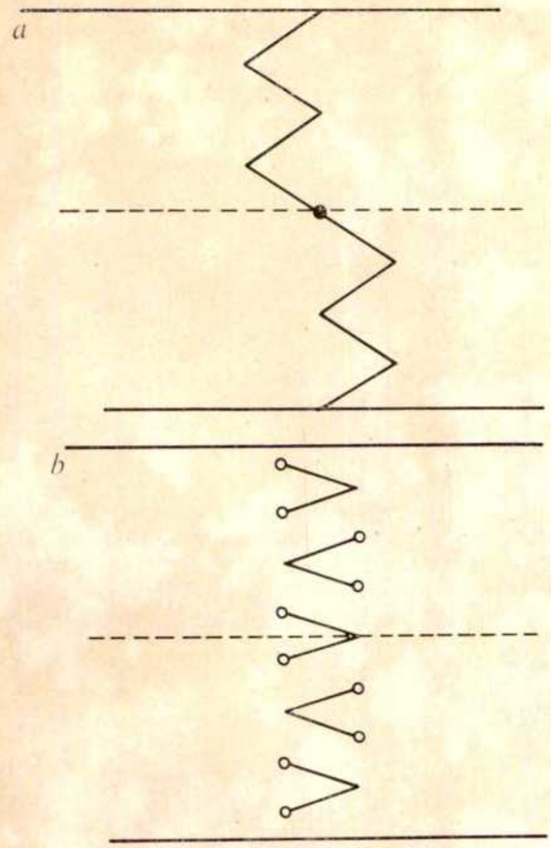

Fig. 1 The significance of a central mirror plane to the zero-beam diffraction symmetry. *a*, Representation of a crystal with the stacking sequence A-B-A-B-A-C-A-C-A. This illustrates the case of a graphite crystal with a central stacking fault. This crystal has no central mirror plane or glide plane, although it has a centre of symmetry[12]. The zero-beam distribution resulting from diffraction will be non-centrosymmetric. *b*, Representation of a molybdenite crystal of five layers ($2\frac{1}{2}$ unit cells), which has a central mirror plane but not a centre of symmetry. The zero-beam distribution will be centrosymmetric. Empirical results are dependent on structure (Table 1). Ray diagrams, incorporating the law of reciprocity, given in publications referenced in the text, make these conclusions obvious.

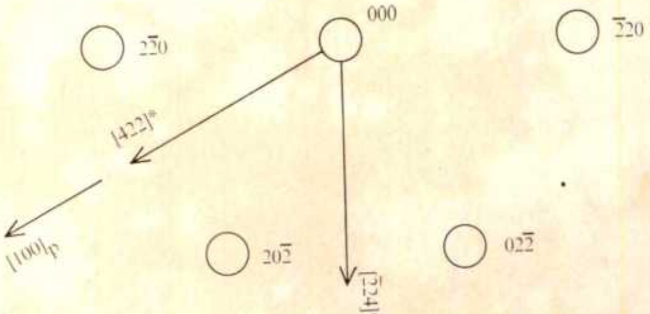

Fig. 2 Indexing of reflections relative to the projection of the surface normal, [100] p, for the [111] pattern; $02\bar{2}$, $02\bar{2}$, are zero-layer reflections. Other 220-indexed reflections, using the present nomenclature, belong to first upper and lower layers.

axis pattern[3,5,6]. First, the condition for a centre of symmetry in the zero-beam pattern is that the crystal as a whole has a mirror or glide plane, perpendicular to the zone axis, midway between its surfaces. Second, an additional condition for a centre of symmetry in the remainder of the diffraction pattern is that there is a centre of symmetry in the two-dimensional projection of the crystal.

These conditions ((1) and (2)) relate, respectively, to upper-layer and zero-layer interactions. The latter terms need definitions appropriate to dynamic scattering. In discussions of X-ray crystallography 'upper layer' and 'zero-layer' are used for a particular zone independent of the scattering experiment, and/or an infinite crystal (thus, crystal boundaries are irrelevant to this nomenclature). It is much better to use another nomenclature for electron diffraction.

'Zero-layer reflections' are defined here as those reflections generated by scattering from the z-independent structure, that is, from the finite crystal with a structure averaged out in the z-direction between the crystal surfaces, where the z-direction is identified with the surface normal. This definition, following the scattering process rather than the unit-cell geometry, allows 'upper-layer interactions' to be associated with effects strictly connected with propagation. This is consistent with established theory[7-9].

Condition (1) can only be fulfilled for a parallel-plate crystal when the surface normal is parallel to the zone axis. This condition refers to the symmetry of the crystal as a whole rather than simply to the space-group symmetries of the unit cell. Condition (1), and thus the zero-beam symmetry, has no direct bearing on the question of whether the crystal as a whole, or the unit cell, has a centre of symmetry (Figs 1*a*, *b*, and 2). Both conditions taken together determine a centrosymmetric crystal. The two conditions can, however, be exploited separately in analyses (Table 1).

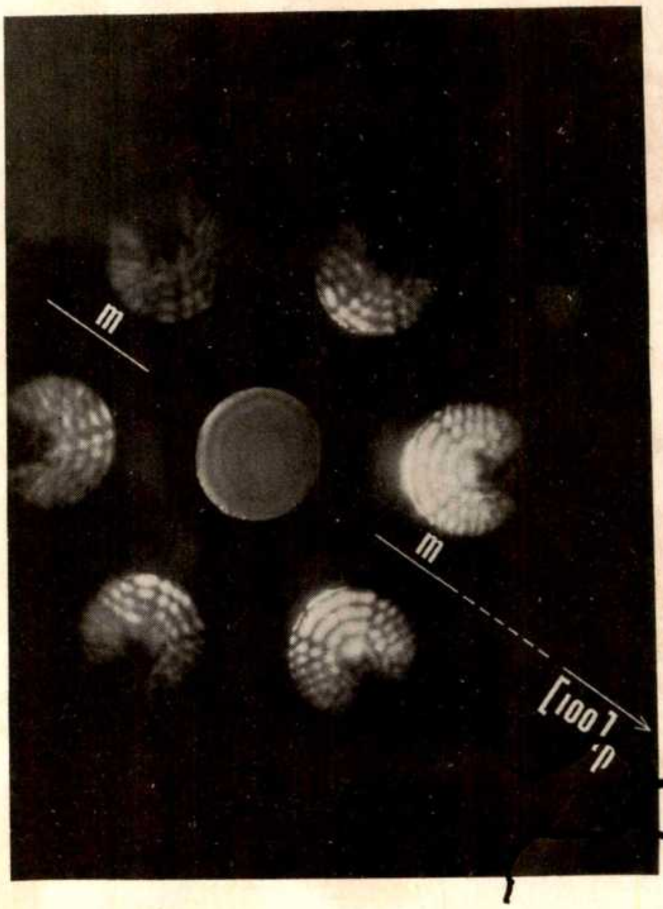

Fig. 3 Convergent-beam diffraction pattern from an MgO platelet with (100) faces, at the [111] zone axis, using 80 kV electrons. Direction of the projection of [100] is indicated. The only symmetry in the diffraction pattern including the zero beam is a mirror line perpendicular to this direction.

Table 1 Effect of structure on empirical results

Crystal symmetry		Diffraction symmetry Zero beam	Diffraction symmetry Rest of pattern
(1) Centrosymmetric crystal	Central mirror plane	Centrosymmetric	Centrosymmetric
	No central mirror plane (examples: Figs 1*a* and 2)	Non-centrosymmetric	Non-centrosymmetric
(2) Non-centrosymmetric crystal, centrosymmetric in projection	No central mirror plane	Detectably non-centrosymmetric only for a large (polar) *c*-axis, or long disorder parameter in the c direction	
(3) Crystal non-centrosymmetric in projection	Central mirror plane (example: CdS, $BaTIO_3$, space group symmetry, Fig. 1*b* (crystal boundaries)	Centrosymmetric	Non-centrosymmetric
	No central mirror plane	Detectably non-centrosymmetric as for (2)	Non-centrosymmetric

As an example in which upper-layer interactions strongly influence the symmetry of the diffraction pattern, consider the [111] zone-axis pattern obtained from an MgO plate with (100) surfaces. I reason that the hexagonal symmetry of a crystal with [111] surfaces will be destroyed by upper-layer interactions. The pattern will only have one mirror line, through its centre, parallel to the set of mirror planes of the whole crystal, that is, parallel to planes containing [100] and [111] (Fig. 3). The pattern symmetry corresponds directly to the three-dimensional symmetry of the crystal in that orientation.

The effect of symmetry on the zero-beam can be increased by tilting the crystal away from the axis, which increases the dynamic coupling. Figure 4 shows the convergent-beam picture for the 'three-beam pattern' near $\zeta_{02\bar{2}} = 0$ and $\zeta_{20\bar{2}} = 0$. With this indexing the projection of the surface normal, [100], is parallel to $[4\bar{2}\bar{2}]^*$. As the space-group mirror line $[22\bar{4}]$†, bisecting the two scattering vectors, is not contained in a mirror plane of the whole crystal, the two reflections have unequal intensity distributions. The asymmetry in the zero-beam distribution about this line demonstrates the upper-layer origin of this effect. An almost perfect mirror line is, however, observed through the $02\bar{2}$ distribution along the line $\zeta_{02\bar{2}} = 0$. This line is parallel to the mirror plane of the crystal.

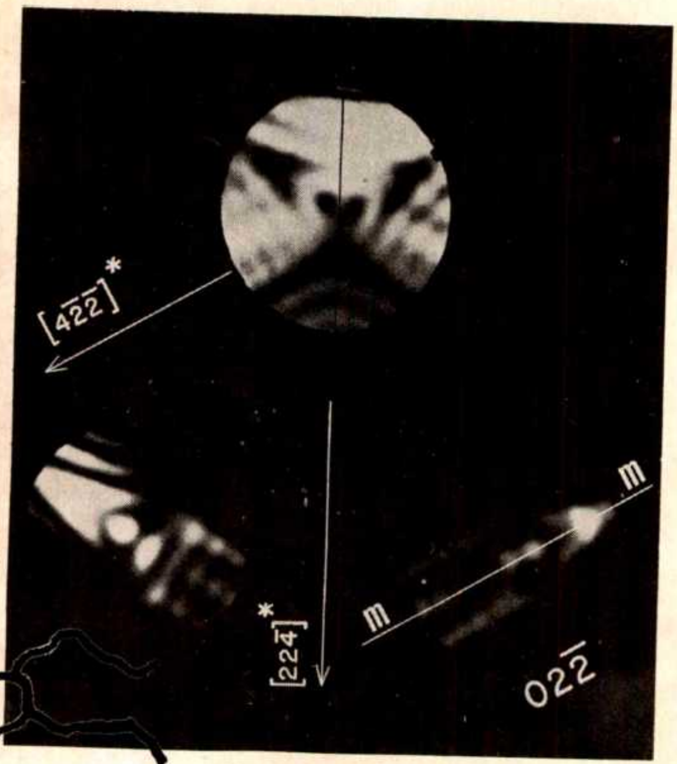

Fig. 4 Convergent-beam diffraction from the crystal used for Fig. 3 tilted to satisfy the $02\bar{2}$ and $20\bar{2}$ reflections. With this indexing the projected [100] surface normal is parallel to $[4\bar{2}\bar{2}]^*$, which is also parallel to the mirror planes of the crystal. The $02\bar{2}$ reflection is symmetric about the line m—m of zero excitation error.

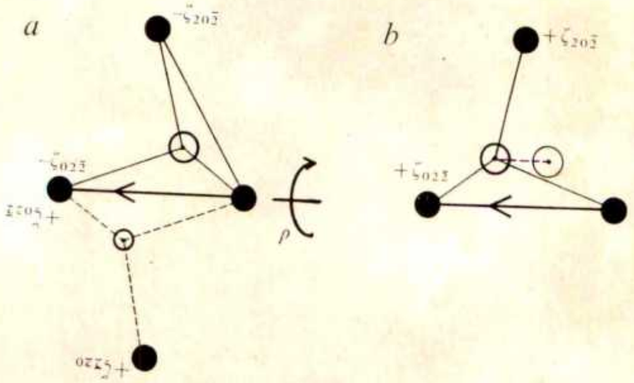

Fig. 5 *a*, The reciprocity construction of Moodie[4] projected on to the plane perpendicular to [111]. The centre of the Ewald sphere is shown encircled; arrow, scattering vector for $02\bar{2}$. The reciprocally related diagram, below the plane of projection, is indicated by broken lines, and its excitation errors and their signs are shown inverted. *b*, Result of rotating the reciprocal diagram of *a* through 180° about the scattering vector. The original Ewald sphere centre is also shown, indicating that its displacement is parallel to the diffraction vector.

It is important to ascertain whether symmetries apparent in the pattern are expected to be exact, or only approximate, theoretically, because the former case provides a good test of experimental accuracy. The construction given by Moodie[6] for the application of the reciprocity theorem allows determination of the symmetry of the $02\bar{2}$ reflection for this crystal. This construction gives the two incident directions leading to identical scattering vectors and amplitudes for any crystal (Fig. 5*a*). Equivalent incident directions are obtained by operations on the diagrams which, because of symmetries, leave the crystal unchanged. To exclude the trivial exercise of equating intensities from crystallographically equivalent zone axes, these operations must leave both crystal and zone axis unchanged.

Equivalent conditions can be found for the $02\bar{2}$ beam by rotating the diagram through 180° (Fig. 5*b*). This operation will leave the crystal unchanged provided it is centrosymmetric (that is, if conditions (1) and (2) are fulfilled) (Fig. 6). Figure 5 gives proof of the existence of a mirror line in the $02\bar{2}$ distribu-

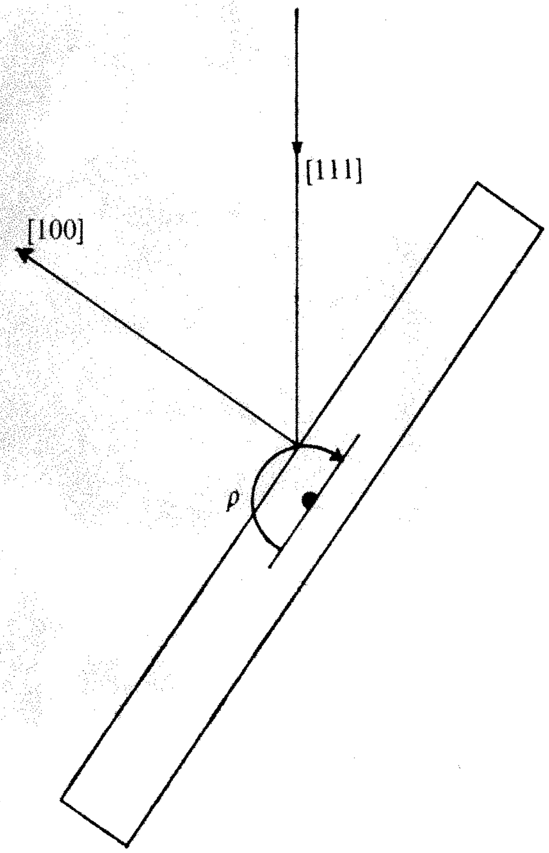

Fig. 6 Diagram showing the tilted crystal. Relationship between surface normal [100], zone axis [111], and the 180° rotation ρ about the 02$\bar{2}$ scattering vector are shown.

tion, for the centrosymmetric MgO structure. The setting of Fig. 4 thus provides the additional information necessary for interpretation of Fig. 3: the asymmetry at the zone axis arises from the influence of crystal boundaries and not from a polar structure. This conclusion follows directly from the proof of Fig. 5.

There are published observations of the effects on symmetry of stacking faults[10]. In MoS_2 the most common cause will be a S/S shear[11] somewhere central in the crystal. The problem is closely related to that in graphite, for which complete calculations exist[12]. In the case of a pure rhombohedral crystal there is a regular rather than an irregular sequence of basal faults, over a finite thickness. I believe that distinguishing these cases from the data, and locating the positions of faults, requires numerical analysis, and that the rules quoted by Steeds *et al.*[2] are not always followed. As extreme examples I refer to the upper-layer unit cell (regular stacking) effects in gold[13]. In these cases there are antisymmetric contours over relatively large angles away from the [111] zone. There is also a strong trigonal pattern caused by a single stacking fault in graphite[12].

Diffraction contoured micrographs allow exploration of a large angular region using one diffraction order, but lack linear mapping and fine specimen resolution, as crystal curvature cannot be controlled. On the other hand, convergent-beam diffraction allows specimen resolution down to 50 Å, with accurate angular resolution, but over a necessarily limited angular region. Wide-angle convergent-beam patterns[14] (with overlapping diffraction orders) can be shown to have arbitrarily imposed symmetries, although a series of normal Kossel-Möllenstedt patterns (non-overlapping orders) can be used to map out the entire region of the zone axis. As specimen resolution is, however, limited, this is not a universal technique, and normal electron micrographs are also required. The relative advantages of either of the conjugate objective planes for structure analysis will be discussed in future (W. C. T. Dowell, and P. Goodman, unpublished).

The wavelength dependence of patterns of the zone axis provides a simple test[15] of the structure factor as distinct from shape-transform[6] dependence. It is misleading, however, to refer to the two-beam approximation in connection with the low-voltage (or large excitation error) zone-axis pattern, and more correct (A. F. Moodie, unpublished) to refer to a different approximation (for example, the second Born approximation, or the thick phase-grating[16] approximation).

DR STEEDS REPLIES: Dr Goodman[1] casts doubt on the bright field rotation method[2] of identifying the presence of faults parallel to the surface of a specimen. The examples quoted in support of his point of view are, however, inadequate. Whereas our experiments are often performed over rotations of 20° or more, in the convergent beam work in gold, cited by Dr. Goodman, the angular range in view is 1.29° at 4.21° from [111], which is much too limited for a test. During large rotations the systematics-only pattern is interrupted by various non-systematic reflections, but there are several ranges of orientation in which non-systematics are not important and the asymmetric pattern returns to essentially the same form. The graphite example is irrelevant because the field of view is restricted to a narrow angular range close to the [0001] zone axis where the pattern is dominated by rapidly varying cross-grating contributions; our 'rule' refers to contours which result essentially from one-dimensional diffraction. Clearly, the misunderstanding arises from the very great difference of angular view in convergent beam and bend contour patterns, despite their formal equivalence (to a first approximation). Effects of inclination, although important for really large tilts, such as the 54° from the normal of the foil used by Dr Goodman, are not in our experience significant for smaller rotations of the order which we propose in our experimental test, at least not for bend contour patterns, where a certain amount of distortion is almost inevitable.

Dr Goodman claims that our reference to "two-beam-like behaviour" is misleading, and so we wish to state explicitly what was meant by that phrase. It is possible to show from the many-beam theory of electron diffraction that (B. Buxton, unpublished)

$$\frac{d\xi_{ij}}{d\beta} = \xi_{ij}\left\{\frac{1}{\beta}+\beta\gamma^2\left[1-\frac{\gamma}{s_i-s_j}\frac{d(s_i-s_j)}{d\gamma}\right]\right\}$$

$$s_i-s_j = (\gamma^{(i)}-\gamma^{(j)})/4\pi k$$

where $\gamma^{(i)}$, $\gamma^{(j)}$ are the eigen values obtained by matrix diagonalisation (usual notation[3]); ξ_{ij} is the extinction distance corresponding to $(i-j)$ dispersion surface transitions; $\beta = v/c$; and $\gamma = (1-\beta^2)^{-1/2}$.

According to strict two-beam theory $d(s_i-s_j)/d\gamma = (s_i-s_j)/\gamma$ and so our result holds. There are, however, a number of other situations, which we call "two-beam-like", in which the second term in the above expression vanishes or is negligibly small. These often occur when there are only two branches of the dispersion surface with excitations which vary rapidly with orientation (characteristic low voltage behaviour). Even in extreme cases of many-beam diffraction, such as in the case of molybdenite in our illustration, the pattern can be regarded as coming largely from transistions between two branches, although the branches involved change with orientation.

We find Dr Goodman's change of definition of zero and upper layer reflections unnecessary and inconvenient[4], involving as it does the surface normal. In our experience, the relative orientation of a zone axis and the surface normal may stray by 20° or more without significantly affecting zone axis patterns. Finally, although Dr Goodman's two conditions are sufficient they are not necessary. To take an extreme case not covered by condition (1) we may obtain a centre of symmetry in the zone beam pattern by diffraction from two different monolayers having centres of symmetry colinear with the mean direction of the incident beam (we are grateful to Professor Frank for making this point).

A new penetrating-radiation image converter

A NEW practical penetrating-radiation television camera tube, termed the Metallonicon, has been built. It operates at X-ray frequencies, and a discernible image is obtained with two mr. s^{-1} incident on the target, which is comprised of a heavy metal layer in intimate contact with a secondary electron enhancing storage layer.

Most imaging systems used in the application of isotopes form an image in a large area scintillation counter crystal, the light output of which is detected by photo-multiplier tubes for storage, subsequent processing and image formation[1]. The work reported here has as its goal the combination of the above image forming capabilities into one relatively simple image transducing surface that would permit variable storage rate displays utilising television techniques.

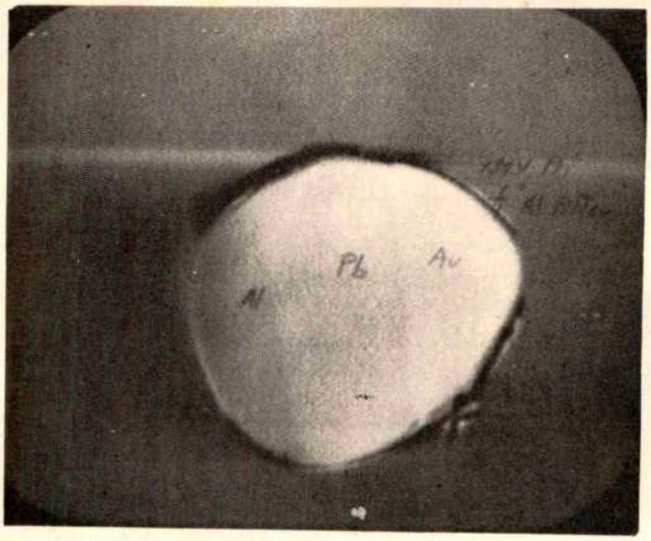

Fig. 1 Variation in sensitivity of metallonicon with differing metal converting layers. The Pb and Au layers are both 6 μm thick. Al is the uncoated signal plate. Note the improved performance of the system obtained when using the Au layer in combination with the CsI storage and signal enhancing layer. The X-ray generator used produces 75 kV potential self-rectified with 130 V applied to the primary. X-ray tube current was 5×10^{-4} A. Tube to target distance was 300 mm. Filter in beam 8 mm aluminium. Target diameter 100 mm. Image display rate 30 frames per second.

At penetrating-radiation energy levels exceeding 150 kV potential, heavy metal intensifying screens are used in preference to, or in combination with, fluorescent screens to provide increased speed and detail resolution for the radiographic process[2,3]. Attempts have been made in the past to utilise this image forming technique in the construction of penetrating-radiation image converters[4]. These have, in general, not been of great practical consequence because of the extremely

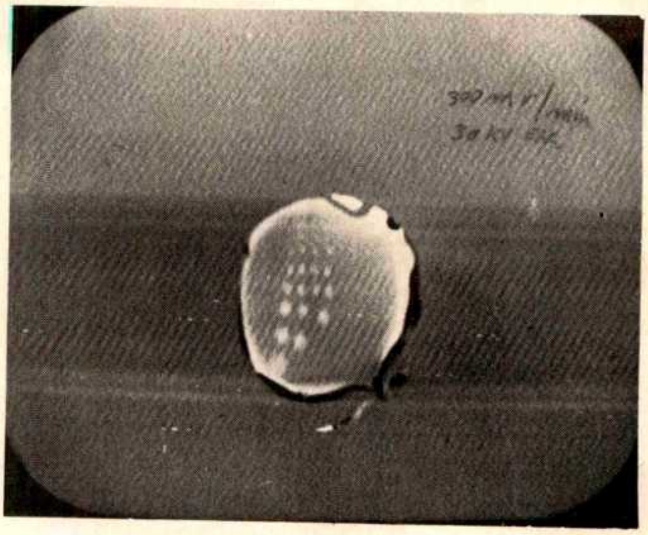

Fig. 2 Resolution obtainable at measure dose rate of 5 mr. s^{-1} at face plate of tube. Object is Pb sheet with holes ranging in size from 5 mm at bottom of image to 1 mm at top. Magnification of object detail due to X-ray generator–object–image target geometry. Diameter of image target 100 mm. X-ray generator 60 kV potential self-rectified. X-ray tube current 2×10^{-3} A. 25.4 mm aluminium placed between object and image tube target to achieve level and quality of radiation noted. X-ray tube to image target distance 300 mm. Image display rate 30 frames per second.

low yield of the absorbed quanta to photoelectron process and the relatively short image integration time

Secondary electron enhancing materials such as KCl and CsI are routinely used as the image storage layer in television camera tubes capable of operation at the low light levels encountered in astronomical studies[5] The tube reported here combines on one scanned surface the high energy conversion method of radiography with the storage and image enhancing features of the SEC target Even at its present stage of development it exhibits characteristics that indicate it has potential value in many applications concerned with the imaging of high energy penetrating radiation fields

This new image tube combines a heavy metal conversion layer (Au, Pb, or Pt) with a high resistivity secondary electron enhancing layer (CsI) to form the target of a television camera storage tube The target of the tubes constructed so far is made using an aluminium substrate covered with an evaporated layer of gold about 6 μm thick upon which a layer of low density CsI is deposited The low density CsI layer, prepared by evaporating CsI in an argon atmosphere of approximately one torr, has a mass per unit area of roughly 4 5 g cm^{-2} When a field is established between the aluminium signal plate and the back surface of this layer by the scanning process, secondary emission is enhanced due to pores in the CsI layer The electron gain obtained with these low density layers is higher by some 40 times than those obtained using bulk CsI

Our work indicates that it is necessary to have a particular heavy metal emitting layer produce the photoelectrons An experiment in which the heavy metal layer was both eliminated and varied in composition is illustrated by Fig 1 Comparison studies between equal thickness Pb, Pt, and Au layers indicate that the Au layer is preferred in combination with the CsI film

Tubes fabricated with 100 mm diameter Au–Cs targets have been tested utilising a half-wave rectified X-ray generator whose effective radiation energy was measured to be 35 kV potential Response time of the tube when scanned at a rate of 30 frames per second was such that a moving object exhibited strobing due to the pulsating nature of the X-ray source In other experiments, the scanning beam was used to charge the target to approximately 40 V potential and then turned off The target was then exposed to 1 0 mr of radiation during a 1 s exposure Following a wait of 5 min, the scanning beam was turned on, at which time the image resulting from this 1 s exposure was seen as the charge pattern was equalised by the scanning beam Figure 2 illustrates the images obtainable at incident dose rates of 5 0 mr s^{-1} of radiation of 30 kV potential effective under continuous scanning at 30 frames per second

The effective X-ray energy of 35 kV potential implies that the photoelectrons were ejected from the L-shell in Au Continuing work indicates that by utilising the high energy photoelectrons and secondary radiation quanta from the K-shell in the energy range of 150 keV together with a micro-pyramidal substrate, a tenfold increase in sensitivity is obtainable

Monomolecular treatment of chemical oscillation

THE mechanism of the Belousov oscillating reaction—the catalytic oxidation of malonic acid with bromate—is highly sophisticated Although considerable progress has been made in revealing the kinetics and mechanism of both the complete oscillating system[1,2], and some of the composite reactions (especially those occurring between bromate and catalyst[3,4]) many points need further investigation

Looking at the temperature dependence of chemical oscillation and the role of different catalysts we thought to propose a simple treatment for the Belousov oscillating reaction The basis for this lies in the fact—supported by early observations, and by our calorimetric and polarographic results—that the most important reaction in a Belousov oscillating system is the autocatalytic oxidation of the catalyst (M^{n+}) by bromate in the presence of malonic acid by the formation bromomalonic acid (BrMA),

$$BrO_3^- + 4M^{n+} + CH_2(COOH)_2 + 5H^+ \longrightarrow BrCH(COOH)_2 + 4M^{(n+1)+} + 3H_2O \qquad (1)$$

In this phase of the oscillating reaction, the rate of heat evolution is very high, and this is synchronised with a sudden potential jump and decrease in bromide concentration[5] This phase is followed by one where ordinary redox reactions (such as the reduction of $M^{(n+1)+}$ by malonic acid, bromate–bromide reaction) proceed and the rate of heat evolution is low The latter phase can be regarded as a comparatively 'restful' one When the bromide concentration in the system falls below a critical value (~3 10^{-6}M) (ref 1), the autocatalytic reaction is switched on again These processes follow each other periodically Thus, the Belousov oscillating reaction can be regarded as a series of autocatalytic reaction 'bursts' occurring with a certain frequency

This consideration led us to treat chemical oscillation as a 'monomolecular' reaction As a first order rate constant (k_ω) we shall use the reciprocal of the period time at initial concentrations From k_ω values measured at different temperatures using the Arrhenius equation the 'activation energy' of chemical oscillation (E_ω) can be calculated (ω refers to chemical oscillation expressing its periodic character)

Reacting oscillating systems with three different catalysts (Ce^{3+}, Mn^{2+} and $Ru(dipy)_3^{+2}$ were investigated at 15, 25 and 35° C The oscillating systems contained malonic acid (0 4 m), potassium bromate (0 1 M), sulphuric acid (1 M) and a catalyst (0 0005 M) (system 1) From the frequency of the second (or third) period of chemical oscillation the activation energy of the oscillating reactions was calculated The frequency changes with time because of concentration changes in the reactants, so it is necessary to choose an early period Figure 1 shows the log k_ω against $1/T$ plots From Fig 1 it is obvious that the Arrhenius equation is valid in the temperature range investigated and that E_ω is practically identical with all the three systems E_ω = 16 1 ± 0 2 kcalorie mol^{-1} (67 5 ± 0 8 kJ mol^{-1})

Using the absolute rate equation, the 'entropy of activation' of the oscillating reactions (ΔS_ω*) was also calculated Actually, ΔS_ω* is the probability of 'autocatalytic reaction bursts' Its value is −12 5 calorie mol^{-1} deg^{-1} (−52 5 J mol^{-1} deg^{-1}) with all three catalysts

We conclude that neither E_ω nor ΔS_ω* depends on the nature (for example, the redox potential) of the catalyst This identi[illegible] the chemistry of the 'burst' reaction (1)

Oscillating systems with different initial concentrations were also investigated In a chemical system containing malonic acid (0 4 M), potassium bromate (0 1 M), sulphuric acid (0 5 M) and cerium (III) or manganese (II) (0 005 M) system 2 (16 5 ± 0 2 kcalorie mol^{-1}) 69 1 ± 0 8 kJ mol^{-1} was obtained for E_ω which is in a rather good agreement with the value obtained for system 1 k_ω, and thus the ΔS_ω*, values, however, differ

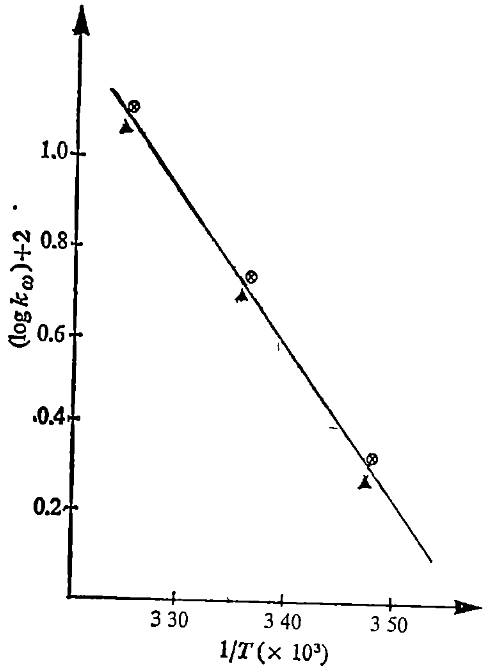

Fig 1 Plot of the logarithm of the reciprocal of the period time ($\log k_\omega$) against $1/T$ ($T=288{,}298$ and 308 K) The chemical systems containing malonic acid (0 4 M), potassium bromate (0 1 M), sulphuric acid (1 M) and catalyst (0 0005 M) ○, Ce^{3+}, × Mn^{2+}, ▲, Ru $(dipy)_3^{+2}$

with the two systems (In system 1 $k_\omega = 0\ 053$ and in system 2 $k_\omega = 0\ 015$ at 25° C) E_ω—at least within certain concentration ranges—is independent of the composition of the oscillating system the probability of 'bursts', however, is a function of the composition

Are there any characteristics of the oscillating reactions which manifest themselves when one catalyst is replaced by another? An exhaustive answer cannot be given yet

Memory for words

LISTENERS do not ordinarily retain the syntax of a sentence for longer than is necessary to grasp its meaning, they rapidly forget both superficial 'surface structure' and underlying 'deep structure'[1-3] What they retain is the sense of the sentence, evidently divorced from its syntax It has been argued that this sense might consist of an associative structure linking representations of the words in the sentence [illegible] meaning is divorced from syntax, it might also be divorced from words Indeed, we shall argue that a semantic representation need not incorporate any direct information about the lexical categories of words, it merely appears to do so because they can often be reconstructed from the meaning of a sentence It follows, of course, that the specific wording of a sentence should ordinarily be rapidly forgotten[5] One simple test of this hypothesis, avoiding the predictability of words from meaning, is to examine a person's ability to recollect whether a certain element of meaning was conveyed by a noun or a verb (Does the reader recollect with any confidence whether, for example, we wrote earlier, "the divorce of meaning from syntax", or "meaning is divorced from syntax"?) We predicted that information about lexical categories would tend to be forgotten if subjects were unaware that their memory for a sentence was to be tested, but that it would tend to be remembered if subjects expected their memory to be tested

Two independent groups of subjects were told that their task was to make up two sentences continuing the theme of a short spoken passage The members of the 'memory' group (M) were also told that they would be given a memory test for the passage, the members of the 'incidental' group (I) were given no such instruction After listening to the tape recorded passage, which described a brief incident in a science-fiction story, both groups were given recognition tests for two of the sentences in the passage

To test the hypothesis, we obviously had to use sentences whose meanings do not allow the lexical categories of their constituent words to be easily reconstructed The third sentence of the spoken passage was therefore one of the following items

(1) The owner of the magic staff dispatched the ship
(2) The dispatcher of the ship owned the magic staff
(3) The owner of the ship dispatched the magic staff
(4) The dispatcher of the magic staff owned the ship

The first pair of sentences are very similar in meaning—what one presupposes the other asserts—yet they convey their meanings by way of totally dissimilar lexical categories, for example, the information conveyed by the verb 'dispatched' in sentence (1) is conveyed by the noun 'dispatcher' in sentence (2) The second pair of sentences stand in a similar relation to one another, but their meanings are quite different to the meanings of the first pair of sentences in the first pair it is the ship that is dispatched, in the second pair it is the magic staff that is dispatched The fifth and final sentence of the spoken passage was selected from the following set of sentences constructed according to the same principles

(5) On earth, the interrogator of the Martians advised the President
(6) On earth, the adviser of the President interrogated the Martians
(7) On earth, the interrogator of the President advised the Martians
(8) On earth, the adviser of the Martians interrogated the President

The sense of the remaining sentences in the passage was sufficiently flexible to accommodate any combination of the different versions of the third and fifth sentences Thus, four different variations of the passage were recorded involving the following combinations of sentences (1) and (6), (2) and (8), (3) and (7), and (4) and (5)

After listening to the passage, each subject was given a recognition test for the third sentence followed by a recognition test for the fifth sentence These tests involved presenting the four versions of each sentence, together with their equivalents in the passive voice, both of the two sets of eight sentences were presented in different randomised orders The subjects, 16 students at Sussex University, were assigned in rotation to a group and to one of the four passages They were tested individually, and they were allowed, if necessary, to make three attempts in each test to select the actual sentence that had occurred in the passage

There was no reliable difference between the groups in their ability to retain the correct meanings of the sentences two subjects out of eight made semantic errors in group M, and four subjects out of eight made semantic errors in group I The crucial distinction between the groups concerned those syntactic errors that reveal an inability to remember the lexical categories of the original sentence even though its correct meaning has been retained, for example, the selection of sentence (2) where the original was, in fact, sentence (1) Only one such error was made by a subject in group M, whereas six subjects produced a total of eleven such errors in group I, the difference in the number of subjects making errors in the two groups was reliable ($P=0$ 02, Fisher Yates exact test) When a subject makes two semantic errors his other attempt is likely to be a guess even if it is correct in meaning, so we excluded the data of two such trials from the totals although their inclusion does not alter the basic pattern of the results

A second experiment with a similar design but different materials examined the ability of a further twenty-four subjects to remember such sentences as

(9) The borrower of the money purchased the car and the seller of the fridge bought the lawn-mower
(10) The purchaser of the car borrowed the money and the buyer of the lawn-mower sold the fridge

This task proved to be more difficult than remembering the sentences of the first experiment The subjects in group I made a total of twenty-two semantic errors and the subjects in group M made a total of eight semantic errors, and the difference between the groups was reliable ($S_0=$ 73 25, $P<0$ 015, Mann-Whitney test) Yet every subject made at least one error symptomatic of a failure to retain lexical categories, for example, confusing sentence (9) with sentence (10)

The results of the experiment suggest that even when listeners successfully recall the meaning of a sentence they can only remember whether an element of this meaning was conveyed by a noun or a verb if they know that they are to receive a memory test They are then liable to implement a method for retaining verbatim information Otherwise, lexical categories appear to be rapidly forgotten along with the superficial and underlying syntax of the sentence One could defend the thesis that sentences are remembered by forming an associative structure linking representations of their nouns and verbs by arguing that the associative machinery deals with nominals derived from verbs in a very similar way to verbs themselves But this argument runs the risk of rendering the thesis untestable It is precisely such items that prevent the automatic reconstruction of lexical categories from the meaning of a sentence One could also defend the thesis that at least word stems are remembered, since it was only the suffixes of words which were manipulated (together with the syntax of the sentence) But this view is incompatible with the results of previous experiments[2 3] We prefer to think that meaning is something that can be put into words with a suitable syntactic structure rather than a direct representation of the structured set of words itself The words and their structure can be thrown away as soon as their meaning has been grasped If this thesis is correct, it is misleading to talk of a memory for the nouns and verbs of a sentence unless one is concerned with a deliberate attempt to memorise them It is similarly misleading to talk of a memory for the underlying subject and object of a sentence, or for its underlying cases Such terminology is tied to the words that occur in a sentence and, as we have shown, it can be misleading to talk of a memory for words

Genotype interaction with undernutrition and external environment in early life

IN spite of the well documented effect of early undernutrition on body and brain size in adult animals[1-3], its reported influence on behaviour has been less consistent Changes in performance in learning tasks and activity tests have been found following undernutrition in early life[4-7] Several studies, however, have shown little or no effect of such a manipulation[8-10] Here we consider two factors which may contribute to variability in later behavioural response to early life undernutrition

Recent work indicates that the type of environment in which animals are reared may modify the behavioural consequences of undernutrition[11-13] Subtle changes in rearing conditions in different laboratories might account for the apparent lack of effect of undernutrition in some cases and its significant influence in others Another important variable which could account for variability in results is the genetic background upon which nutritional treatments are imposed Thus, the effects of undernutrition during the period of rapid development may differ according to the particular genotype selected for study

We examined the interaction of genetic background with both early life undernutrition and differential environmental conditions The C57BL/6J and DBA/2J mouse strains were selected for our experiments because they differ genetically in the control of a large number of behavioural, biochemical and physiological characteristics[14]

Mice were raised in three different environments and two levels of dietary protein Five males and five females from each mouse strain were exposed to each of the above conditions

Litters from dams of the C57BL/6J and DBA/2J mouse strains which had been previously mated in our laboratory were reared after parturition in *ad libitum* or undernourished nutritional conditions in either enriched normal or impoverished environments The enriched condition consisted of a large, clear, lucite box (75×40×20 cm high) divided diagonally in two, containing various manipulanda, the normal condition was represented by opaque, plastic home-cages (30×13×12 cm), the impoverished group was reared in sound-deadened, ventilated chambers in normal home-cages but with sensory input restricted by covering the top of the cages with a white painted, fitted metal sheet Control or undernourished animals were fed a 27% or 8% casein diet respectively, containing 10% fat with minerals and vitamins added The diets were made isocaloric by the addition of dextrose and contained 0 2% saccharin to improve palatability The litters were culled to four animals on day 4 of life After removal of the mother at 21 d, the weanlings remained in the appropriate environmental and nutritional treatment groups until 42 d after birth At this age, they were separated by sex and maintained in normal laboratory conditions with food and water available *ad libitum* until behavioural tests were carried out 90–124 d of age

At this time, animals were exposed to an illuminated (30 foot candles) Lehigh Valley photactometer, 45 cm in diameter, with a solid wood floor painted white, for 2 min on three consecutive days The frequency with which animals intersected the light sources activating the photocells was recorded automatically every 30 s Rearing and defaecation frequency were scored by an observer for each daily trial Two days after the final open-field test, animals were exposed to a 'novel-object test in the same apparatus The number of visits to,

Table 1 The results of open-field and 'novel object' tests administered to mice of the C57BL/6J and DBA/2J strains 90–124 d of age fed either an 8 or 27% casein diet for the first 42 d of life

Test	C57BL/6J Normal ($n = 25$)	C57BL/6J Undernourished ($n = 28$)	DBA/2J Normal ($n = 30$)	DBA/2J Undernourished ($n = 28$)
Mean daily open-field activity (counts per 30 s period)	19 86	16 19	23 26	23 24
Mean daily 'novel object' defaecation frequency	1 93	2 70	4 03	3 53
Mean daily open-field rearing frequency	2 94	2 01	6 87	6 24

Means for replacing missing data were utilised in seven cases in the C57BL/6J plus two cases in the DBA/2J strain The effect of these data substitutions were taken into account in the calculating degrees of freedom, error terms and F ratios Separate analyses of variance of each measure were carried out within each mouse strain In the C57BL/6J strain, undernourishment reduced activity ($F = 3\ 90$, d f 1, 51, $P<0\ 06$) and rearing frequency ($F = 4\ 05$, d f 1, 48, $P<0\ 05$) in the open-field test In the 'novel object' test, undernourishment significantly increased defaecation scores ($F = 4\ 19$, d f 1, 49, $P<0\ 05$) Early life undernutrition had no overall effect in the DBA/2J strain

and the time spent in the centre square containing a black spring mounted on a lucite base were recorded for a single 5 min test session Total activity and number of defaecations were also recorded

Analysis of variance was used to evaluate the main effect and interaction of early life undernutrition and environment and sex within each mouse strain Where measures were repeated either within daily sessions or on consecutive days on the same animals, appropriate partitions of variance were also made[15] This statistical treatment was applied to the three open-field test measures and the four 'novel-object' test scores[15]. Rearing and defaecation scores were transformed by a $\sqrt{(x+0\ 5)}$ transformation to normalise their distribution

Females defaecated significantly more than males in the open-field test in both strains ($F = 11\ 17$, d f 1, 48, $P<0\ 001$ in C57BL/6J strain $F = 5\ 18$, d f 1, 46, $P<0\ 05$ in the DBA/2J strain), but on other behavioural measures, no sex differences were found Higher-order interactions involving sex were not consistent, easy to understand or significant at a very high level and, for this reason, data from both sexes are considered together

In the C57BL/6J strain, early life undernutrition significantly reduced rearing frequency and tended to reduce activity, although the probability level associated with this effect was not very satisfactory ($P<0\ 06$) It also increased defaecation scores in the 'novel-object' test In contrast, the statistical analysis revealed no overall effect of nutritional restriction on any of the seven measures derived from the two tests in the DBA/2J strain Table 1 shows the effects of early life undernutrition in the two strains on those measures which discriminated undernourished from control groups in the C57BL/6J strain

In contrast to the effects of dietary restriction, the external environment for the first 42 d of life substantially influenced mice of the DBA/2J strain On five out of seven behavioural measures, a significant effect of environmental manipulaton was observed in the DBA/2J strain Environmental impoverishment reduced open-field activity and rearing frequency It also reduced activity levels and visits to the centre square and increased defaecation scores in the 'novel object' test

By comparison, the only statistically significant effect of early life environment in the C57BL/6J strain was in the 'novel object' test where impoverishment reduced the frequency of visits to the centre square Table 2 depicts the effects of the manipulation of environmental conditions in early life in the two strains Although the behavioural responses of the 2 strains to early nutritional restriction differed, effects on body weight at the time of testing were almost identical Undernourished animals were 77% and 78% ($P<0\ 001$) of control animal weights in the two strains

Although no effect of undernutrition was detected in the DBA/2J strain when all experimental conditions were combined, undernutrition did consistently affect behaviour of DBA/2J mice raised in the normal environment The interaction of environment × diet × time for open-field activity was statistically significant ($F = 2\ 938$, d f 6, 136, $P<0\ 025$) in the DBA/2J strain Undernutrition was correlated with reduced activity in DBA/2J mice raised in the normal environment, the effect being restricted to the first minute of the 2 min test In contrast, there was no consistent effect of undernutrition in DBA/2J mice raised in the enriched or impoverished environments on this measure A second statistically significant interaction of environment with diet ($F = 3\ 8$, d f 2, 46, $P<0\ 05$) indicated that, if DBA/2J mice were raised in the normal environment, undernourished animals defaecated more than controls in the 'novel object' test By comparison, nutritionally deprived animals raised in the enriched or impoverished environments defaecated less than controls Therefore, although undernutrition had a greater effect in the C57BL/6J strain, the occurrence of these interactions in the DBA/2J strain emphasises the relative nature of the dependence of nutritional and environmental influences on genotype

Our results which demonstrate genetic influences on behavioural response to both early life undernutrition and environmental manipulations should be considered in the light of previous discussions of gene–environment interactions in these mouse strains[16–18] Furthermore, the fact that genetic factors can influence an organism's response to undernutrition suggests a possible explanation of why undernutrition has been shown to influence some human groups but appears to leave others unaffected[10]

Table 2 The results of open-field and 'novel object' tests administered to mice of the C57BL/6J and DBA/2J strains 90–124 d of age raised in environmental enrichment, normal home-cage conditions or environmental impoverishment

Test	C57BL/6J			DBA/2J		
	Enriched ($n = 14$)	Normal ($n = 20$)	Impoverished ($n = 19$)	Enriched ($n = 19$)	Normal ($n = 20$)	Impoverished ($n = 19$)
Mean daily open-field activity per 30 s	18 40	17 72	17 95	25 05	24 76	19 93
Mean daily open-field rearing frequency	2 47	2 38	2 58	8 97	6 82	3 88
Mean novel-object activity scores ,	148 6	131 96	121 85	273 85	202 05	143 40
Mean novel-object defecation frequency	2 05	2 40	2 50	3 10	3 45	4 80
Mean daily novel-object visits	0 88	0 61	0 39	1 28	0 75	0 35

Impoverishment reduced activity ($F = 3\ 53$, d f 2,46, $P<0\ 05$) and rearing frequency ($F = 6\ 73$, d f 2,46, $P<0\ 01$) in the open-field test in the DBA/2J strain In the 'novel object' test, impoverishment decreased activity ($F = 7\ 25$, d f 2,46, $P<0\ 005$) and visits to the centre square ($F = 3\ 52$, d f 2,46, $P<0\ 05$) while increasing defaecation scores in the same situation ($F = 4\ 6$, d f 1,46, $P<0\ 025$) in this strain In the C57BL/6J strain the only statistically significant effect of environmental manipulation was visits to the centre square in the 'novel object' test, where impoverishment reduced the frequency of visits ($F = 3\ 58$, d f 2,50, $P<0\ 05$)

We thank Dr David Quartermain for critical insights and Miss Virginia Hoagland for technical assistance. This work was supported by The Grant Foundation.

The earliest conifer

SMALL leaves and a leafy shoot from the Low Westphalian B (Upper Carboniferous) near Wakefield, Yorkshire, represent the oldest direct evidence for the existence of the order Coniferales (conifers) yet discovered. This material is preserved both as compression fossils and as charcoal.

Unlike most other fossil plants from the Coal Measures these leaves show both epidermal characters and internal structure. Most of the leaves are small (1–5 mm long), narrowly triangular (Fig. 1*a*) and are occasionally forked (Fig. 1*b*), similar in general appearance to Florin's genus *Lebachia*[1]. The leaves are hypostomatic and have a denticulate margin (Fig. 2). The lower epidermis has two wide stomatal bands with closely spaced stomata which often share subsidiary cells and are monocyclic. The leaves are uninerved and the non-stomatal areas of both the lower epidermis and all of the upper epidermis consist of elongate cells interspersed with smaller cells. The outer (periclinal) wall of the epidermal cells (presumably including both cuticle and underlying cellulosic wall) is very thick (Fig. 3); this seems to have been burnt off in some of the leaves. A layer of fibrous tissue immediately underlies the epidermis, while mesophyll tissue is generally less well preserved. The nature of the vascular trace is ambiguous but it is believed that the tracheids have annular or scalariform thickenings.

This earliest record of conifers has both evolutionary and environmental significance. It is suggested that the leaves have been charcoalified by forest fire and have been fragmented during transport to their site of deposition. Many of the leaves show typical features of rapid burning such as collapse of epidermal cells (Figs 2 and 4), occasional absence of cuticle and the three-dimensional nature of the leaf—the cell lumina still remaining open (uncrushed; Fig. 3). The early conifers are rare, previous records coming from the Westphalian D (high Upper Carboniferous) and above. These all belong to the broadly based form genus *Walchia* Sternberg which Florin subdivided into two genera, *Lebachia* and *Ernestiodendron* on differences in their leaf arrangement, reproductive structures and cuticular characters. This new material has not been assigned to a genus as yet but is believed, from the information available, to belong to the family Lebachiaceae. No reproductive structures have yet been found but it is believed that the information obtained from the vegetative material is sufficient to justify inclusion in both the order Coniferales and the family Lebachiaceae. This will be discussed in detail elsewhere.

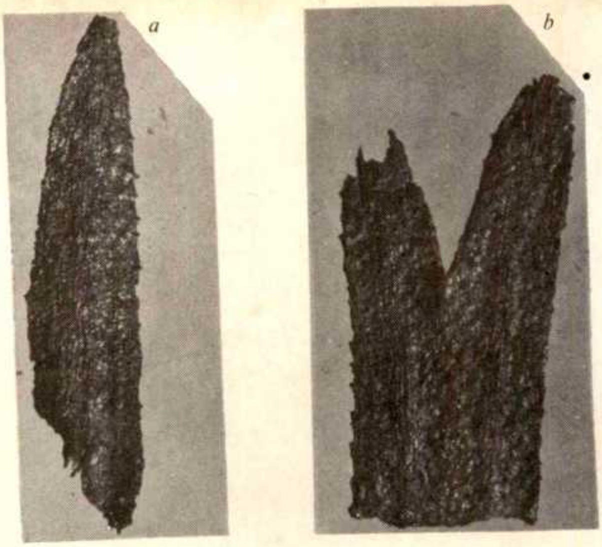

Fig. 1 Light micrographs of charcoalified conifer leaves. *a*, Small needle-like leaf (×30); *b*, forked leaf (×30).

Such early conifers have not been found commonly in the fossil record presumably because their environment of growth differs from those plants normally found in the Coal Measures[2]. The depositional environments in the Stephanian (high Upper Carboniferous) and Permian, especially in Europe, favoured the preservation of such plants.

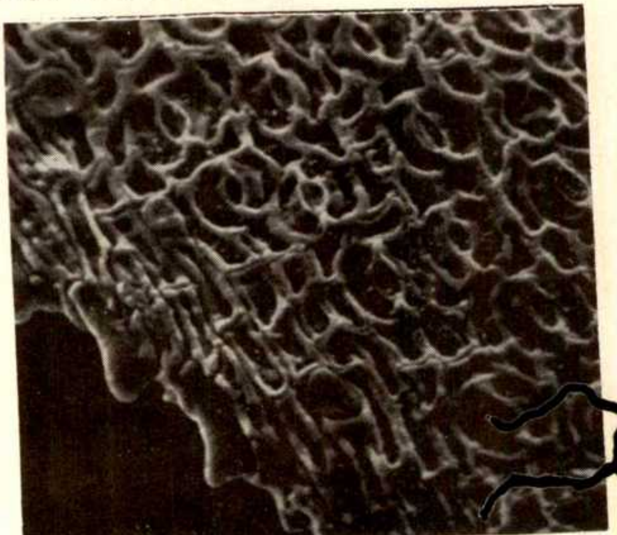

Fig. 2 Scanning electron micrograph of part of the lower epidermal surface of a leaf showing a stomatal band and a denticulate margin (×465).

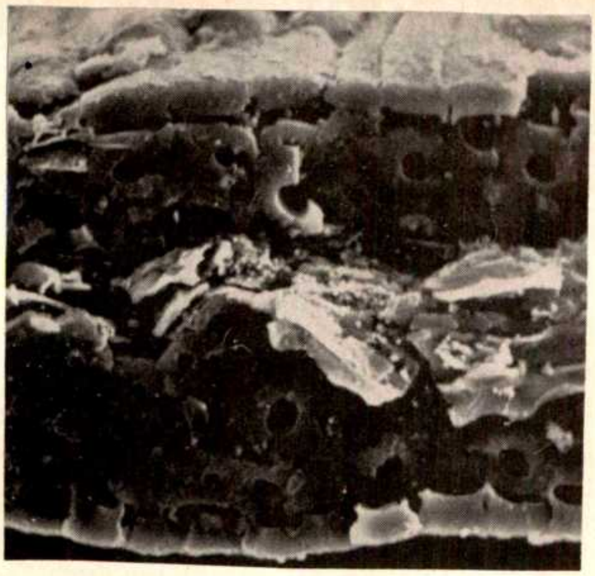

Fig. 3 Scanning electron micrograph showing part of the cross section of a typical leaf (thick cuticle, subepidermal fibres and crushed mesophyll tissue) (×900).

Pollen called *Potonieisporites* Bharadwaj has been shown to belong to the genus *Lebachia* Florin in the Permian[3]. Pollen of this type is also known from the Upper Carboniferous (Westphalian and Stephanian). It is now evident that such pollen may have been produced by conifers.

The discovery of conifer material, by bulk maceration of thin clay bands containing fusain within a poor coal, is important to the understanding of Upper Carboniferous floras as a whole. There is growing evidence that a fairly substantial flora is present in a charcoalified state, possibly of plants living associated with the conifers, and this may give insight into the palaeoecology of these (?hinterland) floras.

Harris[4] has discussed forest fire in the Mesozoic and others (A.S., and de Klerk, unpublished) have considered it as a fossilising mechanism in the Tertiary. It is not surprising, therefore, that forest fire may have played an important role in the Upper Carboniferous and the nature of fusain bands within coals and shales must again be open for debate. Early records of conifers in the form of such charcoalified fragments may now be sought using the bulk maceration technique in the hope of learning more of their origins and ecology.

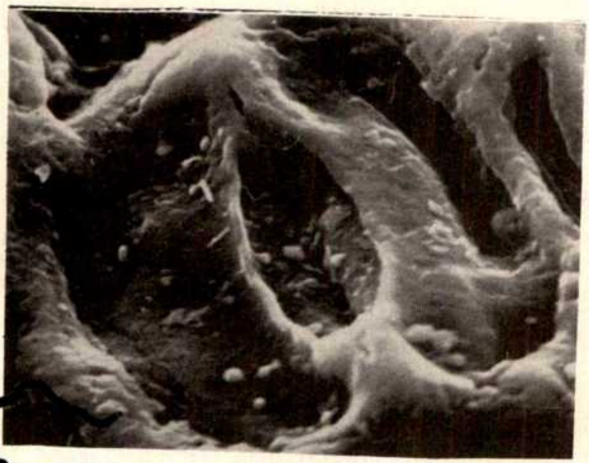

Fig. 4 Scanning electron micrograph of a single stoma showing upstanding anticlinal walls and collapsed guard cell walls. (An alternative explanation is that the guard cells are sunken below the surface and exposed only around the stomatal pit at the centre and that there are only two subsidiary cells which have themselves collapsed.) (×4,500).

I thank Professor W. G. Chaloner for supervising this work and the N.E.R.C. for supporting the project.

A model for stably inherited environmentally induced changes in plants

THE phenotypes of some inbred lines of *Linum usitatissimum* (flax) and *Nicotiana rustica* can be altered environmentally by fertiliser treatments, and the fertiliser-induced phenotypes show stable inheritance independent of the inducing conditions[1–3]. In flax, the stably inherited large (L) and small (S) phenotypes can be induced from the plastic (*Pl*) genotype *Stormont Cirrus* by one generation of growth with high nitrogen or phosphorus fertiliser treatments respectively. The induced phenotypes of L and S, differing for example in plant weight and degree of branching, behave in most respects as distinct genotypes and have been termed genotrophs.

Current genetic theory offers at least two explanations for such changes; biological examples of both types are examined in relation to the flax system.

(1) Informational nucleic acid may be introduced into flax under the inducing treatments, and be maintained in subsequent generations. Several groups[4–7] have shown that exogenous DNA can be taken up, expressed and maintained by plants, though whether it is integrated into the host genome is uncertain. In flax, possible nucleic acid donors could be among the soil flora. Under the inducing treatment the soil flora may change, or conditions for uptake or incorporation of nucleic acid may be favoured. It could be established if flax DNA contains sequences hybridisable to DNA extracted from soil flora. This idea predicts that the induced changes should not occur with flax grown under sterile conditions.

Changes in the DNA content of the flax genotrophs do occur[8,9], but their relevance remains uncertain because the changes can be reversed without loss of either the induced phenotype or its stable inheritance[10]. The DNA changes are partly caused by variation in the redundancy of ribosomal DNA[11]. It is unlikely that this change would be the primary event in genotroph induction, but could be a consequence of a regulatory switch such as described below.

(2) Some change in a regulatory circuit has been effected by the inducing conditions; this change persists after removal of these conditions, and involves no qualitative change in genome. Lysogens of bacteriophage λ show a temperature-induced loss of immunity in the host *Escherichia coli*, that is stably inherited independent of the inducing conditions with no change in the phage genome[12,13]. λ prophage synthesises the *cI* gene product, the repressor protein, that renders the host *E. coli* immune to further homoimmune λ infection. *cI*857 prophage has a temperature-

sensitive repressor protein active at 32° C but inactive at 42° C *E coli* containing prophage with genotype *c*I857 N^- (O^- or P^-) are immune at 32° C, but growth at 42° C inactivates the repressor and immunity is lost At 42° C synthesis of the *cro* gene product (normally repressed by repressor) occurs and *cro* product prevents further repressor synthesis On return to 32° C, *cro* product continues to prevent repressor synthesis, immunity is not regained and the immunity loss is stably inherited and dependent upon formation of the active *cro* product

The λ system is analogous to genotroph induction and suggests a model for the induction and stable inheritance of the *L* and *S* genotrophs from the *Pl* flax genotype Figure 1*a* represents the regulatory system of the *Pl* phenotype under non-inducing conditions, this system contains three regulatory proteins which act and remain in the flax cell nuclei and are coded on distinct structural genes A control protein (CP) is made which controls its own synthesis in a positive manner CP is also a negative control element preventing synthesis of two other regulatory proteins, an activator protein (AP) and an inhibitor protein (IP) AP and IP are involved in triggering sequences of events leading to the L and S phenotypes The model is not dependent upon the precise mechanism of these events, though modulation of a plant hormone level may be involved The site of CP regulation is shown as transcriptional, but could be translational Figure 1*b* illustrates the switch from the *Pl* to the L form under inducing conditions High nitrogen fertiliser treatment increases the concentration in the plant of some effector molecule E^L

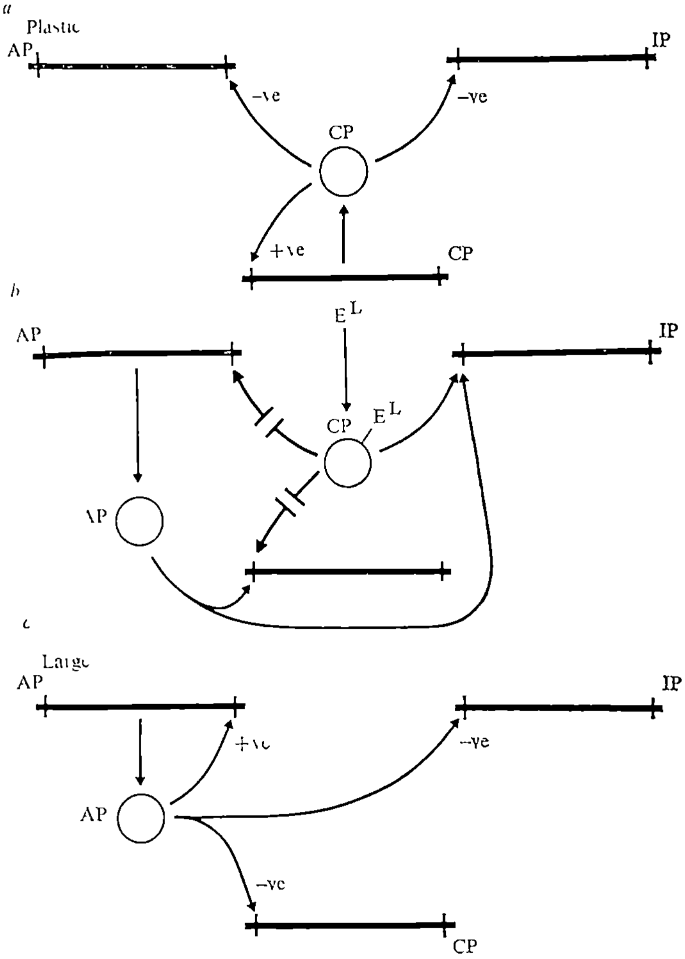

Fig 1 Regulation of the *Pl* phenotype and the induction and stable inheritance of the L phenotype in flax The structural genes for the three regulating proteins are indicated by heavy lines, for simplicity the haploid situation is shown, the inbred lines being assumed isogenic The regulating proteins are shown as circles and behave as transcriptional control elements

CP binds E^L to form a CPE^L complex inactive in controlling CP and AP synthesis, but still active in preventing IP synthesis Consequently AP synthesis starts, CP synthesis stops and IP synthesis remains inhibited AP triggers the L phenotype event sequence, inhibits CP and IP synthesis, and is a positive control element in its own synthesis AP will now continue to be made in the absence of the inducing conditions (Fig 1*c*), and the L phenotype will be stably inherited A similar regulatory switch triggers the S phenotype from the *Pl* one under inducing conditions Here some effector E^S increases in concentration in the plant inactivating CP so that IP is synthesised which triggers the S phenotype event sequence IP has analogous control properties to AP and the S phenotype is stably inherited

The model explains other findings in the flax system The F_1 progeny of an $L \times S$ genotroph cross are intermediate in plant weight, show high plant weight variance and are non-inducible by fertiliser treatments[1] In such a cross both zygotes contribute equal amounts of the nuclear regulatory proteins AP and IP, there are no maternal effects, and an unstable mix of both regulatory proteins each capable of inhibiting synthesis of the other occurs In phage λ, the outcome of such a match between opposing gene functions can depend upon additional variables[14,15] In flax, individual plants should have a certain probability of changing from the mixed to the AP or IP regulatory mode This could result in a wide population variance in plant weight, the extremes of which (sole AP or IP control) would be stably inherited Similar explanations exist for the outcome of crosses that mix the CP and AP or IP regulatory proteins

The primary sites of action of the AP and IP proteins could be modulation of plant hormone levels or regulation of synthesis of growth inhibitors Determining the levels of plant hormones and growth inhibitors in *Pl*, L and S plants seems a necessary step to biochemical analysis of induced changes

The model predicts the properties of some mutations in the regulatory genes A search for and genetic analysis of such mutants will both test the model and give more information on the nature of induced changes Three pleiotropic loci, the structural genes for CP, AP and IP, should be identifiable and distinguishable from mutations in other genes altering components not directly related to the regulatory switch Mutants in these loci should show stable L or S phenotypes independent of inducing conditions, or plastic phenotypes with altered inducibility

Control of food intake by energy supply

A WIDE variety of metabolic influences on appetite have been proposed, including glucose utilisation rate[1], influences from adipose tissue[2,3] or plasma amino acid pattern[4,5] and the heat increment during absorption of a meal[6] It is difficult to relate short term effects of the metabolism of absorbed nutrients which indeed occur[7], to the long term precision with which energy exchange is often regulated

A direct signal from fat stores to the brain has been postulated[3] but an alternative is the modulation of a short term 'glucostatic' signal by a 'lipostatic' signal[8] A more general proposal along the latter lines is that the signal at the neural receptors controlling feeding in the omnivore reflects the current supply of energy for intermediary metabolism from whatever source, including sugars, amino acids, fatty acids, ketones, glycerol and lactate[7,9] There is some reason to believe that this metabolic control is primary in the control of food intake, with control by sensory and gastrointestinal mechanisms normally being adjusted according to metabolism[11–13]

The theory that current energy supply is the primary factor controlling appetite has now been incorporated for the rat in a computerised physiological control model illustrated in block diagram form in Fig 1 The pattern of feeding is correctly predicted within the limits of accuracy of the physiological data which completely determine the computation (Table 1)

The rate at which the rat feeds is taken to be constant throughout a meal, as an initial simplification A feeding rate of 1,000 calorie min^{-1} (about 0 3 g min^{-1}) is an intermediate value from the literature[14,15] The rate at which the gut clears nutrient energy is taken to be proportional to the square root of the amount of energy contained in the gut, a function based on studies of gastric carbohydrate clearances[9,16] The constant of proportionality (K) is higher (0 9) by night than by day (0 6) in the rat, a nocturnal animal, this value is taken to change linearly over 2 h around dawn and dusk These calculations predict the variations in rate of absorption of energy-yielding substances during and between meals

Another source of variation in total energy flow is storage and mobilisation of fat This has been based in the model on the results of Le Magnen and Devos[17], which indicate mainly net subtraction of energy from fat store by day and net addition of fat by night

Threshold values for initiation and termination of feeding purely on the basis of total energy flow were based on amounts found in the gut at the start and end of meals and on the effects of infusing glucose into the hepatic portal vein in the rat[18] Feeding is initiated when energy supply rate falls to below 18 calorie min^{-1} It is fully suppressed on a single diet when energy is supplied at or above 60 calorie min^{-1} In this initial approximate model these estimated values are taken to be without statistical variation

The complete system was programmed for a digital computer, using a method of successive addition all variables were adjusted once every 10 s of real time The simulation was run for 6 d of real time, to give the data of Table 1 All correlations, real and modelled, are associated with a probability of $P < 0\ 01$ Considering the simplified picture of the total energy flow and the considerable assumptions underlying the estimates of flow on which the calculation is based, the agreement with the food intake characteristics of real rats is reasonable It may be seen that there is a significant correlation between the size of a meal and the time to the onset of the next meal Correlations of meal size to premeal interval are smaller and less reliable statistically in both real and modelled rats

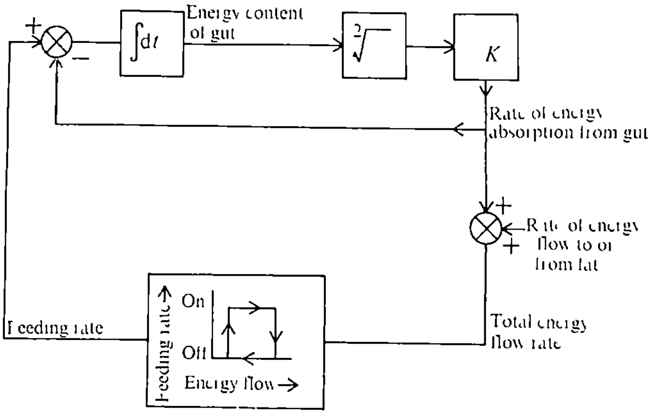

Fig 1 A model of feeding

The success of the simulation is not a confirmation of simple homeostatic concepts, for the model is based on rates of energy flow, not directly on amounts of energy eaten or stored Further preliminary work suggests that the model can be extended to include estimates of increments in body energy which would link short term control to long term regulation

Where the physiological data are available, conditions other than *ad libitum* maintenance of intact animals can be modelled Indeed, an homologous model can be constructed for man Hitherto, models of the control of food intake have not been based on physiological data[19], have been unprogrammable and non-predicting block diagrams[10,20–22] or have been computerised by postulating unmeasured variables and deciding parameters by fiat[23] The conditions simulated to date using the present model have generated realistic predictions The dynamic and static phases of the hyperphagia which follows lesions of the ventromedial hypothalamus have been successfully simulated[24] This implies that the hyperphagia is secondary to hormonal abnormalities The feeding pattern of the recovered lateral hypothalamic aphagic rat is mimicked by the model, if feeding rate is substantially slowed This suggests that disruption of oral reactions is primary in the residual deficits of this condition

The chronically diabetic rat has been modelled on the basis that in this condition there is no net storage or mobilisation of fat and only one-third of the ingested energy is able to act on receptors suppressing feeding[25,26] The model correctly predicts a food intake of about 60 g per 24 h The real rat, however, takes the food in many meals distributed throughout the day and night[25] whereas the model of Fig 1 predicts a single very prolonged meal in each lighting phase A simple addition, that of an inhibitory pathway from stomach stretch receptors to the hunger system[3] brings the model into agreement with reality

Table 1 Feeding pattern parameters in real and modelled rats (means ± s d)

	Real rat			Modelled
	A*	B†	C†	rat
Dark Phase				
Total intake (g in 12 h)	13 0	17 3±3 4	14 2	13 3±1 6

Comparative activity of red cell adenosine deaminase allelic forms

CERTAIN enzymes have allelic forms which can be distinguished electrophoretically The variability of the structural genes determining these enzymes[1] is one of the most challenging problems in modern biology, since no particular reason can be found for their selection during evolution and so they form the main subject of debate between the 'pan-neutralists' and the 'pan-selectionists' To try and throw some light on this problem we have compared the enzymic activity of the different electrophoretic forms of human red cell adenosine deaminase

Only a few enzymes have previously turned out to be suitable for this type of comparison[2,3]—those with at least two common electrophoretic phenotypes and a simple quantitative assay

Adenosine deaminase (ADA) presents an electrophoretically demonstrable polymorphism depending upon an autosomal gene with two common codominant alleles *ADA*^{1} and *ADA*^{2}, as shown by Spencer *et al*[4] A number of cases of ADA deficiency have also been reported[5] They were associated with a severe combined immunodeficiency disease[5], and a causal relationship between the enzyme deficiency and the immunological disease mediated by the resulting pyrimidine starvation has been suggested[6] (see also Giblett *et al*[7])

We devised a new, simple and reliable quantitative assay of the red cell ADA activity With this method we found that the mean activity of the red cell ADA in the ADA 1 is higher than that of the ADA 2–1 phenotype This shows that the activity associated with the *ADA*^{1} allele is greater than that associated with the *ADA*^{2} allele

A random sample of 196 undergraduate students (first year) of the University of Rome was studied The red cell ADA phenotypes were determined according to Spencer *et al*[4] The red cell ADA activities were all assayed within a few hours after bleeding The present method is an adaptation to red cell lysates of Kalchar's method[8] The lysates were incubated with adenosine in excess The reaction was stopped with perchloric acid and the quantity of adenosine consumed was estimated from the decrease of $E_{2,680}$ (inosine and hypoxanthine have the same $E_{2,680}{}^{\mathrm{Mol}}$ which is about half that of adenosine[9] In our hands the $\Delta E_{2,680}{}^{\mathrm{Mol}}$ of the transformation adenosine into inosine or hypoxanthine was $6\ 77\times10^3$) Linearities with time and haemolysate concentration were checked Haemoglobin concentration was determined with the

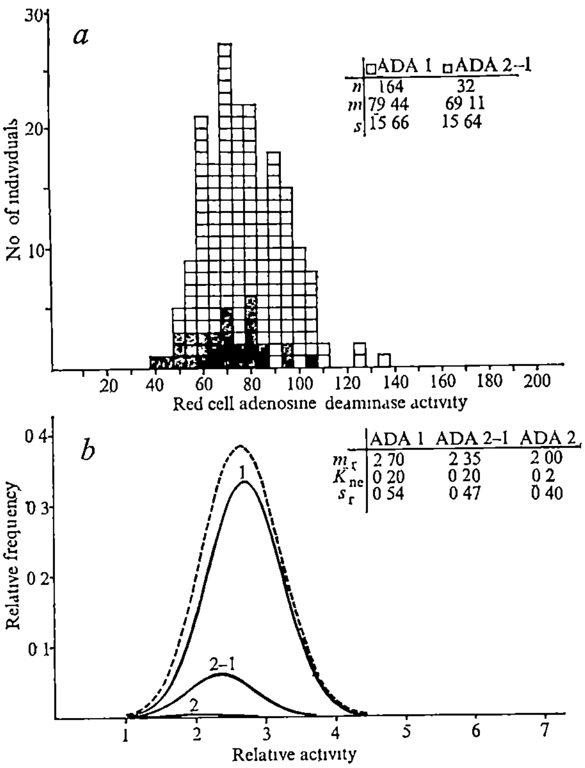

Fig. 1 Distribution of red cell adenosine deaminase activities *a*, Observed distribution in a sample of 196 random individuals *b*, Expected normal distributions in the ADA 2, ADA 2–1 and ADA 1 phenotypes with relative mean activities, m_r, 2 00, 2 35 and 2 70, respectively The coefficient K_{ne} of intraphenotypic variation, that is of the non-electrophoretic variation, is assumed to be 0 20 for all the three phenotypes The relative areas correspond to the expected relative genotype frequencies, $p^2=0\ 007$, $2pq=0\ 150$ and $q^2=0\ 843$

Packed red cells washed three times with isotonic saline were lysed by a triplicate cycle of freezing (in acetone and dry ice) and thawing The lysates were diluted 50 times with Sørensen phosphate buffer 1/15 M *p*H 7 5 preincubated at 37° C The reaction was started within 15 min (the enzyme activity is stable in these conditions for at least 1 h) by mixing 1 vol of lysate with 5 vol of a preincubated solution of 0 337 mM adenosine in the same buffer At 0 time and 75 min three aliquots were transferred into equal volumes of 8 7% PCA After at least 15 min the precipitates were spun down and 5 ml of the clear supernatants were neutralised with 0 35 ml of 5 M K_2CO_3, transferred into a freezer for about 10 min and filtered The $E_{2\ 680}$ were then determined Haemoglobin was determined in the assay mixture (adenosine+lysate)

The activity is expressed as μmol of adenosine consumed per h at 37° C per g of haemoglobin cyanmethaemoglobin method[10] The precipitation of proteins makes this method more laborious but more sensitive (a more concentrated lysate may be used) and less expensive (no need of xanthine oxidase) than that of Hopkinson *et al*[9]

Figure 1 shows the distributions of the red cell ADA activities observed in the two ADA phenotypes found in the present sample

The difference between $\overline{\text{ADA 1}}$ and $\overline{\text{ADA 2–1}}$ (the mean enzyme activities of the ADA 1 and ADA 2–1 phenotype, respectively) is statistically significant ($t=3\ 41$, $P<0\ 001$) in spite of the large intraphenotypic variation The enzyme activity (expressed as µmol of adenosine consumed per h at 37° C per g of haemoglobin) associated with the ADA^1 allele, estimated as $(\overline{\text{ADA 1}})/2$, is 39 77, that is, 35% higher than that associated with the ADA^2 allele (29 34) estimated by subtracting the ADA^1 activity to $\overline{\text{ADA 2–1}}$, on the assumption that no interaction occurs between ADA^1 and ADA^2 alleles in the heterozygote This seems to be a quite reasonable assumption, considering that no hybrid ADA molecules are present in the heterozygotes

A portion of the variation of the red cell ADA activity can thus be accounted for in terms of the difference existing between the activities associated with the two common electrophoretically distinguishable alleles of this enzyme This portion can be conveniently expressed as the corresponding partial variance, which is estimated to be, in our sample, 0 019 if one designates as 1 the activity associated with the ADA^2 allele (see Fig 1) This variance is in fact equal to $2pq\,d^2(1+K_{ne}{}^2)$ (see Modiano[3]) where $p(_{ADA}{}^2)=0\ 08$ and $q(_{ADA}{}^1)=0\ 92$ are the gene frequencies found in the present sample (which are similar to those previously reported for the same population[11]), d, the relative difference between the ADA^1 and ADA^2 activities, is 0 35 (see legend of Fig 2), and K_{ne}, the coefficient of the non-electrophoretic variation (standard deviation divided by the respective mean within each electrophoretic phenotype), is rounded to 0 20 for all the three ADA phenotypes Since the observed total variance was 0 282, it may be concluded that 0 019/0 282, that is about 7% of the total variation of the red cell ADA activity, is associated with the electrophoretically demonstrable genetic variation of this enzyme The nature of the remaining major portion of variation (the intraphenotypic or non-electrophoretic variation) remains unknown It is also unknown why the ADA 1 and ADA 2 allelic enzymes present different activities in the red cell lysates and whether or not this difference applies to other tissues as well These questions remain unanswered for most of the interallelic differences so far identified

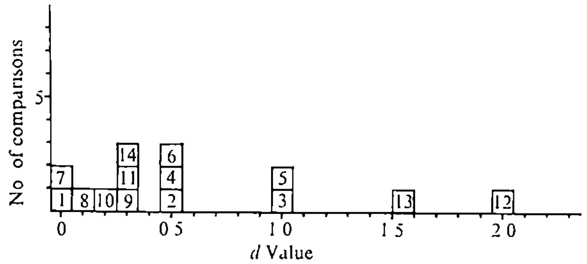

Fig 2 The distribution of the 14 relative differences, d, known at present between the enzyme activities associated with common electrophoretic alleles of red cell enzymes*

d is the relative difference between the enzyme activities associated with different alleles expressed in terms of the activity of the least active allele For example, if the absolute allelic P^a, P^b and P^c activities are 60, 90 and 120 as in the red cell acid phosphatase, their relative activities are 1 0, 1 5 and 2 0, respectively, with three d values $d_{P^b-P^a}=1\ 5-1\ 0=0\ 5$, $d_{P^c-P^a}=2\ 0-1\ 0=1\ 0$, and $d_{P^c-P^b}=2\ 0-1\ 5=0\ 5$ The comparisons refer only to those allelic enzymes whose associated activities have been compared because they were known to be electrophoretically different

A list of the 14 comparisons Each comparison is represented in the figure by the number in the corresponding box acid phosphatase[12 13] (1) P^r–P^a, (2) P^b–P^a, (3) P^c–P^a, (4) P^b–P^r, (5) P^c–P^r, (6) P^c–P^b, phosphoglucomutase[14,15] (7) $PGM_1{}^1$–$PGM_1{}^2$, glucose-6-phosphate dehydrogenase[16 17] (8) Gd^B–Gd^A, Adenylate kinase[18,19] (9) AK^1–AK^2, 6-phosphogluconate dehydrogenase[20–22] (10) Pgd^a–Pgd^b, Glutathione reductase[23] (11) $GSSG$–R^S–$GSSG$–R^F, Glutamic pyruvic transaminase[24,25] (12) Gpt^1–Gpt^2†, Uridine monophosphate kinase[7] (13) $UMPK^1$–$UMPK^2$, Adenosine deaminase (14) ADA^1–ADA^2 (this paper)

* See Modiano[3] for detailed references

† The difference in the figure is that reported by Chen *et al*[24]

Table 1 Non-random assortment* of the relative activities and frequencies of the common alleles of red cell enzyme polymorphisms

	Polymorphisms in which the most active allele is	
	the most common allele	the least common allele
Observed	12†	1‡
Expected	6 5	6 5

* The likelihood of a discrepancy from randomness like the one observed or greater, in either direction, is $2\,(13+1)\times(1/2)^{13}\simeq 0\ 003$

† The following is the list of these twelve red cell enzyme polymorphisms acid phosphatase[12 13] (the findings in Caucasians where the most common allele is the one with intermediate activity have not been considered informative), glucose-6-phosphate dehydrogenase[16 17], adenylate kinase[18,19], 6-phosphogluconate dehydrogenase[20–22], glutamic-pyruvic transaminase[24 25], galactose-1-phosphate uridyltransferase[26], nicotinamide adenine dinucleotide nucleosidase[27], phosphoglucomutase (PGM_2)[28], peptidase C[29], peptidase A[30 31], uridine monophosphate kinase[7], adenosine deaminase (this paper)

‡ Gluathione reductase[23]

The difference in activity between the different allelic forms is a common finding Figure 2 shows that, as a rule, common electrophoretic alleles are associated with considerably different ($d\simeq 0\ 6$) enzyme activities in red cell lysates (12 out of 14 comparisons)

Further evidence suggesting that the common structural gene variations are not neutral is the non-random relationship between the relative frequency and activity found among the common alleles of the red cell enzyme polymorphisms studied so far (see Table 1)

In vitro V_{max}, however, is a poor measure of the enzyme's function *in vivo* Significant progress along these lines may therefore be expected from interallelic comparisons involving more significant enzyme characteristics, such as K_m (in relation with the *in vivo* substrate concentrations) and the *in vivo* stability But so far, only glucose-6-phosphate dehydrogenase has been studied at such a level[33–36] The use of intact red cells under physiological or suitable stress (such as drug induced) conditions[37] or of other cells and tissues should also provide further rewarding information

Population size and natural selection in the land snail *Cepaea nemoralis*

ALTHOUGH most investigators have concluded that protein polymorphisms are maintained by balancing selection[1,2], some contend that they are the consequences of random drift of neutral or nearly neutral alleles[3,4] Many empirical data seem to support the selectionist view, although the mechanism that might be involved is not well understood In any case, critical data on changes in allelic or genotypic frequencies through time are not available for most natural populations Therefore, the major evidence for selective responses is provided by deviations from expected zygotic proportions at some given time

Studies of laboratory populations have indicated that some enzyme polymorphisms are examples of heterosis (overdominance), since experimental results consistently show heterozygote excesses over expected values[5,6] Data from natural populations are, however, harder to interpret[7,8] For example, heterozygote deficiencies can result from inbreeding or disruptive selection, or they can be an artefact caused by small sample sizes, scoring errors, sampling before completion of selection[9] or inappropriate pooling of subpopulations Although data on the size and spatial structure of the populations studied would often facilitate interpretations of genetic results, they are usually not available and with certain organisms are almost impossible to obtain[7] I have now obtained such data for populations of the helicid land snail *Cepaea nemoralis* and found that heterosis maintains polymorphisms at two enzyme loci

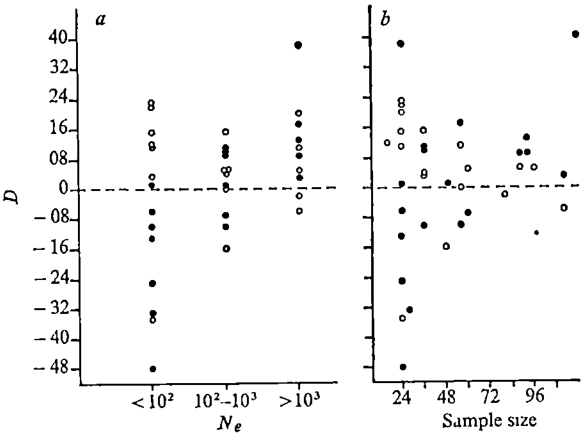

Fig 1 *a*, Effect of adult population size (N_e) on heterozygote deviations (D) at the *PGM-2* and *LAP-2* loci in *C nemoralis* The zero line represents exact Hardy-Weinberg equilibrium where $D = H_o - H_e/H_e = 0$ Heterozygote deficiencies appear below the zero line, excesses above it *b*, Effect of sample size on heterozygote deviations at the *LAP-2* (○) and *PGM-2* (●) loci. See text for further explanation

Because of their highly polymorphic shell patterns, populations of *C nemoralis* have been subject to evolutionary study in Europe (see ref 10 for a review) for decades The species has been introduced into North America on several occasions, and colonies are now found in various localities in the eastern United States and Canada They rarely occur outside towns or other habitats perpetuated by human disturbances The colonies are either subdivided into small, local populations, or may occupy areas much larger than the estimated panmictic unit of the snails[11] For this reason, the snails provide excellent opportunities for studying the effects of spatial patterning and population size on genetic variation

In addition to their shell colour and banding polymorphisms, *C nemoralis* populations found in the Piedmont and Great Valley of Virginia are polymorphic at one phosphoglucomutase locus (*PGM-2*), and at one leucineaminopeptidase locus (*LAP-2*) *PGM-2* has two alleles and *LAP-2* usually has three The enzymes provide clear electrophoretic patterns with good separation of all allelic variants Thus, the possibility of scoring errors is remote The genetic bases for the observed variation have been verified experimentally[12]

To study the effects of spatial patterns and effective population size (N_e) on genetic variability in *C nemoralis*, 303 immature individuals 9 mm or more wide and 586 mature specimens were collected from 18 Virginia localities between June 1972 and October 1973 The area occupied by the snails was measured or estimated at each site

Although *C nemoralis* is monoecious, it is an obligate outcrosser Therefore, the maximum N_e of a population approximates the numbers of mature individuals in that population[11] It is difficult to estimate the number of snails in natural populations since they move around too slowly for ordinary capture–recapture methods, and their patchy distribution makes quadrat or transect counts unreliable[15] Small areas, however, could be searched completely, and estimates of N_e in these populations were obtained by direct count Few mature specimens could have been

N_e is given for each population

overlooked, and this procedure for determining N_e in small populations is probably less biased than any other

Numbers of adult snails in the larger populations were estimated by a time-unit removal method The principle is that if a known number of snails is removed from a designated area in a fixed time, the number found subsequently is affected The rate at which catches fall off (a geometric series) is directly related to the size of the total population and the number previously removed[14] By taking samples from relatively large plots (9 m^2), I minimised the problem of temporary patchiness about single plants or other objects, and average density estimates of mature individuals were reasonably consistent from plot to plot within a population Average numbers of adult snails per unit area were then multiplied by the total area occupied by the population to estimate maximum N_e The size of the panmictic unit in large populations of *C nemoralis* has been estimated to be more than 1,000 individuals[15] My own unpublished data for North American populations confirm this

I used the horizontal starch-gel electrophoresis techniques of Selander *et al*[16], modified as described before[12] Allele frequencies, determined by direct count from the phenotypes observed on the gels, were used to calculate the expected genotypic frequencies by Levene's[17] method for small samples Deviations of observed from expected values were tested for significance using the G test for goodness of fit[18] For statistical analysis $LAP\text{-}2^b$ was pooled with the second least common allele in most samples There were departures from Hardy-Weinberg expectation in all cases except one (*LAP-2*, Staunton 1a, see below), though statistical significance was not noted in any

Heterozygote deviation (D) was calculated by the formula

$$D=(H_o-H_e)/H_e$$

where H_o and H_e are the observed and expected numbers of heterozygotes, respectively Table 1 lists the sample sizes, allele frequencies and values of D for both loci, and the estimated size of N_e

At the *LAP-2* locus, 13 of 17 populations showed a heterozygote excess, which was unlikely by chance alone ($P=0$ 025, sign test) (The eighteenth population, Staunton 1a, was not considered since the only variant in it was one $LAP\text{-}2^{a/c}$ heterozygote) This result does not conform to the hypothesis of neutral alleles, which would predict a statistically equal number of heterozygote excesses and deficiencies The simplest explanation for the heterozygote excess is some sort of balancing selection which results in some degree of superior heterozygote survival

On the other hand, at the *PGM-2* locus seven of the 18 populations showed a heterozygote deficiency, indicating no overall tendency toward heterozygote excess ($P=0$ 24, sign test) However, if the populations are grouped according to size, six of seven populations with N_e estimated to be less than 100 show heterozygote deficiencies, while nine of 11 populations with N_e greater than 100 show heterozygote excess These differences from expectation are significant ($P<0$ 025, Fisher exact test), and indicate a strong interaction between heterozygosity and population size (Fig 1*a*)

No interaction is evident between sample size and the direction of D, although, as would be expected, values of D tend to have higher variances at lower sample sizes (Fig 1*b*)

The findings suggest that the *LAP-2* and *PGM-2* polymorphisms are maintained in these natural populations by heterosis Selection for heterozygotes may be stronger at the *LAP-2* locus, since heterozygote excesses are present even in populations with small N_es A possible explanation is that LAP catalyses the degradation of a diversity of substrates, some of which presumably enter the snail from the environment[19] Individuals heterozygous at this locus may be able to utilise a greater diversity of energy or nutrient sources by virtue of having two forms of the enzyme An alternate explanation is that this locus is closely linked to another which is subject to heavy selection

PGM, on the other hand, has only been shown to catalyse the conversion of α-D-glucose-1-phosphate to α-D-glucose-6-phosphate The apparently milder heterotic effects may result from favourable interactions with other gene products rather than from a capability to handle a greater variety of substrates The validity of such speculations can only be established when the functional properties of the electrophoretic variants are understood In any case, these data indicate that the effects of stochastic processes in small populations are strong enough to override any heterozygote advantage, either at this locus or at any closely linked to it

This research was supported by grants from the United States National Science Foundation and the National Institutes of Health I thank my colleagues, especially R.

Alternate host for mosquito parasite *Coelomomyces*

THE water mould *Coelomomyces* (Chytridiomycetes, Blastocladiales) is an obligate parasite of mosquito larvae The fungus develops in the haemocoel of the host and is first visible as small unwalled hyphal bodies, which later differentiate into masses of thick-walled resistant sporangia In appropriate conditions, each sporangium releases a large number of posteriorly uniflagellate zoospores[1] Field studies of this pathogen indicate that it may be responsible for significant epizootics of mosquito larvae and considerable interest has been generated over its possible use in biological control of these troublesome insects[2-6] This potential has not been confirmed in the laboratory The production of infected larvae in controlled environmental conditions has proved to be a difficult and erratic task[1,7] Couch[8] has devised a technique for the production of large numbers of infected mosquitoes but this method uses quantities of microalgae and water from the original infection site

Our studies have focused on *C psorophorae* in *Culiseta inornata* The fungus was first discovered in 1956 in the irrigated districts of southern Alberta[5] It has reappeared every year since that date and has often induced high mortalities in the mosquito populations Attempts to establish infected colonies in the laboratory encountered the same problems noted by earlier workers Limited infection was obtained by the Couch method, but only after adding water, algae and other substrates from the Canadian collection site Efforts to increase the infection rate by modifying first the environment (for example, *p*H, temperature, water character, light and redox potential), second the number or condition of the host and, third, the quantity of fungal inoculum, were inconclusive This work did permit the removal of algae from the infection trials but did not materially improve their reliability

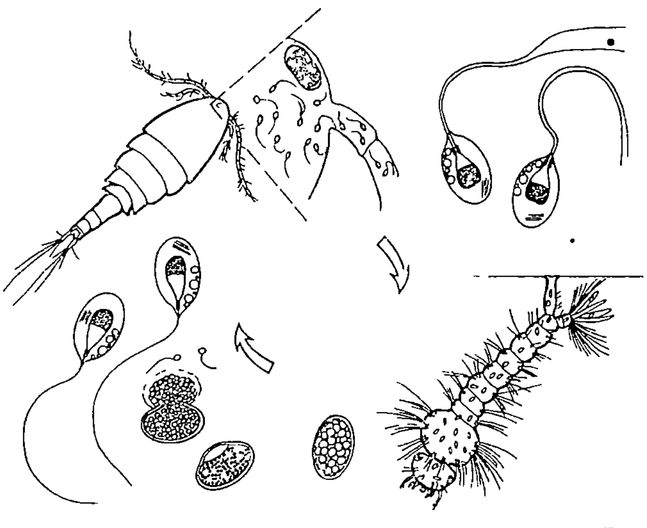

Fig 1 Life history of *Coelomomyces psorophorae* Resistant sporangia from the body of the mosquito release zoospores which infect *Cyclops* Biflagellate spores from the *Cyclops*/*Callimastix* phase infect mosquito larvae

Attempts to infect mosquitoes in simple, clean systems using synthetic pond water, and clean fungal inoculum failed repeatedly Sequential addition of individual components from our 'gross' infection pans to our 'clean' trials has provided the key to the infection problem Addition of the copepod *Cyclops vernalis* to pans containing fungi and mosquito larvae resulted in the appearance of infected mosquitoes Control pans lacking copepods have never yielded diseased larvae, in spite of the addition of masses of zoospores and/or sporangia This implied that *Coelomomyces* had an alternate, copepod host To test this hypothesis, washed copepods, from pans with a record of high infectivity, were combined with mosquito larvae in synthetic pond water Within a few days, 40% of these larvae were obviously infected with *C psorophorae*

Examination of the copepods revealed the presence of an 'unknown' phase in the life history of *Coelomomyces* The body cavities of the diseased *Cyclops* were packed with swarming zoospores At escape, the spores were found to be predominantly biflagellate, but otherwise similar to the zoospores produced in the resistant sporangia of *Coelomomyces* Mosquitoes exposed to a suspension of these spores displayed typical *Coelomomyces* hyphal bodies and sporangia within a few days of inoculation

These results indicate that the life history of *C psorophorae* includes two different hosts (Fig 1) Attempts to infect mosquitoes with spores from the resistant sporangia produced in the mosquito or to infect copepods with spores from other infected *Cyclops* have consistently failed and it seems that alternation of different hosts is obligatory Such heteroecism is common in rust fungi, but has not been previously reported for the Chytridiomycetes or other phycomycetes

The copepod phase of the fungus resembles the *Cyclops* parasite *Callimastix cyclopis* Weissenberg[9] Originally described as a protozoan parasite, it has more recently been allied to the Blastocladiales[10,11] The zoospores are characteristically multiflagellate, with all the zoospores from one copepod bearing the same number of flagella (for example, 2–5 per spore) The zoospore of *Callimastix* carries a peculiar paracrystalline body[11], which is also found in *Coelomomyces*[12,13], but has not been reported from other fungal zoospores The ultrastructure of the unwalled plasmodia and spores, the swarming of the spores in the host body, and the general morphological development of the copepod phase of *Coelomomyces* indicates that this phase may be considered as a biflagellate species of *Callimastix* As the latter genus was described earlier than *Coelomomyces*[14] it would seem to have nomenclatural priority

The discovery of heteroecism in *Coelomomyces* has obvious implications for its possible use in biological control of mosquitoes Whether other species and strains of *Coelomomyces* and *Callimastix* have complementary hosts requires further study It is interesting to note, however, that in the earlier *Callimastix* studies, infected *Cyclops* were obtained from field collections or gross cultures and Vavra and Joyon[11] speculate on an unknown phase in the development of their copepod parasite

We thank Linda B Travland for assistance in electron microscopy This work was supported by a grant from the National Institutes of Health

Abscisic acid levels in relation to drought tolerance in varieties of *Zea mays* L.

THE level of growth inhibitor in plants increases when they are subjected to water stress and the major constituent of this inhibitor is abscisic acid (ABA)[1-3] By its effect in closing stomata, ABA can control the rate of transpiration[4-7] and it is therefore likely that ABA may be involved, to some extent, in the mechanism conferring tolerance of plants to drought

Palacios[8] and Muñoz[9] have developed a line of maize (Latente) which shows enhanced ability to withstand drought conditions Seed of this line was obtained from Mexico and it was decided to investigate whether its higher resistance to water stress was related to a capacity to produce appreciable quantities of abscisic acid Accordingly we have compared the levels of ABA in detached leaves of Latente with those of two European varieties (Anjon 210 and LG 11) which have not been bred for tolerance to drought

Seeds of each variety of *Zea mays* L were sown in vermiculite and the seedlings raised in a growth room with a 15 h photoperiod (Mazda 'daylight' fluorescent tubes) at 21 5° C and a minimum relative humidity of 75% At the end of the dark period on day 12, by which time ligules from the second leaves were exposed, 25 g batches of leaves were collected by excision 2 mm above the coleoptiles and laid on sheets of dry filter paper in a glass container Warm air (35 ± 2° C at leaf surface) from three hair driers was directed across the leaves until a loss of 10% in fresh weight had occurred (about 10 min) The leaves were then placed for 4 h in a closed glass chamber on four thicknesses of filter paper moistened with 20 ml distilled water The controls were not subjected to the water stress treatment but were kept at the same high relative humidity for 4 h At the end of this period, treated and control leaves were cut into small pieces and extracted in methanol for 48 h at—20° C After the removal of the solvent under reduced pressure, the extract was partitioned twice between 2% sodium bicarbonate and redistilled ether The aqueous fraction was washed with more ether and then acidified to *p*H 2 8 with 2 N H_2SO_4 The free acidic compounds were extracted with ether and the extract dried over anhydrous sodium sulphate Most of the solvent was then removed

Table 1 Determination of free ABA in detached leaves of wilted and non-wilted maize seedlings

	Free ABA (µg equivalents)					
	Latente		Anjon 210		LG 11	
	Control	Wilted	Control	Wilted	Control	Wilted
Experiment 1	12 8	50 3	2 4	21 1	3 1	11 8
Experiment 2	13 5	50 2	2 2	16 4	2 5	26 0
Mean	13 1	50 2	2 3	18 7	2 8	18 9

Data are from two independent experiments in which a Mexican line (Latente) and two European varieties of maize (Anjon 210 and LG 11) were grown in vermiculite

Further separation was carried out on 20×20 cm fluorescent silica-gel coated TLC plates (Merck GF_{254}, 0 25 mm thick), which were developed in *n*-propanol–*n*-butanol–0 88 ammonium hydroxide–water (6 2 1 2 v/v) (ref 10) The zone on each plate corresponding to an ABA marker spot (ultraviolet identification) was scraped from the chromatogram and eluted with methanol Each eluate was concentrated for the second TLC stage and developed six successive times in chloroform–benzene–acetic acid (100 100 1 5 v/v) The silica in the ABA region was then removed and eluted with methanol Final purification was carried out by ascending paper chromatography (Whatman No 1) using *iso*propanol–0 88 ammonium hydroxide, water (8 1 1 v/v) and that part of the paper corresponding to the ABA zone (R_F 4 5–8 5) was divided into eight equal segments These were assessed for inhibitory activity in the wheat coleoptile straight growth test[11] The mean length of the ten coleoptile sections used in each assay was expressed as a percentage of the length of the controls A dose-response curve was obtained for synthetic (±) ABA so that the inhibitor extracted from maize could be expressed as µg equivalents of ABA (ref 3)

The free ABA in detached non-wilted maize leaves in Latente, which is tolerant to water stress, was found to be more than four times that found in the less tolerant varieties Anjon 210 and LG 11 On subjecting the detached leaves to water stress the level of ABA increased in all varieties, confirming similar observations by Wright[1] and Wright and Hiron[3] (Table 1)

Although water stress produced a greater relative increase of ABA in the varieties Anjon 210 and LG 11 than in Latente, the level of ABA in the wilted Latente leaves was much higher Such high levels would be expected to have a profound effect in closing leaf stomata thereby reducing transpiration and protecting the plant against water loss Not only this, but the well-established effects of ABA in inhibiting the activity of growth hormones would be expected to operate strongly, thereby restricting growth and conserving energy normally utilised in growth processes Our results indicate that such protective mechanisms may be more well developed in the drought tolerant Latente maize than in the other two varieties studied

We thank Drs H Wilkins and S T C Wright for assistance and helpful discussions and Dr Muñoz for providing the Latente seed

Altered fucolipid patterns in cultured human cancer cells

STUDIES in this laboratory[1] have shown that fucolipid metabolism is markedly altered in membranes of cells transformed by oncornaviruses Transformed cells exhibit a sharp decrease in radioactive fucose incorporation into chromatographically less mobile, presumably more complex, fucolipids with a corresponding rise in radioactivity in more mobile fucolipids Studies of fucolipid metabolism in normal rat kidney (NRK) cells transformed by a cold-sensitive transformation mutant of murine sarcoma virus (NRK (MSV-1b)) revealed a correlation between the appearance of the transformed phenotype and altered fucolipid synthesis[2] The fucolipids of SV40 and herpes simplex virus-transformed cell lines have also been examined[3], some of the transformed lines were oncogenic while others were not when injected into appropriate animals The cell lines which were capable of producing tumours had a block in the synthesis of the complex fucolipids comparable with that observed in the oncornavirus-transformed cells In contrast, the transformed cell lines that did not produce tumours showed only a minor block in the formation of the complex fucolipids

We have now examined the fucolipids of a number of cultured human tumour cell lines[5] The results indicate a block in synthesis of the complex fucolipids that is comparable with that observed in virus-transformed cells

The human tumour cell lines used included those isolated and characterised by Giard *et al*[4] A-375, malignant melanoma A-204, rhabdomyosarcoma, and A-549 lung carcinoma In studies[4] with mice treated with antithymocyte serum (ATS), A-375 produced rapidly growing subcutaneous tumours resembling amelanotic melanomas, A-204, slowly growing sarcomas, and A-549, rapidly growing subcutaneous and intracerebral carcinomas Additional cell lines included SV40-transformed human cell line (SV80)[5] and 8387, a human fibrosarcoma cell line[6] In addition, several strains of normal human embryonic cells were examined The cells were grown in glass bottles in Eagle's minimal essential medium (MEM) supplemented with 10% foetal calf serum, and were labelled 3–5 d after plating with 1-^{14}C-fucose (0 5 μCi ml^{-1}, 57 mCi mmol^{-1}) or with 1-^{3}H-fucose (5 μCi ml^{-1}, 1 4 Ci mmol^{-1}) Cell monolayers were washed three times with cold phosphate-buffered saline (PBS), removed by scraping into PBS and sedimented to a pellet The pellet was washed with PBS and the lipid was extracted[1]

Chromatographic analysis of the fucosylglycolipids was accomplished by thin-layer chromatography (Q-5 plates, Quantum Industries, Fairfield, New Jersey) in 2-propanol NH_4OH H_2O (7 2 1, by volume) The amount of radioactivity was estimated by scraping the plate in 1-cm strips from origin to solvent front and counting the fractions in a scintillation spectrometer[1] When ^{14}C-fucose-labelled lipid was examined, the plates were visualised, before scraping, by exposure to Kodak No-screen X-ray film

It seemed unlikely that nonlipid contaminants (that is fucose, GDP-fucose, fucose-1-phosphate or fucopeptide) might have been present in the lipid extract The materials characterised as fucolipids did not dialyse, were unaffected by snake venom phosphadiesterase or by *Escherichia coli* alkaline phosphatase, and did not have the same R_F values as those of authentic fucose, GDP-fucose or fucose-1-phosphate These properties argue against the possibility of contamination with the small molecular weight material indicated above Further, chromatography of the cytosol fucose radioactivity did not reveal components with the same R_F values as those of the fucolipids, whereas the lipid extract from a thoroughly washed high speed pellet yielded the identical fucolipid patterns as those obtained from

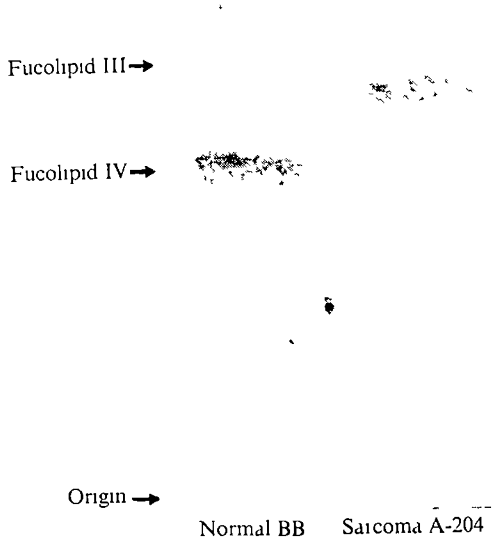

Fig 1 Autoradiogram of one dimensional chromatograms of ^{14}C-fucose-labelled lipids of BB (normal human embryonic lung) and A-204 (sarcoma) cells Cells were cultured in medium supplemented with ^{14}C-fucose as described in the text, as are the conditions for collecting, extraction and chromatography of the fucolipids The figure is a composite of autoradiograms of two thin-layer plates, 5×20 cm, chromatographed in parallel, solvent was $CHCl_3$ CH_3OH NH_4OH (7 2 1, by volume) Fucolipids III and IV are shown, the more chromatographically mobile fucolipids (I and II) are not visible because of the relatively low level of radioactivity (see Table 1) in these components

Table 1 Incorporation of ^{3}H-labelled fucose into lipids of normal human embryonic lung (BB) and human tumour cell lines

Fucolipid	BB (normal)*		8387		A-204		SV80		A-549		A-375	
	%	c p m per mg protein	%	c p m per mg protein	%	c p m per mg protein	%	c p m per mg protein	%	c p m per mg protein	%	c p m per mg protein
I	2 8	166	6 8	494	6 7	394	1 8	167	10 3	506	16 3	852
II	8 3	491	11 0	799	10 7	630	3 6	333	14 7	722	24 5	1,281
III	16 7	987	21 9	1,591	80 0	4,711	73 2	6,772	50 0	2,457	44 9	2,347
IV	72 2	4,269	60 3	4,381	2 7	159	21 4	1,980	25 0	1,228	14 3	748

Each cell line was grown for 72 to 96 h (to obtain low and high cell density) in the presence of ^{3}H-fucose (5 μCi ml^{-1}, 1 4 Ci mmol^{-1}) Conditions for collecting and for lipid extraction are indicated in the text

* The fucolipid pattern of many different strains of normal human embryonic cell lines were studied, with comparable results to those seen for BB cells

extracted whole cells In addition, the fucolipids did not bind to DEAE-cellulose, which not only rules out negatively charged small molecular weight material (that is fucose-1-phosphate, GDP-fucose) but also makes it less likely that the compounds were fucoprotein Further evidence to rule out the possibility of fucoprotein (or fucopeptide) included total resistance to exhaustive pronase digestion It is also noteworthy that the Sephadex G-50 elution profiles of the major fucolipids (that is III and IV below) failed to manifest any overlapping with fucopeptides prepared according to Buck *et al*[10] We feel that the above evidence strongly supports the lipid nature of the fucose-labelled components Nevertheless, we are attempting to accumulate a sufficient amount of these lipids, which are present in extremely low amounts, to carry out definitive chemical analyses

Figure 1 is an autoradiogram of a one-dimensional chromatogram of the ^{14}C-fucose-labelled lipids of normal human embryonic cells (Fig 1, lane 1) and of cultured human rhabdomyosarcoma (A-204) cells (Fig 1, lane 2) Approximately equivalent amounts of radioactivity were chromatographed with each sample It is apparent that the least chromatographically mobile fucolipid (that is FucCer IV) is greatly reduced in the rhabdomyosarcoma culture In a comparable experiment the alternative isotopic form of fucose (^{3}H) was used to label the fucolipids of a number of human tumour cell lines, including those in Fig 1 The results (Table 1) show that four of the tumour cell lines had a significant reduction in the incorporation of ^{3}H-fucose into fucolipid IV, the chromatographically least mobile component In contrast, its incorporation into fucolipid IV in the 8387 cell line obtained from a fibrosarcoma was similar to that for the normal cell line The experiment presented in Table 1 is representative of three separate experiments, each done in duplicate In addition, comparable results to those seen in Table 1 were observed when ^{14}C-fucose was used with the same cell lines (Fig 1) Several other normal human embryonic cell strains gave patterns similar to those shown for BB cells

It has been shown that the membranes of human adenocarcinomas lack the blood group haptens A and B but accumulate the Le^{a} and H haptens[7] More recently, Stellner and Hakomori[8] demonstrated that the altered fucosylglycolipid patterns (that is blood group determinants) in adenocarcinoma tissue are due to a deficiency in glycosyltransferases rather than to enhanced hydrolase activity Likewise, Fishman *et al*[9] noted the absence of a specific ganglioside galactosyltransferase in mouse cells transformed by murine sarcoma virus

One of the problems in examining human tumour material is the difficulty of obtaining adequate normal control cells Although we have not resolved this issue, it is noteworthy that regardless of the tissue source (kidney, lung or embryo) of the normal cells studied, or the cell type (epithelial or fibroblastic), or the species of primate from which the cells were derived, the fucolipid pattern was constant.

In the present study, altered patterns of incorporation of isotopically labelled fucose into the fucolipids of several types of cultured human tumour cells were observed The altered fucolipid patterns probably reflect changes in the glycosyltransferase activities similar to those reported[8] for adenocarcinoma tissue It is noteworthy that the fucolipid changes observed in the human tumour cells were similar to those observed in oncornavirus-transformed cells and in DNA-transformed, oncogenic cells Three of the human tumour cell lines (A-204, A-549 and A-375) had been found to produce tumours in ATS-treated mice[4] The cells of the 4th line, 8387, were fibroblastic in nature, although they piled up more than fibroblasts derived from healthy tissue, however, they failed to grow in ATS-treated mice[6] In this manner, the 8387 line acted like those SV40- and herpesvirus-induced cell lines that are transformed but not oncogenic[3] The SV80 line produced tumours in ATS-treated mice but they were then rejected, perhaps because SV40-transformed cells contain stronger antigens than spontaneous tumours[5]

These studies on human cancer cells in culture are built on our previous investigations of virus-transformed lines They offer a much needed biochemical method for identifying human cell lines that remain cancerous after being grown in culture

This work was supported by a research contract from the Special Virus-Cancer Program and research grants from the National Cancer Institute, National Institutes of Health S S is a recipient of an NIH special fellowship from the National Cancer Institute Seed cultures of the cell lines shown in Table 1 were supplied by Dr George Todaro, National Cancer Institute We thank Raymond Lewis and Yongsoon LaBelle for technical assistance

Essential fatty acids in cystic fibrosis

THE nature of the metabolic defect in cystic fibrosis (CF) has, to date, not been elucidated. Elliott[1] reported that intravenous administration of soybean oil and lecithin to children suffering from CF caused their sweat sodium concentration to decrease towards normal values. This prompted us to investigate the fatty acid spectra of the various serum lipid classes of children with CF. We have found that affected children are deficient in certain essential fatty acids.

Table 1 Fatty acid spectra of serum lipid classes of children with cystic fibrosis and of normal children

‡$P = <0.05$

§$P = <0.02$

¶$P = <0.01$

‖$P = <0.001$

Sera were obtained from five children (aged 4.5–12.5 yr) with CF, and compared with sera from four normal children (aged 5–12 yr). Serum lipids were extracted with chloroform–methanol (2:1)[2] and subjected to thin-layer chromatography on silica gel G using hexane–ether–glacial acetic acid (first 60:40:1 and then 90:10:1) as developing solvents[3]. The lipid classes were visualised on the plates with iodine vapour[4] and after sublimation of the iodine, the appropriate areas were scraped, and the lipids were eluted and transesterified with a BF_3–methanol mixture. The resulting fatty acid methyl esters were analysed by gas–liquid chromatography using a column of 16% diethylene glycol succinate on 100–120 mesh Gas-chrom P. An argon ionisation detector was used. The column was standardised for retention times and quantitated at 175° C and 20 lb inch^{-2} of argon gas using purified standards.

The results are summarised in Table 1. There are significant differences between CF and normal sera in all the classes of serum lipids analysed. In the cholesterol esters, the CF sera contained significantly more myristic, palmitoleic stearic and oleic acids and significantly less linoleic acid. In the triglycerides the CF sera were richer in palmitic, palmitoleic and oleic acids but contained less stearic acid. Serum triglycerides of CF children contained 34% less linoleic acid but the difference was not statistically significant. In the phospholipids, the CF sera contained significantly less linoleic and arachidonic acids and more oleic acid. Kuo and Huang[5] found significantly less stearic and linoleic acids in the serum free fatty acids of CF children and significantly more palmitoleic acid and acids of chain length below that of palmitic acid (presumably myristic acid). Caren and Corbo[6] found that the major change in the free fatty acid fraction of CF children was in the large increase in palmitoleic acid. Our data confirm their other findings which were assessed from the standpoint of relating CF to impairment of liver function.

The data suggest another approach to the study of the metabolic defect in cystic fibrosis. There is an apparent deficiency in essential fatty acids, and a marked reduction in serum vitamin E levels has also been reported in CF[7]. These conditions might be partially corrected by intravenous injection, or possibly feeding of, lipids containing essential fatty acids with concomitant administration of vitamin E. The observed deficiency in essential fatty acids may be produced by a reduced ability to absorb these acids from the diet and this, in turn, may result in defects in membrane structure or stability. Reduced levels of vitamin E in CF may reflect a reduced requirement for this vitamin because of the lower levels of essential fatty acids. It is also possible that the observed deficiency in serum levels of essential fatty acids may lead to less than normal production of prostaglandins. These approaches are under investigation.

This investigation was supported, in part, by funds from the National Cystic Fibrosis Research Foundation (to M.L.R.) and by a grant from the United States Public Health Service and a research career award from the National Heart and Lung Institute (to D.K.).

Alteration of fibroblast gene products *in vitro* from a subject with Werner's syndrome

CULTURED human fibroblasts have a limited replicative capacity[1] and provide an excellent model for the study of biological ageing[1-4]. Recent studies have demonstrated that toward the end of their replicative lifespan, normal fibroblasts accumulate a significantly higher proportion of defective enzymes and simultaneously incorporate increased amounts of amino acid analogues[5,6]. In addition, the RNA base analogue, 5-fluorouracil induces premature senescence of cultured cells which is preceded by the appearance of altered enzyme[5]. These results have been taken to suggest that the fidelity of protein synthesis decreases, possibly causally, during cellular ageing *in vitro*[5-7].

Cultured fibroblasts derived from subjects with Werner's syndrome, a hereditary disease of accelerated ageing, show a markedly curtailed lifespan compared to normal age-matched controls[3,8,9] Accordingly, one might predict that such cells would show the earlier appearance of abnormal gene products, a higher proportion of abnormal gene products, or a combination of both Since it is difficult to obtain cultures from Werner's subjects before the disorder is clinically fullblown, all strains so far examined have grown poorly from the outset and have lost their replicative capacity quite prematurely Thus, although the first prediction is difficult to test, the second possibility can be analysed Here we demonstrate that a strain of Werner's fibroblasts contains a high defective proportion in 3 different gene products, HL-A2 and HL-A9, two histocompatibility antigens on the cell surface and glucose-6-phosphate dehydrogenase (G-6PD), a cytoplasmic enzyme in the pentose shunt

Cultures were derived in our laboratory following explantation of skin of the anterior forearm as previously described[2] The subject with Werner's syndrome (H McG) was a 56-yr-old female who had already been studied *in vivo*[10] and *in vitro*[3] This strain of Werner's fibroblasts again showed a reduced lifespan so that only five to six subcultures were possible at a 1 8 split ratio, that is, 15–18 mean population doublings (MPD) before total cessation of growth[1-3] Normal controls were capable of 15–25 subcultures (45–75 MPD) in the same conditions G-6PD was assayed for thermolability using crude cell extracts as described by Holliday and Tarrant[5] Briefly, cultures were allowed to grow to confluence and then collected Following rinsing, cells were suspended in 0 05 M Tris buffer, *p*H 8 0, containing 10^{-3} M NADP and sonicated followed by centrifugation for 30 min at 30,000*g* The supernatant was then heated at 60° C Aliquots were removed after various times and immediately placed in an ice bath till assay on a Gilford ultraviolet spectrophotometer HL-A phenotypes were first determined on circulating lymphocytes of the skin fibroblast donors by a microdroplet cytotoxicity technique[11], modified slightly for fibroblasts[12] Quantitative absorption studies were performed using appropriate antisera as previously described[13]

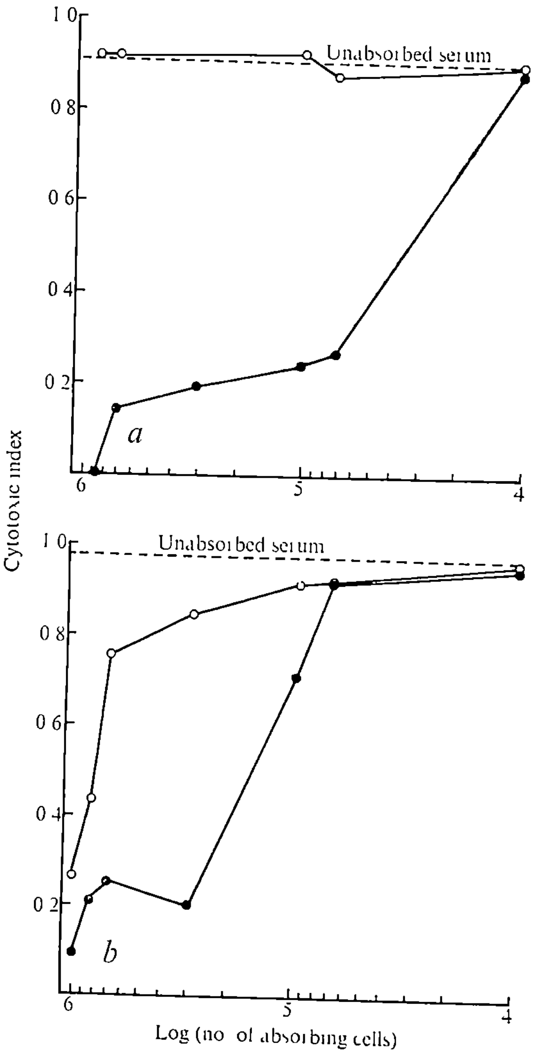

Fig 1 Cytotoxicity of *a* anti-HL-A2 serum and, *b* HL-A9 serum following absorption by fibroblasts from Werner's syndrome and a normal 36-y-old male (HL-A2,9,7,12) Fibroblasts at the concentrations indicated were suspended in 10μl of antiserum and incubated for 40 min with mixing followed by centrifugation and testing of the supernatant against appropriate target lymphocytes Werner's cells were at 15 and 12 MPD (total capacity 18) in *a* and *b*, respectively Normal cells were at 21 and 36 MPD (total capacity 60) ○, Werner's syndrome, ●, normal

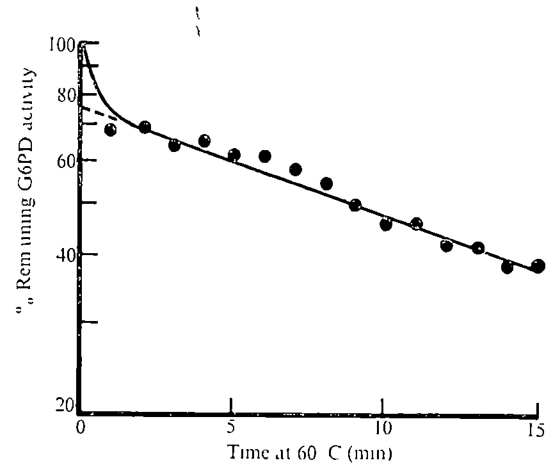

Fig 2 Heat inactivation of glucose-6-phosphate dehydrogenase in extracts of skin fibroblasts derived from a patient with Werner's syndrome Cells were at 12 MPD

The HL-A phenotype of the patient with Werner's syndrome, as determined on her peripheral blood lymphocytes, was HL-A2, 9, 5, W15 All four antigens were detected on cultured fibroblasts by the cytotoxicity method but the results became erratic following the first subculture The results of quantitative absorption studies for two antigens, HL-A2 and HL-A9, are given in Fig 1 The expression of HL-A2 (Fig 1*a*) was markedly reduced on fibroblasts from Werner s syndrome compared to the normal control HL-A9 expression was also reduced (Fig 1*b*) but not as markedly as that of HL-A2 Taking the 50% level of cytotoxicity as a reference point, the quantitative expression of antigens can be calculated[13,14] Thus, HL-A2 expression was reduced more than 50-fold in Werner's fibroblasts compared to the normal control while HL-A9 expression was reduced about 4 5-fold The expression of each antigen in normal strains from donors aged 27–76 yr varies less than twofold throughout the culture lifespan as we and others had described previously[15,16]

Figure 2 indicates that extracts of Werner's fibroblasts had 24% heat-labile G-6PD On two other occasions at similar MPD levels, Werner's cells had 14% and 22% heat-labile G-6PD In contrast, early-passage cultures from normal controls aged 28–76 yr averaged 1 0% heat-labile G-6PD (range 0–4% in five strains tested 17 times) while late-passage controls averaged 4 3% (range 0–10% in four strains tested 17 times) An equal part mixture of extracts from Werner's cells (24% heat-labile) and normal cells (0% heat-labile) gave 9% heat-labile G-6PD, close to the predicted value of 12% This suggests that proteolytic or other detrimental factors are not responsible for the greater degree of heat-labile G-6PD in Werner's cells and conversely, that a deficiency of stabilising factors is probably not involved

The data indicate that three diverse gene products, HL-A2 and HL-A9, two surface-related antigens which are coded for by autosomal genes[17], and G-6PD, a cytoplasmic enzyme which is genetically X linked[18], are markedly abnormal in cultured cells from Werner's syndrome Virtually identical results on G-6PD have recently been found on a different strain of Werner's fibroblasts by Holliday *et al*[9], although the differences between early and late-passage normal cells in this report are much less than previously observed by Holliday and Tarrant in MRC-5, a strain of male foetal lung fibroblasts[5] We recognise that controversy exists regarding the composition of HL-A antigens[19-21] Indeed, if these molecules turn out to be glycoproteins[22] it is possible that their expression depends on glycosyl transferases as well as the protein component coded for by HL-A genes Thus, the altered reactivity with antiserum of HL-A2 and HLA-9 in Werner's fibroblasts may reflect aberrations in more than a single gene product But this does not affect the conclusions and it seems likely, therefore, that these cells have a widespread defect in cellular proteins which is more severe in extent than in ageing normal cultures In other studies, we have found similar disturbances in HL-A antigen expression[13,15] and heat lability of three different cytoplasmic enzymes in fibroblasts derived from subjects with progeria, another disease of premature ageing (S G , unpublished) Additionally, a fraction of clonal subpopulations within normal mass cultures may also develop altered HL-A expression during ageing *in vitro*[12,15]

Although no proof exists that accumulation of defective proteins is the cause rather than the result of cellular ageing[7], our evidence strengthens the concept that the rate of fibroblast ageing *in vitro* is directly related to the rate of ageing *in vivo* Nevertheless, information is still needed to explain how a diversity of protein defects in ageing cells predisposes individuals with Werner's syndrome to diabetes mellitus, severe atherosclerosis and neoplasia[10], the same diseases that increase exponentially during normal biological ageing[4,15,23,24]

We thank Dr G M Martin for providing skin samples from H McG and Mrs E Moerman and Mr R Cordeiro for technical assistance This work was supported by grants from the Medical Research Council of Canada and the Canadian Diabetes Association Foundation Fund during the tenure of an MRC scholarship (S G)

Effects of prostaglandin E_2 on human platelet adenyl cyclase and aggregation

The ability of prostaglandins to affect platelet function has been described in many laboratories[1,2]. The most potent of these, prostaglandin E_1 (PGE_1), has been found to inhibit platelet aggregation and stimulate platelet adenyl cyclase The effect of prostaglandin E_2 (PGE_2), however, has been either inhibitory or stimulatory, depending both upon the species of animal examined[3] and the concentration of prostaglandin used[4]

Recent demonstrations of the ability of platelets to produce and secrete prostaglandins[5,6] have stimulated new interest in the effects of the different prostaglandins on platelet activity

The present investigation was designed to re-examine the effect of PGE_2 on human platelets, using concentrations of prostaglandin comparable with the levels that platelets produce and secrete[5,6] It was found that PGE_2 stimulated platelet adenyl cyclase and inhibited both ADP- and collagen-induced platelet aggregation

Blood was collected into sodium citrate (0 38%) from normal human donors who had not ingested aspirin for a minimum of 14 d Blood or platelets contacted only siliconised glass or metal surfaces, or non-wettable plastic The platelet-rich plasma (PRP) was collected after centrifugation at 150*g* and maintained at room temperature Aggregation was followed by the turbidimetric procedure of Born[7], measuring absorbance decrease at 600 nm at 37° C in either a Gilford 2000 or Unicam SP800 spectrophotometer with magnetic stirring (1,000 r p m) Varying concentrations of either PGE_1 or PGE_2 (Ono Pharmaceuticals) dissolved in dimethylformamide (DMF) (10 µl) were added to the PRP (2 7 ml) and incubated without stirring at 37° C for 10 min At time zero, inducers were added and stirring commenced Appropriate controls preceded and followed each PG aggregation Inducers were ADP (Sigma), 10 µl, in aqueous solution (final concentration, $0\ 9 \times 10^{-4}$ to $1\ 8 \times 10^{-4}$ M) and collagen, 50 µl, prepared according to Hirsch, *et al*[8]

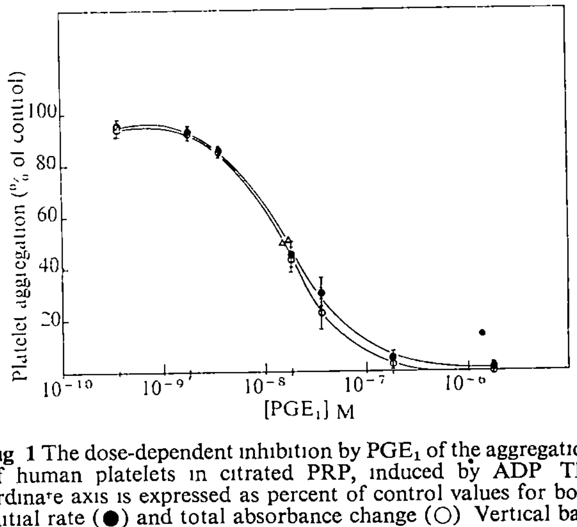

Fig 1 The dose-dependent inhibition by PGE_1 of the aggregation of human platelets in citrated PRP, induced by ADP The ordinate axis is expressed as percent of control values for both initial rate (●) and total absorbance change (○) Vertical bars show standard error of the mean (s e m), 5–8 replications per point The ID_{50} concentration is marked on each curve (△) For other details, see text

Adenyl cyclase studies utilised platelets obtained from EDTA–anticoagulated blood by the method described by Haslam[9] The washed platelets, resuspended in 10 mM Tris (pH 7 5 at 20° C), were kept intact at 4° C until used Cyclase activity was determined in triplicate by measuring conversion of α–^{32}P–ATP to ^{32}P–cyclic AMP Added ^{3}H–cyclic AMP was used as an index of recovery Platelets were used without being lysed Lower levels of cyclic AMP were obtained in platelets lysed either by sonication or freeze–thawing

The assay mixture contained the following components in a final volume of 1 0 ml α–^{32}P–ATP (New England Nuclear), 6 mM (0 5 µCi), phosphoenolpyruvate (Sigma), 0 1 mM, pyruvate kinase (Sigma), 1 0 unit, magnesium chloride, 9 mM, theophylline (Sigma), 10 mM, cyclic AMP (Sigma), 2 0 mmol, potassium chloride, 5 5 mM, Tris buffer, 40 mM, pH 7 5 (20° C), approximately 10^8 washed human platelets

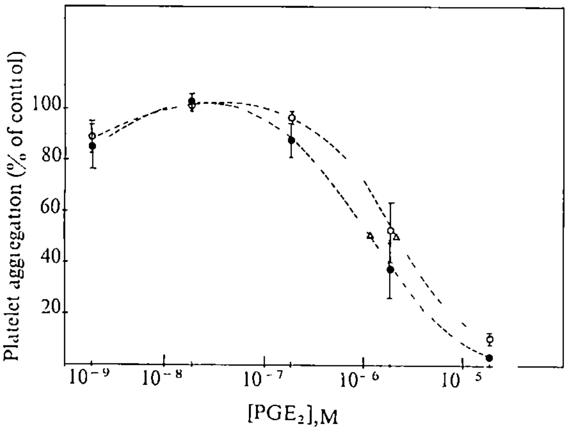

Fig 2 The dose-dependent inhibition by PGE$_2$ of the aggregation of human platelets in citrated PRP, induced by ADP, 8–12 replications per point The ordinate axis, symbols and details are as in Fig 1

As in the aggregation work, prostaglandins were added in DMF, with appropriate blanks and controls Methodology used by one of us (M D) differed slightly and was described previously[10]

After incubation at 37 °C for 15 min, the reaction was stopped by adding 0 1 µCi of ^{3}H–cyclic AMP (50 µl) to each tube followed by heating for 5 min in boiling water The cyclic AMP isolated by the methods described by White[11] and Ramachandran[12] was counted for both ^{3}H and ^{32}P

PGE$_1$ inhibited the ADP-induced aggregation of citrated PRP in the expected dose response relation over a concentration range of $3\ 7\times10^{-10}$ to $1\ 8\times10^{-6}$ (Fig 1) This was evident both when the inhibition was measured as decrease in initial absorbance rate and when it was measured as total absorbance change The correlation between the two measured parameters was excellent with an ID$_{50}$ of $1\ 6\times10^{-8}$ to $1\ 7\times10^{-8}$ M

The effect of PGE$_2$ on ADP-induced platelet aggregation in citrated PRP was similar to that of PGE$_1$ Thus, over a concentration range of $1\ 8\times10^{-9}$ to $1\ 8\times10^{-5}$ M, only inhibition was observed in both the initial rate (ID$_{50}$ = 5×10^{-6} M) and total absorbance change (ID$_{50}$ = 1×10^{-5} M) parameters (Fig 2) PGE$_2$ was therefore only 1/500 to 1/250 as potent as PGE$_1$ in inhibiting the ADP-induced aggregation of citrated PRP Stimulation by PGE$_2$ alone or augmentation of ADP-induced aggregation by PGE$_2$ was never seen

The collagen-induced aggregation in the same system was also inhibited by PGE$_1$ (Fig 3) over the same concentration range ID$_{50}$, measured by initial rate inhibition, was $1\ 2\times10^{-6}$ M • For total absorbance change, the ID$_{50}$ was $2\ 1\times10^{-6}$ M Although it seems that greater inhibition was obtained at the lowest PGE$_2$ concentration, than at a tenfold higher concentration, these data were not statistically different from control values

Platelet adenyl cyclase was stimulated by both PGE$_1$ ($5\ 0\times10^{-9}$ to $5\ 0\times10^{-6}$ M) and PGE$_2$ ($1\ 0\times10^{-7}$ to $2\ 0\times10^{-4}$ M) as shown in Fig 4 Both compounds displayed only stimulation above basal levels, even at the lowest concentrations, in classic dose-response relationships The ED$_{50}$ for PGE$_1$ was 5×10^{-8} M and for PGE$_2$ was 7×10^{-6} M Thus, about 140 times more PGE$_2$ was required to equal a given PGE$_1$ level of stimulation Although absolute amounts of adenyl cyclase activity varied among platelet samples, the ED$_{50}$ values obtained for both PGE$_1$ and PGE$_2$ were consistent and reproducible These effects were obtained whether the platelets were prepared as described here or by a previously published method[13]

Several studies using PGF$_{2\alpha}$ (Fig 4) were also performed Though stimulation was minimal, a decrease of adenyl cyclase activity below basal levels was never seen

In the platelet aggregation studies, the effects of PGE$_1$ and PGE$_2$ were inhibitory only, as measured by two parameters over a wide concentration range Contrary to published results[3,14], no stimulation of either ADP- or collagen-induced aggregation at low PGE$_2$ concentrations was observed The difference between this and previous studies may be in the reproducibility of aggregation results In citrated PRP, even a series of control experiments on the same platelet sample will yield results that vary with time and other factors we have not yet identified, under presumably identical conditions To circumvent this, the values obtained for each prostaglandin treatment were compared with control values obtained both before and after the PGE inhibition experiment Many experiments were performed at each inhibition concentration with many different platelet samples In the ADP-induced aggregation studies inhibited by PGE$_2$ below 2×10^{-6} M, over 60 separate experiments, exclusive of controls were performed with platelets from 17 different donors The collagen-induced experiments were replicated fewer times, hence the larger standard errors (Fig 3) Even in these experiments though, inhibition was obvious

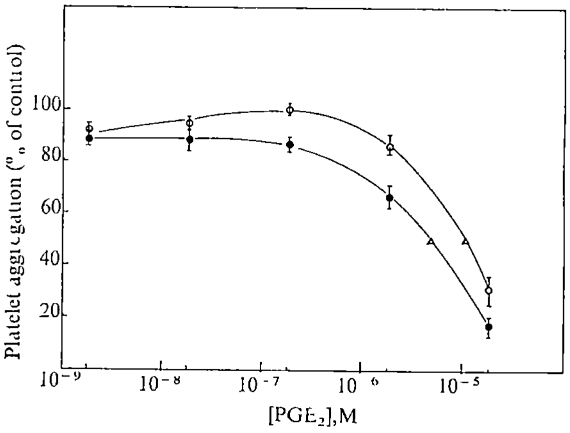

Fig 3 The dose-dependent inhibition by PGE$_2$ of the aggregation of human platelets in citrated PRP, induced by collagen, 4 replications per point The ordinate axis, symbols and details are as in Fig 1

The stimulation of platelet adenyl cyclase activity by PGE$_1$ at various concentrations agrees with previously reported data[10,13] PGE$_2$ similarly elicited no response other than stimulation of the platelet adenyl cyclase This is contrary to previous published reports[4] in which PGE$_2$ at $2\ 8\times10^{-7}$ M (0 1 µg ml^{-1}) was found to inhibit adenyl cyclase activity In the earlier work, emphasis was given to the finding that only at low concentrations did PGE$_2$ inhibit adenyl cyclase activity Concentrations which we found stimulatory, however, were the same as those previously reported as inhibitory The reason for this discrepancy is not clear

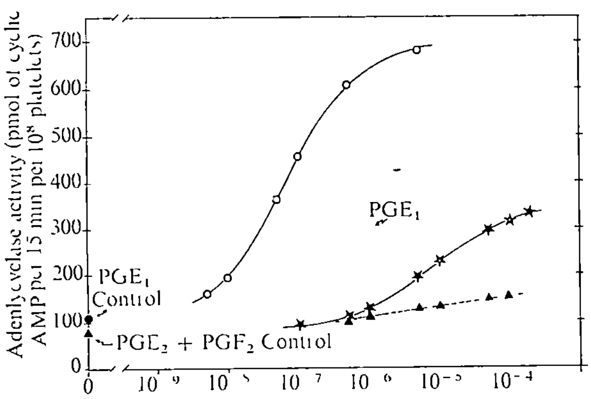

Fig 4 The effects of PGE_1 (○), PGE_2 (★), and $PGF_{2\alpha}$ (▲) on washed human platelet adenyl cyclase The PGE_1 data were obtained using different platelets from the PGE_2 and $PGF_{2\alpha}$ data For reference, a single concentration of PGE_1 (△) was assayed in the PGE_2–$PGF_{2\alpha}$ platelets In other experiments not reported, PGE_2 and $PGF_{2\alpha}$ were studied at concentrations as low as 10^{-8} M with results similar to PGE, (M D) At PGE_1 concentrations above 10^{-5} M, a decreased output of cyclic AMP has been observed (unpublished data) It has not been possible to show this effect with PGE_2, possibly because of difficulties in getting high enough concentrations in solution

Recent studies have suggested the existence of a regulatory or feedback mechanism of platelet function in which prostaglandins, produced and secreted in response to thrombin, may stimulate platelet adenyl cyclase to produce cyclic AMP and thereby modulate the release and aggregation processes (refs 6, 15 and M D, unpublished data) Our findings that both PGE_2 and PGE_1 stimulate adenyl cyclase supports this hypothesis, especially as we found that presumably physiological levels of PGE_2 (refs 5, 6) were stimulatory

Delayed fertilisation in senescent golden hamsters

REPRODUCTIVE senescence in the female golden hamster occurs after 14 months of age and is characterised by a significant decline in the production of offspring[1] Recent studies in our laboratory concerned with the cause(s) of this decline have revealed large numbers of non-viable ova in aged hamsters before implantation[2] and a developmental delay of approximately 12 h in preimplantation and implantation stages of embryos from senescent hamsters when compared with young females at the same hour of pregnancy[3,4] Since the elapsed time for the union of gametes is important for normal fertilisation and development we examined ova for the onset of fertilisation in young and aged hamsters

One hundred and twenty young virgin (3–5 months old) and 170 multiparous senescent (14–17 months old) hamsters, cycling regularly, were mated with young males (3–6 months old) at the onset of behavioural oestrus Ovulation was considered to occur 8 h from the onset of oestrus[5] and all developmental stages are based upon this assumption All animals were from the Oregon colony, except for 72 senescent females from commercial breeders Ova collected from 1 h through 12 h and at 1, 1½, 2, 2½, 3 and 3½ d intervals, were either mounted *in toto* and examined with differential interference contrast microscopy (Nomarski optics) or compressed, fixed and stained with lacmoid

Most of the ova from senescent females showed a 2 to 5 h delay in fertilisation compared with young females (Table 1) The delay was not merely an inbred characteristic of females from the Oregon colony, since aged females from two commercial animal farms demonstrated the same trait

Although there seemed to be a short delay in the completion of ovulation in the senescent hamster 1 h after ovulation (10 5±1 12 compared with 13 8±0 91 for young females), there was no statistical difference in the number of ova at 2 h (12 8±2 25) compared with ova from young hamsters 1 h after ovulation The total number of ova recovered from young and senescent females was similar throughout the first 12 h (young 13 2±0 33, senescent 12 1±0 38), but a real difference was apparent when the number of normal-appearing ova was determined (young 12 6±0 40, senescent 10 9±0 30), large numbers of non-viable ova were found in the aged hamsters Some ova were apparently defective at the onset of ovulation since they were in an advanced state of deterioration at the time fertilisation normally occurs in young females Other fertile ova of normal appearance stained with lacmoid revealed anomalies commonly associated with a delay in fertilisation, such as fragmented pronuclei (6 ova), dispermy (3 ova), trispermy (1 ovum) and androgenesis (1 ovum) On examining zygotes

Y, Young
S, Senescent
* Ova stained with lacmoid

from the uterus, we found that approximately 40% of the ova from senescent females were incapable of implantation so that preimplantation loss seems a major factor. Unfertilised ova made up a small percentage of the non-viable ova (1.4% compared with 1.3% for young females), therefore, it is conceivable that the delay in fertilisation was sufficient to have caused some embryonic loss.

Researchers have shown that delaying fertilisation in young golden hamsters by artificially inseminating[6] or naturally mating females[7] 3 h after ovulation, results in considerable embryonic loss (14% to 61%). In both studies capacitation of the spermatozoa would have required between 2 and 4 h (ref. 8), therefore, the ova were between 5 and 7 h old before fertilisation. In our study many ova from aged hamsters were not fertilised until 5–8 h after ovulation.

Spermatozoa may be slowed in their ascent through the aged reproductive tract, although oviducts compared from several young and senescent females allowed to breed for 1 h from the beginning of coitus revealed no difference in the approximate number or location of spermatozoa. No spermatozoa were detectable, however, in ampullae of oviducts of either group. A more probable cause for the delay is prolonged capacitation. This may explain why some ova from senescent hamsters in the present study are fertilised at a time when hamster spermatozoa have been shown to be no longer viable[9]. Raised levels of plasma progesterone have recently been reported in some senescent hamsters during oestrus and the first day of pregnancy[10]. This may indicate that the ageing hamster uterus is less capable of binding progesterone, a condition noted *in vitro* with the senescent rabbit uterus[11]. A refractory uterus could be causing a delay in fertilisation in hamsters since subcontraceptive levels of progesterone may delay fertilisation in rabbits[12] either by slowing spermatozoa migration through the reproductive tract and/or by prolonging capacitation[13,14].

Abnormal potassium conductance associated with genetic muscular dystrophy

DYSTROPHIC diseases not only lead to progressive deterioration of muscle, but alter several properties of the erythrocyte surface[1-4], and permeability of various other membranes[5-7]. Muscular dystrophies are also associated with defects in the nervous system, so that a neurogenic aetiology[8] has been suggested, there being reports of peripheral neural dysfunction[9], increased frequency of mental retardation[10] and defective auditory acuity[11].

Many of these non-muscular (systemic) features of the dystrophic condition are associated with cellular membranes, indeed dystrophic muscle itself has an abnormal membrane composition[12] and greater than normal calcium-linked ATPase activity in the sarcoplasmic reticulum[13]. Moreover, dystrophic muscle exhibits a significantly altered ionic content and abnormally large potassium conductance[14], although these attributes may only reflect the characteristic degeneration of such tissue. I report here that diverse membrane systems in dystrophic animals and humans conduct potassium more rapidly than in the case of normal subjects. This higher conductance could, in principle, account for the disease process.

Table 1 shows passive K+ efflux from erythrocytes from normal subjects and patients with Duchenne muscular dystrophy where the rate of efflux is about five times greater. In other experiments, the cardiac glycoside, ouabain, was without influence on the efflux and addition of the K+-conducting antibiotic, valinomycin, stimulated it. The extent of K+ loss in the presence of valinomycin, suggests that there is no consistent difference between the K+ content in normal and dystrophic erythrocytes.

Table 1 Efflux of potassium from human erythrocytes

Source of cells	No. of subjects	Potassium efflux (nmol per min per 10^8 cells)
Normal subjects	8	21.6±2.4
Duchenne dystrophy patients	7	107.9±7.5

Results are expressed as mean and standard error of the mean. Samples of venous blood were drawn into a heparinised tube, cells were sedimented at 1,500*g*, resuspended in isotonic saline, washed twice and finally resuspended in about one-tenth of the original volume of saline. All operations were carried out at 0° C. Potassium efflux was measured at 20° C with a Corning model 476132 potassium electrode which exhibited an 80-fold selectivity of potassium as compared with sodium. The medium contained 360 mM sucrose, 15 mM NaCl and 0.1 mM KCl in a volume of 10 ml to which was added 0.4 ml of an erythrocyte suspension containing approximately 10^9 cells per ml.

Figure 1 shows light scattering changes after addition of potassium acetate to suspensions of mouse liver (*a*) and brain (*b*) mitochondria. Normal mitochondria from both organs are relatively impermeable to K+ whereas those from dystrophic animals took up a significant amount. I have observed a similar increase in K+ conductance with liver mitochondria from a second strain of dystrophic mice (129ReJ-dy) and from nutritionally dystrophic rats maintained on a vitamin E-deficient diet. This last observation suggests that membrane dysfunction may be the basis for similarity between genetic and nutritional dystrophy. Addition of Na+ and Li+ acetate does not result in significant changes in light scattering by mitochondria from either normal or dystrophic animals. In dystrophic mitochondria, the uptake of K+ is probably energy-linked, as subsequent addition of 2 µM carbonylcyanide *p*-trifluoromethoxyphenylhydrazone, an uncoupler of oxidative phosphorylation, returns the absorbance to its initial value.

Thus there is greater than normal conductance of K+ across erythrocyte, liver mitochondrial and brain mitochondrial membranes in the dystrophic state. Since none of these tissues seem to degenerate as muscle does, the genetic defect in muscular dystrophy may give rise to membranes, throughout the organism, which are leaky to K+, and muscle deterioration may be a consequence of that leak. This may occur through defective excitation-coupling where rapid K+ movement might serve to collapse charge dislocation required for a cycle of membrane depolarisation–repolarisation. In this connection, it is interesting that the T tubular system, a major locus for K+ transport to the muscle interior, has been shown to be structurally altered in muscular dystrophy[15].

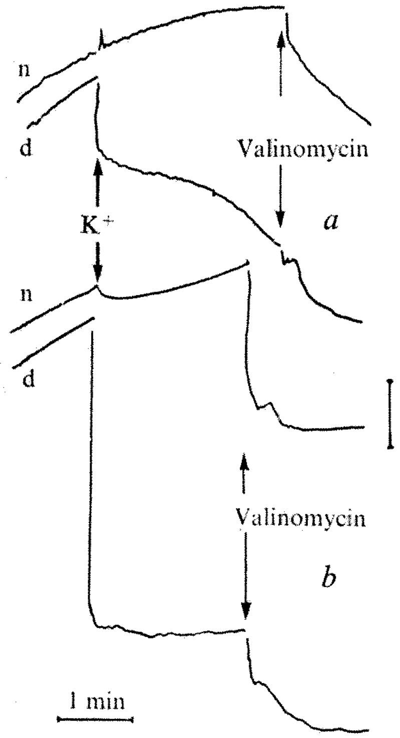

Fig. 1 Light scattering changes caused by addition of potassium acetate to mitochondria. *a*, Liver mitochondria; *b*, brain mitochondria. n denotes mitochondria isolated from normal mice (Bar Harbor strain C57BL/6J); d denotes mitochondria isolated from genetically dystrophic mice (Bar Harbor strain C57BL/6J-dy^{2}J). K$^+$ denotes addition of 4.0 µeq potassium acetate; valinomycin denotes that of 0.5 µg of the potassium ionophore, valinomycin. Light scattering was measured as the change in absorbance at 540 nm at 20° C, a downward deflection corresponding to swelling (uptake). Liver mitochondria were isolated in 250 mM sucrose while brain mitochondria were isolated in a medium containing 300 mM mannitol and 0.1 mM ethylenediamine tetra-acetate and adjusted to *p*H 7.4. The light scattering measurements were carried out in 3.0 ml of the appropriate isolation medium supplemented with 5.0 mM bicine, *p*H 7.4. The vertical bar in the figure indicates an absorbancy difference of 0.003 units.

Finally, the K$^+$ leak as an explanation for the origin of muscular dystrophy is consistent with the observation that hypokalaemic periodic paralysis, which clearly reflects anomalous K$^+$ distribution across membranes, frequently occurs in families with a history of muscular dystrophy[14]. It should also be viewed in light of the report that serum creatine phosphokinase activity, a measure of muscle deterioration, decreases in dystrophic patients after administration of lithium gluconate[16], which is a non-competitive inhibitor of K$^+$ translocation in various biological systems[17].

This research was supported by grants from the Muscular Dystrophy Associations of America Inc. and the National Institutes of Health. I thank Dr Surendra Katyare for preparation of brain mitochondria and Mrs Barbara Hess and Mrs Jane Havey for technical assistance.

Possible role of zonula occludens of the myelin sheath in demyelinating conditions

AUTOIMMUNE mechanisms may play a major role in several human demyelinating diseases[1]. Myelin contains components, principally a basic class of protein, which, when injected systemically with an adjuvant, elicit in the experimental animal a demyelinating encephalomyelitis or neuritis with perivascular infiltration of lymphocytes and inflammatory cells[1,2]. A satisfactory hypothesis is that the potential self-antigens are secluded from the immune systems in the normal living animal[3]. Evidence for such a specific compartmentation of myelin components, however, has been lacking up to now. This has led several authors to suggest alternative explanations[1,4,5]. Here we demonstrate the structural basis for a seclusion mechanism within both peripheral and central myelin sheaths in different animal species.

A continuous tight junction, or zonula occludens, is present at the borders of each myelin segment. This junction separates an intramyelinic extracellular space from the intercellular compartment of the nervous tissue. In addition, the junctional strand separates the internal portion of the glial membrane exposed to the tissue space from the internal portion of the glial membrane exposed to the intramyelinic extracellular space and constituting the compact myelin.

Blocks of peripheral nerve and of various regions of the CNS, including cerebellum, medulla oblongata, optic nerve and forebrain, were obtained from turtles, chickens and rats perfused with fixatives containing aldehydes, or with ferrocyanide-reduced osmium tetroxide[6], and processed for thin sectioning and freeze-fracturing according to routine methods[7,8]. In a more extensive article[9], we have shown that thin sectioning of blocks fixed with ferrocyanide–osmium and freeze-fracturing confirm the existence, already partly established in the literature[10], of an extracellular space within the myelin sheath, not only in the peripheral but also in the central nervous system. This extracellular space is situated between the paired minor dense lines (that is, the external leaflets of the myelin membrane) as predicted from X-ray diffraction studies[11].

In sections, the tight junctions of the myelin sheath appear as spots of membrane fusion (Fig. 1 *a*, *b*). In peripheral sheaths they occur at the internal and external

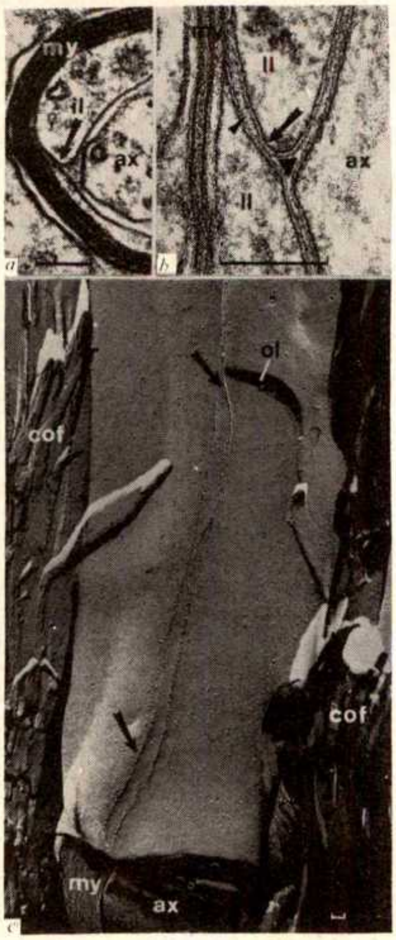

Fig. 1 *a*, Electronmicrograph of a central myelinated fibre showing the tight junction (arrow) of the internal mesaxon, that is, the site where the inner loop (il) joins the compact myelin (my). The axon is labelled ax. *b*, a central myelinated fibre showing the tight junction (arrow) between two paranodal loops (ll) near the Ranvier node. The paranodal loops represent the winding lateral loop passing repeatedly through the plane of section (compare Fig. 2 *d* and *e*). The arrowhead indicates the intramyelinic extracellular space, and the triangle the periaxonal space. *c*, Electronmicrograph of a replica of a freeze-fractured peripheral myelinated fibre. The arrows indicate tight junctional strands cleaved with the A face of the Schwann cell membrane at the external mesaxon (that is, the site where the outer loop terminates the myelin sheath). The cross-fractured outer loop is labelled ol; cof indicates collagen fibres. The scales in the photographs represent 0.1 μm.

'mesaxons' and between adjoining 'paranodal loops' (terminology explained in the figure legends). In central sheaths the tight junctions occur at the mesaxon (internal), between adjoining paranodal loops[32], and at the site where the outer loop (or outer tongue) joins the compact myelin. The latter site is considered, therefore, as the equivalent of the external mesaxon of peripheral sheaths.

Freeze-fracturing confirms these findings. This technique splits cell membranes, thus producing two artificial fracture surfaces, referred to as A (cytoplasmic) and B (external) 'faces', which complement each other in the hydrophobic interior of the membrane[12]. As for the tight junctions in other tissues[15], strands (Fig. 1 *c*) and furrows are seen on the A and B faces, respectively, at all sites where spots of membrane fusion were observed in thin sections. In addition, the replicas of freeze-fractured myelin sheaths give a more complete tridimensional picture of this tight junctional system, demonstrating that there is a continuous zonula occludens extending from the outer to the lateral and inner loops. This is shown schematically in Fig. 2 *d*, *e*, where the myelin sheaths have been represented as 'unwrapped'. The outer, lateral and inner loops represent portions of the continuous marginal belt of the glial sheet which contains a rim of cytoplasm.

Tight junctions are also present between the loops of the circumferential Schmidt-Lanterman incisures and between the longitudinal protoplasmic islands. These are channels of cytoplasmic retention which occur in some sheaths and which interrupt the compact myelin. The strand(s) of these junctions are continuous with the junctional strands of the mesaxons[9]. There is, therefore, no interruption of the zonula occludens at these sites.

It has been demonstrated in several organs that the zonula occludens, although partly permeable to water and small solutes, constitutes an efficient barrier to the extracellular diffusion of large molecules[15]. While the joining of three neighbouring cells in epithelia might represent the site of small leaks, the zonula occludens of the axonal sheath is formed by a single cell, and the barrier might turn out to be particularly effective. Lanthanum has been observed occasionally to penetrate into the myelin sheath[13,14], but this might be an artefact. Tracers of large molecular weight do not enter the intramyelinic extracellular space[16–18]. The existence of a zonula occludens was not considered in the experiments with tracers. We suggest here that it is the zonula occludens at the inner, outer and lateral borders of the sheets forming the myelin tube that makes the myelinic extracellular space a secluded compartment, thus sequestering some myelin components. According to various authors, the basic encephalitogenic protein is located, at least in

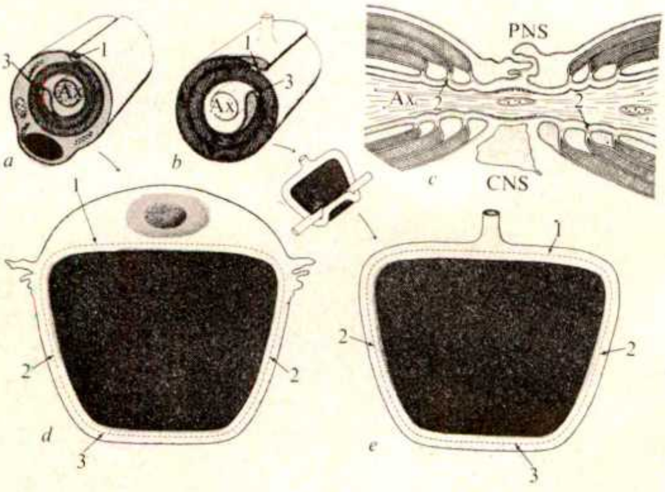

Fig. 2 Diagrammatic representation of peripheral and central myelin sheaths. The illustrations *a*, *b* and *c* are quasi-realistic. In *d* and *e* the axon (Ax) has not been represented, and the complete sheath of one internode has been figuratively unrolled as shown in the unlabelled inset. Portions of peripheral (*a*) and central (*b*) myelin sheaths in tridimensional view. The intramyelinic extracellular space (cross-hatching), comprised between the paired minor dense lines, is emphatically exaggerated. The arrows point to the tight junctions separating this space from the extracellular space within the tissue (arrow 1) and the periaxonal space (arrow 3) (also exaggerated). *c*, Schematic view of the Ranvier node and the paranodal region of peripheral (PNS) and central (CNS) myelinated fibres in longitudinal section. The arrows (labelled 2) point to tight junctions of the spirally winding lateral loop. The periaxonal space is communicating with the extracellular space through the channels of the paranodal axoglial junction. This junction, corresponding to the scalloped portion of the axolemma, has not been represented here and is described in refs 9, 31–33. Peripheral (*d*) and central (*e*) myelin sheaths represented as unwrapped. Arrows 1, 2 and 3 indicate the outer, lateral and inner cytoplasmic loops, respectively. The dashed line shows the extent of the zonula occludens encircling the area of compact myelin (shaded area). For the sake of simplicity, this dashed line corresponds to only one-half of the complete junctional specialisation and is drawn on the middle rather than on the side of the lateral loops and on the axonal aspect of the inner loop rather than on the opposite aspect.

part, at the minor dense line[19,20], that is, it borders on the intramyelinic extracellular space Following damage to the myelinic tight junctions, components of this normally secluded compartment may leak out, thus provoking phagocytic and ultimately autoimmune reactions

The presumptive role of the zonula occludens suggested above is probably a corollary of other functions which might be first, the maintenance of the homeostasis of the extracellular material providing interlamellar adhesion in the compact myelin, and, second, the separation of two different intramembranous regions of the same cell, that is, the glial outer membrane and the membrane of compact myelin

There are experimental conditions in which degeneration of the myelin sheath and its removal by phagocytes is produced without concomitant damage to the axon[21–25] but without proven involvement of the immune systems We wonder whether or not the effect of the experimental damage involves the strand(s) of the zonula occludens also in these cases

There are other organs and tissues which contain potential self-antigens We are particularly struck by certain analogies between the spermatic system and the myelin Sperm contain antigens which can elicit formation of serum sperm agglutinins and immobilisins as well as cellular infiltrates in the testis[26,27] It has been shown[28] that in the spermatic pathways there is a luminal barrier to extracellular diffusion constituted by epithelial zonulae occludentes In addition, at the seminiferous tubules, where sperm are formed, there is a blood–testis barrier[29] Thus, the sperm are secluded from the immune systems[30] The compartmentation produced by the myelinic zonula occludens and by the blood–brain barrier[16] might have, to some extent, functional implications analogous to the compartmentation in the spermatic system

Light-evoked release of glycine from the retina

GLYCINE is one of the amino acids now regarded as putative neurotransmitters It is present in high concentration in the retina[1,2] and an active high affinity uptake system into a type of amacrine cells has been demonstrated[3,4] Moreover, glycine has inhibitory effects in the retina[5,6]

It has been demonstrated in other parts of the central nervous system that amino acids can be released by electrical stimulation or ionic shock[7–14] It has also been shown, however, that such crude methods of stimulation will release glycine (and some other amino acids) from tissues where it is unlikely to be a neurotransmitter[15] We have therefore studied the release of glycine from the retina, which can easily and effectively be stimulated by light flashes, either *in vivo* or *in vitro*

The anterior segment and the vitreous were carefully removed from the eyes of Nembutal anaesthetised cats, exposing the retinae for the *in vivo* studies Rabbit retinae were carefully excised with the choroid and maintained in a small organ bath at 37° C for the *in vitro* experiments The retinae were exposed to tritiated glycine by superfusing them at a rate of 1 ml min^{-1} for 10 min with a salt solution containing 40 μCi glycine-2-^{3}H or by injecting 10 μCi intravitreally (rabbits) 2 h before excising the retina Initially 0 9% NaCl was used in the cats, but later, Krebs–Ringer–bicarbonate was used with equal results In the rabbit, the solution described by Ames[16] was used The retinae were washed (1 ml min^{-1}) in darkness with the salt solution for 20–40 min and then exposed to one or two 10 min periods of light flashes (2 H$_2$) 10 min apart From the washing and onwards, the salt solution contained 0 1 mg ml^{-1} glycine The radioactivity of the superfusate was monitored by liquid scintillation spectrometry either directly or in the glycine spot in thin layer silica gel chromatography (solvent *n*-propanol water, 70 30 v/v)

The site of uptake of radioactivity into retinae was checked by autoradiography in two experiments and was found to be almost exclusively in a type of amacrine cells, in good agreement with previous results[3,4,17] More than 95% of the radioactivity in the retinae or in the superfusate moved like glycine in the chromatograms.

Thirty-three experiments were performed on rabbit retinae. The radioactivity of the superfusates was usually decreasing throughout the experiments, on the average by a factor 0·79 (s.e.m. = ±0·029) during the 5 min preceding the light stimulation. During this, however, the radioactivity increased by a factor 1·30 (s.e.m. = ±0·103), measured from the start of the stimulation to the peak of the release (which appeared after 3–7 min). The difference between the two factors is highly significant ($P < 0.001$ in the Student's two-tailed *t*-test). One experiment is shown in Fig. 1. In this particular one and also in another, small aliquots of the superfusate fractions were chromatographed, and the radioactivity of the glycine spots were measured. A peak was seen, exactly matching that of the crude superfusate fractions (see Fig. 1). Autoradiograms of the thin layer chromatograms did not reveal any other radioactive spot.

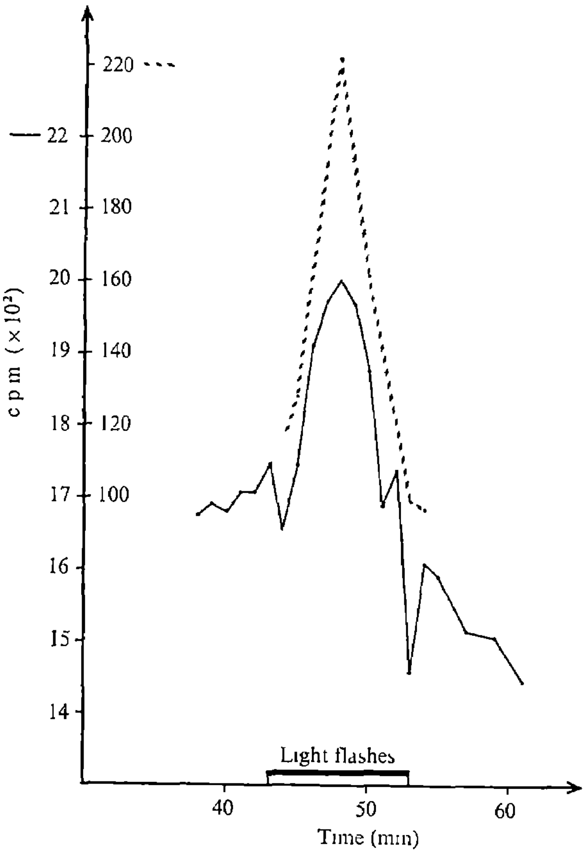

Fig. 1 Efflux of radioactivity in a single experiment from light stimulated rabbit retina *in vitro* after incubation with ^{3}H-glycine ——, radioactivity of the crude effluent (scale on the left hand side of the ordinate), - - -, radioactivity in the glycine spot from silica gel thin layer chromatograms of the effluent (scale on the right-hand side of the ordinate). The difference in absolute radioactivity in the two curves is caused chiefly by differences in sample size. The light flashes were given at 2 Hz with a xenon flash tube driven by 0·6 J per flash and located 30 cm from the retina.

The ^{3}H-glycine was given by intraocular injection in 14 of the 33 rabbit experiments, and by incubation in the remaining 19. There was no statistically significant difference between the results of these two subgroups. The increase in the outflow of radioactivity was highly significant ($P < 0.005$) in each of them.

A second stimulation was given in 13 of the rabbit experiments, and resulted in a smaller and less distinct increase of the radioactivity of the superfusate than the first stimulation. During the five minutes immediately before the second stimulation the radioactivity on average decreased by a factor 0·92 (s.e.m. = ±0·042), and during the stimulation it rose on average by a factor 1·15 (s.e.m. = ±0·100) above the starting value. The difference is possibly significant ($P < 0.05$).

In the experiments on anaesthetised cats, the results were very variable, usually for obvious technical reasons such as incomplete removal of the vitreous, bleedings clogging the superfusion cannulas, movements of the animal and so on. In about twenty attempts, five superfusates showed a smooth baseline curve with a clear peak appearing during the light stimulation. On the average, the peak of these five curves reached 2·94 times (s.e.m. = ±0·485) above the level at the beginning of the stimulation, this contrasts with the preceding 5 min, when the radioactivity fell, on average, by a factor of 0·79 (s.e.m. = ±0·093).

Thus, light stimulation can release radioactivity from retinae preloaded with ^{3}H-glycine. The chromatograms of the superfusate or of the whole retina suggest it is glycine that is released. Serine is a precursor and also a metabolite of glycine, however, and does not separate well from it in chromatograms. Therefore, the experiments do not show to what extent the released radioactivity might represent serine. This is not highly neuroactive, however, and is not generally regarded as a putative neurotransmitter. On the other hand, glycine has been shown to fulfil several criteria of a neurotransmitter in the retina: it is present in high concentration[1,2]—although the precise cellular location remains to be established, there is an efficient neuronal uptake mechanism that conceivably inactivates released glycine[3,4], and applied glycine has clear inhibitory effects[5,6].

Our demonstration of light-induced release of radioactivity from retinae preloaded with radioactive glycine further supports that it is a retinal neurotransmitter. It is of particular importance that the release can be achieved both *in vivo* and *in vitro* and with a physiological stimulus, as this suggests that it is the result of normal nerve activity.

Does the central human retina stretch during accommodation?

Clear evidence that the human retina stretches during accommodation was presented by Moses[1], but his measurements were all made at the anterior margin of the retina, so they did not show how this stretch is spatially distributed. If it is largely confined to the region of the *ora serrata*, its contribution to the perceptual correlates of accommodation will be much less than if the central retina is distorted as well. A perceptual effect involving accommodation-dependent distortions in the visual field has recently been attributed by its discoverers[2] to such a stretching of the central retina, although non-retinal explanations for this effect are also tenable.

It seemed worthwhile to do an experiment in which the possibility that the central human retina stretches during accommodation could be evaluated, and in which the magnitude of any stretch which was found could be assessed.

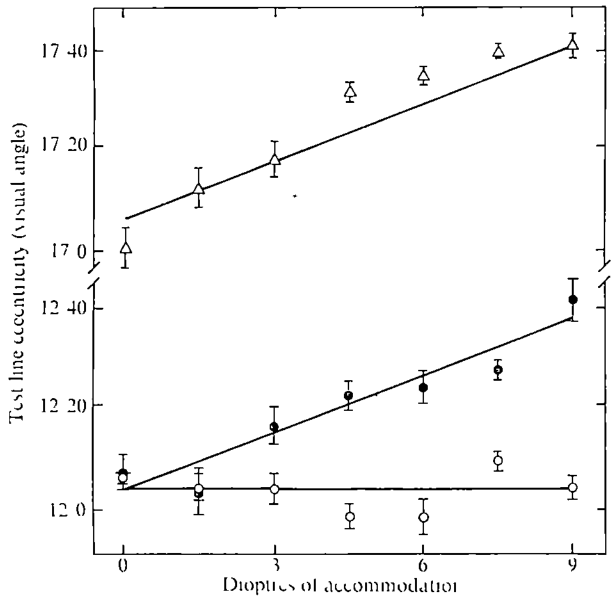

Fig. 1 Test line settings made by the first observer are shown as a function of dioptres of accommodation. Closed filled circles refer to the near edge of the blind spot, the line drawn through them by eye indicating a 4.7% increase in visual angle over the range of accommodation. A line parallel to this has been drawn through the triangles which refer to the far edge of the blind spot. The open circles are control data obtained during cycloplegia: a horizontal line has been drawn through them to indicate that there is no stretching of the retina in these conditions. Error bars show 1 s.e.m. above and below each point, which is the mean of ten determinations. A long test line (2° from top to bottom) and a high retinal illuminance for the background (5.6 log trolands) were used to make the line as conspicuous as possible once it had emerged from the blind spot.

The observer's left eye was patched throughout, and the right provided with a Maxwellian view of a fixation cross and a vertical test line, both seen in silhouette against a background of monochromatic yellow (575 nm) light. The test line was located to the right of the fixation cross, its exact horizontal position was under the observer's control. Because the eye was positioned one focal length behind the Maxwellian lens, the apparatus served as a Badal optometer: that is, movements of the target plane (containing both the fixation cross and the test line) along the optic axis stimulated different degrees of accommodation but did not affect the size of the retinal image.

The observer's task was to fixate the centre of the cross and to keep it in sharp focus, while at the same time moving the test line until it was just visible on the near side of the blind spot (the side closer to the fixation cross). Measurements were made at seven different levels of accommodation (Fig. 1) to plot the distance in visual angle between the fixation cross and the test line. Since the test line marks the near edge of the blind spot, the data imply that the fovea and the optic disk are more widely separated when accommodation is strained than when it is relaxed.

An alternative interpretation of the data would be that threshold criteria changed systematically as a result of accommodative effort, or that the target was focused on the retina more sharply at one level of accommodation than at another. These possibilities were tested, as a class, by measurements analogous to the first set but now localising the far side of the blind spot: if blurring or criterion shifts were involved, the line should have been set closer to the fixation cross as accommodation increased. Just the opposite was found (Fig. 1), thus eliminating these possibilities. The results of these two experiments were confirmed on a second observer.

There remained the chance that some misalignment of the apparatus, rather than a stretching of the retina, produced the effect. To rule out this possibility a control was run with accommodation paralysed with 1% Cyclogyl, but with the target plane moved along the optic axis as before. A smaller aperture stop was now used to reduce the diameter of the pencil of light passing through the pupil centre to less than 0.5 mm, thereby ensuring that the stimuli would always be seen in sharp focus despite the lack of accommodation. The effect found earlier was now clearly absent (Fig. 1).

A final experiment was undertaken to determine how great a contribution to the effect is made by changes in the magnifying or other properties of the crystalline lens. It is known[3] that convergence can bring about accommodation, and it seems likely that in a presbyope, devoid of accommodative ability, convergence would still be accompanied by a central command for accommodation. The lens would not respond to such a command, but if the ciliary muscle contracted, then the retina might be stretched just as in a younger subject.

This possibility was investigated using a 66-yr-old presbyopic observer. A different apparatus (with slightly different stimulus dimensions) was employed so that the observer could be presented with the fixation cross binocularly, while the test line was as usual seen by the right eye only. Natural viewing at a distance of 3 m was used, and the observer moved the test line with a pulley so that it fell on the near margin of the blind spot. While the right eye remained in the primary position throughout, mirrors were introduced in front of the left eye to make it converge a total of 25°. Measurements made both with and without the mirrors showed that the visual angle between the fixation cross and the blind spot increased some 4.6% when convergence was brought into play, this is comparable to the figures obtained during actual accommodation in the initial experiments: 4.7% for one subject (age 28) and 4.4% for the other (age 23). This similarity of results for the presbyopic and non-presbyopic observers suggests that changes in the lens do not play a primary role in producing the perceptual effect under study.

The results of the present study, taken together, argue persuasively that the central region of the human retina stretches substantially—some 4½%—during marked (9 dioptre) accommodation. This is much larger than the figure of 2% stretch, which is obtained by dividing Moses' measured 0.5 mm advance of the *ora serrata* by the distance from the *ora* to the optic disk[4], the reason for this difference remains unknown. The stretching reported here has implications for our understanding of accommodative micropsia[5] and other perceptual phenomena: in particular the stretch (if it is non-uniform) may underlie the spatial distortions discovered by Blank and Enoch[2], as in fact they propose, but this remains to be established. The stretching of the central human retina may also be of interest to those who study the eye from a clinical point of view.

I am indebted to Professor Harriet Rheingold and Ms Donna Bryant for generously donating their time as observers. This work was supported by the National Eye Institute and the University of North Carolina Research Council

Acetylcholine as an excitatory neuromuscular transmitter in the stomatogastric system of the lobster

THERE is much physiological evidence that L-glutamate acts as an excitatory transmitter at many arthropod neuromuscular synapses[1-3] The only suggestion that acetylcholine (ACh) has such a function is due to Futamachi[4] He showed that the nerve terminal region innervated by the largest crayfish slow flexor excitatory motor neurone is depolarised by iontophoretic applications of ACh, but not L-glutamate I now have biochemical and physiological evidence that ACh is the neurotransmitter at some, but not all, of the excitatory neuromuscular synapses of the lobster stomatogastric system

The stomatogastric ganglion of the spiny lobster, *Panulirus interruptus*, contains about 30 neurones, 23 of which are motor neurones and make excitatory neuromuscular synapses with 38 pairs of striated muscles which move the lobster's stomach[5] These muscles are typical of crustacea, with fibres approximately 100 μm in diameter and up to several centimetres long According to present knowledge, their sole motor innervation is from the stomatogastric ganglion[5] The motor neurone somata are 40–100 μm in diameter, show both attenuated action potentials and considerable sub-threshold synaptic activity[6], and are identified physiologically by the motor nerve in which their axons are found[7]

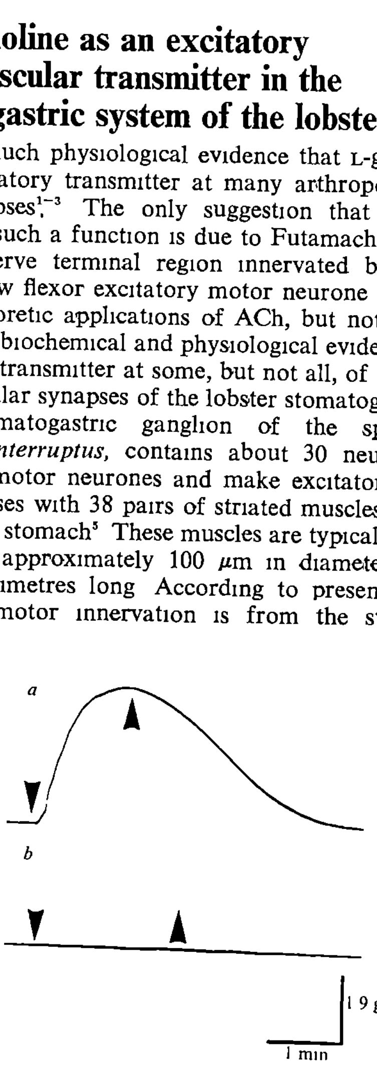

Fig. 1 Effects of bath application of ACh and L-glutamate on a dorsal dilator muscle The muscle was connected to a Grass FT03 force displacement (tension) transducer, and the output was displayed on an oscilloscope and photographed with a kymograph camera The muscle was placed in a 1 5 ml chamber through which saline flowed continuously at 6–8 ml min^{-1} *a*, 2 × 10^{-5}M ACh with 0 01 mg ml^{-1} Tensilon was introduced into the chamber at the downward arrow The muscle contracted, and the upward arrow indicates the start of the wash in normal saline *b*, 1 × 10^{-3}M L-glutamate was introduced to the chamber at the downward arrow, causing no response, and the wash was started at the upward arrow The muscle continued to contract in the presence of ACh for 6 h after the test with L-glutamate

Choline acetyltransferase catalyses the enzymatic biosynthesis of ACh and correlates well with the presence of ACh in *Aplysia* neurones[8] I have assayed this enzyme in individual somata of physiologically identified stomatogastric neurones First, neurone somata were penetrated with microelectrodes for identification of the cells, a drawing was made of their relative positions, and then the cells were dissected individually into small glass tubes by the method of Giller and Schwartz[9], after being frozen in a mixture of 70% ethylene glycol and 30% *Panulirus* saline The tubes containing the cells were kept frozen on dry ice until the assay was performed, usually within 2 d of dissection

Each ganglion contains 2 PD (pyloric dilator) motor neurones and one LP (lateral pyloric) motor neurone[6] Table 1 shows a summary of choline acetyltransferase assays on single PD and LP somata The PD somata contained choline acetyltransferase activity in 16 out of 18 cells assayed The actual values obtained showed a large variation which may reflect damage caused during the identification or dissection, or actual variation in the amount of the enzyme present in different cells The mean of these measurements is 12 6±8 1 pmol ACh per cell per h which may be somewhat low because I made no attempt to discard values from cells which may have been damaged I estimate that the amount of enzyme is about 125 pmol ACh produced per nl cell volume per hour This value is comparable with those found in cholinergic neurones in Aplysia[9]

Table 1 Acetylcholine transferase in single PD and LP somata

	pmol ACh, per cell per h*	No of somata with activity No of somata assayed
PD cells	12 6 ± 8 1	16/18
LP cells	<2 7 ± 0 8	1/10
Limit of sensitivity	2 4 ± 0 7	

* Means plus standard deviations of values from 10 experiments

PD cells showed activity in all but two cells assayed, with a range between 4 0 and 29 9 pmol ACh per cell per hour The LP cells were below the limit of sensitivity in all cases but one, where a low level of activity was found Assays were performed as by Coggeshall *et al*[10] 10 µl of buffer-substrate (final concentrations, 0 1M NaPO$_4$, *p*H 7 9, 0 25M NaCl, 10 mM choline chloride, 1 mM EDTA, 0 1 mM eserine, 16 mM MgCl$_2$ and 0 4 mM^{14}C acetyl CoA, specific activity 5–10 µCi µmol^{-1} (New England Nuclear Corp)) was added to the tubes containing cell somata and to empty tubes (blanks) Tubes were incubated at 38° C for 30 min The reaction was stopped with 100 µl of 50 mg ml^{-1} sodium tetraphenylboron in 3-heptanone Tubes were mixed, 100 µl of 0 2 M NaPO$_4$, *p*H 7 0, was added, mixed and spun in a table-top centrifuge for 2 5 min 50 µl of the organic phase was counted in 10 ml of scintillation fluid Ten to twenty blanks were run with each assay, and the limit of sensitivity was estimated on the basis of the variation in the blanks and the specific radioactivity of the reaction mixture

In all experiments but one, the LP cell showed no acetylcholine transferase activity As the LP cell is frequently the largest cell in the ganglion, and is always one of the largest, this difference in enzyme activity is not a trivial consequence of differences in the size of the PD cells and LP cell within a ganglion

The PD neurones innervate the dorsal dilator muscle (muscle cpv 1a,b according to Maynard and Dando's terminology[5]) Figure 1 shows the effects of bath application of ACh and L-glutamate on the dorsal dilator muscle Figure 1*a* shows the tension produced by 2×10^{-5}M ACh with 0 01 mg ml^{-1} Tensilon (an acetylcholinesterase inhibitor) Dose-response curves show that the threshold for

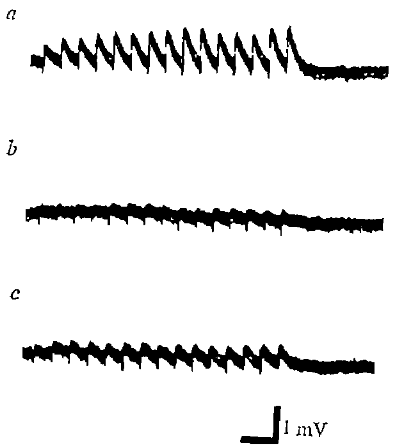

Fig 2 The ejps recorded in a dorsal dilator muscle fibre are reversibly blocked by D-tubocurare The ejps were recorded with a 30 MΩ 2 5M KCl-filled electrode and conventional electrophysiological equipment The ejps were elicited by stimulating the PD motor nerve with a suction electrode in trains of 15 pulses at 10 per s for 1 5 s *a*, ejps recorded in normal saline, *b*, the same penetration 7 min after the addition of 5 × 10^{-5}M D-tubocurare The ejps were almost completely blocked, *c*, the same penetration after 10 min wash with normal saline The ejps returned, although not to the size in (*a*) The resting potential was −64 mV

contraction was 1×10^{6}M ACh and that maximal tension was produced by 2×10^{-5}M ACh D-Tubocurare (1×10^{-4}M) shifted the ACh dose-response curve to the right, characteristic of a competitive inhibitor of the ACh response 5×10^{-7}M α-bungarotoxin (gift from Dr Hannah Friedman) completely blocked the response to 2×10^{-5}M ACh Figure 1*b* shows that 10^{-3}M L-glutamate produced no tension in this muscle, nor did high concentrations (10^{-4}M) of dopamine, serotonin, octopamine, L-aspartate, GABA, glycine, noradrenaline or taurine In a similar experiment the muscle innervated by the LP neurone (p2a)[5] did not contract when 1×10^{-3}M ACh with Tensilon was added, although when the nerve innervating the muscle was stimulated, the muscle did contract[11] These results show that ACh causes contraction in the dorsal dilator muscle while the LP muscle does not respond to ACh

Figure 2 shows that excitatory junctional potentials (ejps) in the dorsal dilator muscle fibres were blocked reversibly by D-tubocurare, a known cholinergic antagonist After 7 min in 5×10^{-5}M D-tubocurare, the normal ejps (Fig 2*a*) were considerably attenuated (Fig 2*b*), after 10 min of washing in normal saline they had recovered, although not completely

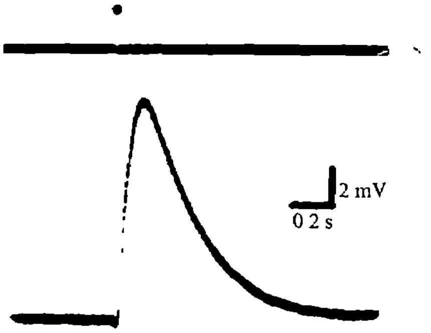

Fig. 3 Iontophoretic application of ACh to the surface of a dorsal dilator muscle fibre The iontophoretic electrode was filled with 3 M ACh and had a resistance of about 90 MΩ A bucking voltage was applied to minimise leakage of the ACh A 30 MΩ electrode filled with 2 5 M KCl recorded membrane potential of the fibre The top trace shows a current monitor The iontophoretic pulse was 100 nA for 20 ms The bottom trace shows the intracellular recording electrode Resting potential was −65 mV Horizontal calibration bar is 200 ms Vertical calibration bar is 100 nA for the top trace and 2 mV for the bottom trace

Figure 3 illustrates the response of a dorsal dilator muscle fibre to iontophoresis of ACh on to its surface Iontophoretic responses of this kind can be recorded from many areas of these fibres The time course and amplitude of the potentials recorded are very sensitive to the position of the ACh electrode, and the ACh response desensitises with repeated applications to the same spot

The data presented here suggest very strongly that ACh is the neurotransmitter at the PD neurone-dorsal dilator muscle synapse, but not at the LP neurone–LP muscle synapse Definitive proof of this requires further experiments, but it is clear now that the PD and LP cells utilise different neurotransmitters Furthermore, it is difficult to argue that L-glutamate is the neurotransmitter at the PD-dorsal dilator synapse, which clearly points to the dangers in making sweeping generalisations about 'the arthropod excitatory neuromuscular transmitter' It is interesting that there is no known peripheral inhibition in the stomatogastric system[12], while many arthropod muscles receiving L-glutamate excitation also receive inhibitory innervation It is also important that the PD and LP neurones make inhibitory synaptic connections within the stomatogastric ganglion[6] There appears to be heterogeneity in excitatory neuromuscular transmitters among the neurones within this one crustacean ganglion, and some of these neurones appear to make cholinergic neuromuscular junctions

I thank Allen Selverston for support and advice, Dave Schubert for allowing me to do acetylcholine transferase assays in his laboratory, and R E McCaman for helpful suggestions I am a predoctoral fellow of the Office of Schizophrenia Research of the Scottish Rite This work was funded by grants from the United States National Science Foundation and the National Institutes of Health to Dr Selverston

Methylation of ribosomal proteins *in vitro*

STARVATION of an *Escherichia coli rel*$^-$ (RC$^{\mathrm{rel}}$) strain for an essential amino acid results in the synthesis of ribosomal RNA (rRNA) without the concomitant synthesis of proteins[1,2] Ribosomal precursor particles accumulate in these conditions and such precursor particles have been shown to be deficient in the methylation of rRNA (ref 3) We have observed that in addition to proteins L7 and L12, which were previously reported to be methylated[4], several other ribosomal proteins from the 50S subunit were also methylated in the unstarved culture[5,6]. Similar observations have also been made by Alix and Hayes[7], but are the precursor particles generated by *rel*$^-$ strain after starvation for methionine also deficient in the methylation of the ribosomal proteins and if so, can such particles be methylated *in vitro*?

Here we have determined the proteins that were methylated *in vitro*. More than 80% of the incorporated methyl groups was found to be located in one protein (L11). The methylated amino acids present in this protein were also characterised. This information could enable the isolation and purification of protein methylases and the study of the function of protein methylations.

E. coli strain 1500, an *rel*$^-$ mutant of a K-12 strain isolated by Durwald and Hoffmann-Berling[8], was obtained from the Coli Genetic Stock Center in New Haven, Connecticut. The *met B* marker was introduced by P1 transduction from JC-355 (which is a K-12 *met*$^-$ strain originating with A. J. Clark. Cells were grown with a limiting methionine concentration (0.8 μg ml^{-1}) and collected 1.5 h after exhaustion of methionine. During this period of starvation, RNA continues to be synthesised at a linear rate. About 1.2 g of cells were suspended in a buffer containing 0.05 M Tris-HCl, *p*H 7.8, 0.1 mM $MgCl_2$, 0.05 M KCl, and were disrupted with a French press. After centrifugation at 30,000 *g* for 30 min, the supernatant fluid was layered on top of a 5–20% linear sucrose gradient prepared in the same buffer and centrifuged overnight at 18,000 r.p.m. in an SW 25.2 rotor. Fractions containing the 50S peaks were collected and concentrated by ethanol precipitation[9]. Analysis of RNA by the gel electrophoresis procedure of Dahlberg *et al.*[10] revealed that 20% of the total RNA in the pooled 50S particles was in the precursor form. The analysis also showed the presence of less than 4% 16S rRNA which was due to the contamination by 30S subunits. The methylating enzymes were obtained from the 0.5 M KCl wash of 70S ribosomes according to the procedure of Vogel *et al.*[11] from cells grown in the presence of 20 μg ml^{-1} methionine.

Figure 1 shows that the methylation of the 50S ribosomal proteins, as analysed by the one-dimensional polyacrylamide gel electrophoresis, was dependent upon the addition of the methylating enzymes. In the absence of the added enzyme (Fig. 1*a*), very little methylation occurred and the major methylated protein(s) comigrated with a major protein peak at 3.5 cm from the top of the gel. After the addition of the enzymes, methylation of two protein bands at about 2.0 cm from the top was observed (Fig. 1*b*). The latter methylation was dependent upon previous starvation of the culture with methionine as the 50S particle derived from the culture which was not starved with methionine was only methylated to a very small extent in the same conditions.

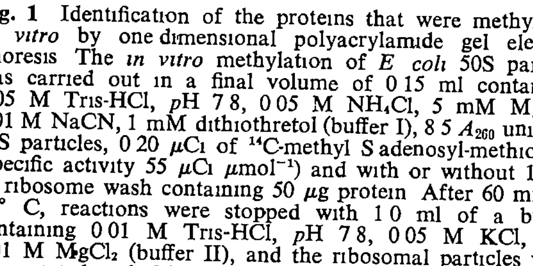

Fig. 1 Identification of the proteins that were methylated *in vitro* by one dimensional polyacrylamide gel electrophoresis. The *in vitro* methylation of *E. coli* 50S particle was carried out in a final volume of 0.15 ml containing 0.05 M Tris-HCl, *p*H 7.8, 0.05 M NH_4Cl, 5 mM $MgCl_2$, 0.01 M NaCN, 1 mM dithiothretol (buffer I), 8.5 A_{260} units of 50S particles, 0.20 μCi of ^{14}C-methyl S-adenosyl-methionine (specific activity 55 μCi μmol^{-1}) and with or without 15 μl of ribosome wash containing 50 μg protein. After 60 min at 37° C, reactions were stopped with 1.0 ml of a buffer containing 0.01 M Tris-HCl, *p*H 7.8, 0.05 M KCl, and 0.01 M $MgCl_2$ (buffer II), and the ribosomal particles were precipitated with 0.75 ml of cold ethanol[9], and dissolved in 40 μl of 4 M urea and 2 M LiCl. After 16 h at 0° C, the ribosomal RNA was removed by centrifugation. The supernatant ribosomal proteins (about 100 μg proteins) were then electrophoresed[13]. After staining of the proteins by amido black, the gels were traced at 650 nm (———) using a linear transporter. The gels were then sliced and autoradiographed[14] and the film was traced at 410 nm (- - -). *a*, The ribosome wash is absent and, *b*, the ribosome wash is present.

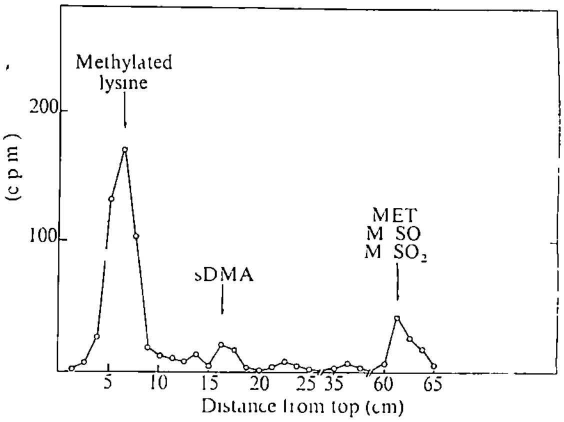

Fig. 2 Analysis of the methylated amino acids derived from protein L11 after *in vitro* methylation of the precursor 50S particle. The reaction conditions were the same as in Fig. 1 except 40 A_{260} units of the 50S particle and 1 μCi of ^{14}C-methyl S-adenosylmethionine in 0.7 ml of buffer I were reacted for 60 min at 37° C. The reaction was stopped with 2.0 ml of buffer II and the ribosomal proteins prepared according to the acetic acid procedure of Hardy *et al.*[15] The ribosomal proteins were lyophilised to dryness and dissolved in 0.15 ml of the sample gel solution used for the first dimension run (*p*H 8.6) of the 2-dimensional electrophoresis procedure of Kaltschmidt and Wittmann[12]. After electrophoresis, protein L11 was cut out from the gel and extracted for 16 h at 30° C with 0.01 M sodium phosphate buffer containing 0.1% sodium dodecyl sulphate (SDS). This was followed by dialysis against three changes of water to remove the excess dye and SDS. The dialysate was filtered to remove the gel and then lyophilised to dryness. The protein was then hydrolysed with 2 ml of redistilled 6 N HCl in a sealed tube at 110° C for 24 h. The hydrolysate was evaporated to dryness under reduced pressure and redissolved in 2 ml of water, followed by evaporation again to dryness. The final pellet was dissolved in 40 μl of water. 20 μl of the above sample were applied to a Whatman No. 3MM (20 × 110 cm) paper together with 10 μg of each of the following standard methylated amino acids: ε-monomethyllysine (MML), ε-dimethyllysine (DML), ε-trimethyllysine (TML), monomethylarginine (MMA), N^G,N'^G-dimethylarginine (uDMA), N^G,N^G-dimethylarginine (sDMA), 1-methylhistidine (1-MH) and 3-methylhistidine (3-MH). The electrophoresis was carried out in a buffer containing pyridine–acetic acid–water (25:1:225), *p*H 6.5, for 3.5 at 4,440 V. After electrophoresis, the paper was sprayed with 0.4% ninhydrin in acetone and the methylated amino acids located by heating for 5 min at 70° C. The oxidised forms of methionine—methionine sulphoxide (M-SO) and methionine sulphone (M-SO_2) migrated with methionine (Met). The paper was then cut into 1.25-cm pieces and counted in a scintillation counter after the addition of 5 ml toluene-based scintillation fluid (4 g Omnifluor per litre toluene).

It was of interest therefore to identify the proteins from the 50S subunit that were methylated *in vitro*. The two-dimensional polyacrylamide gel electrophoresis procedure of Kaltschmidt and Wittmann[12] was used. More than 80% of the incorporated methyl groups was located in protein L11. Proteins L1, L3 and L5 were also labelled to a small extent. Independently, Alix and Hayes[7] have also observed the *in vitro* methylation of protein L11 in cells grown in the presence of ethionine—a methionine analogue.

The nature of the methylated amino acids in protein L11 was also determined. Figure 2 shows protein L11 contains methylated lysine(s) and a very small amount of a compound tentatively identified as N^G,N'^G-dimethylarginine (sDMA). The nature of the methylated lysine was further characterised to be ε-trimethyllysine The presence of ε-trimethyllysine was also verified by the use of the amino acid analyser (C N C , and F N C , unpublished) It should be mentioned that we have also observed the presence of these two methylated basic amino acids in protein L11 obtained from cells grown with ^{14}C-methyl methionine[6] Since the other proteins (L1, L3 and L5) were methylated to a much lesser extent, we have not been able to identify their methylated amino acids

An attempt was also made to calculate the stoichiometry of ε-trimethyllysine in protein following in vitro methylation In the *in vitro* experiment about 55% of the 8,000 c p m incorporated into the 50S particle (8 5 A_{260} units) was found in the protein fraction As 20% of the isolated *rel*$^-$ 50S particles was in the precursor form which was predominately methylated (Fig 1), the amount of incorporation of the methyl groups to protein L11 (which accounts for 80% of the total incorporation into proteins) can be calculated from the specific activity of ^{14}C-cethyl methionine (55 mCi mmol^{-1}) and 50% counting efficiency It was found that there is about 0 30 molecules of ε-trimethyllysine per protein L11 This is lower than the value which we have observed for the *in vivo* methylation of L11 (0 8 molecules/L11) in exponential growth[6] The discrepency between these two results could arise because only a fraction of the precursor particle(s) was methylated or because there was a pool of methylated protein L11 present before the starvation which combined preferentially with the precursor 23S rRNA This would lead to the lower incorporation of methyl groups to protein L11 *in vitro*

We have recently shown that several ribosomal proteins form the 50S subunit (L1, L3, L5, L7, L9, L11, L12, L18 and L33) were methylated *in vitro*[5,6] The failure to observe methylation of some of these proteins (such as L7, L9, L12, L18 and L33) *in vitro* in these experiments could either be due to these proteins being methylated already because they are essential for functioning, or due to the lack of methylases which specifically recognise these amino acids in the above proteins These possibilities are now under investigation Thus, the 50S particle obtained from *rel*$^-$ strain after starvation for methionine should provide a good substrate for the assaying and eventual characterisation of protein methylases

RNA–RNA hybridisation using ^{125}I-labelled RNA from tobacco necrosis virus and its satellite

SINCE the description by Commerford[1] of a simple method of iodinating nucleic acids, RNA labelled *in vitro* with ^{125}I has been used in structural studies[2], and in DNA–RNA hybridisation studies *in vitro*[3] and *in situ*[4] This technique has considerable potential, especially in studying RNAs which are difficult to label *in vivo*, but most of the information available concerns the labelling of small RNA molecules and there is no information about the stability of large molecules under conditions necessary to obtain high specific activity Furthermore, a recent report[5] suggests that ^{125}I-labelled RNA with high specific activity is degraded on storage and its ability to form DNA–RNA hybrids is lost

Here we show that large plant virus RNA species can be

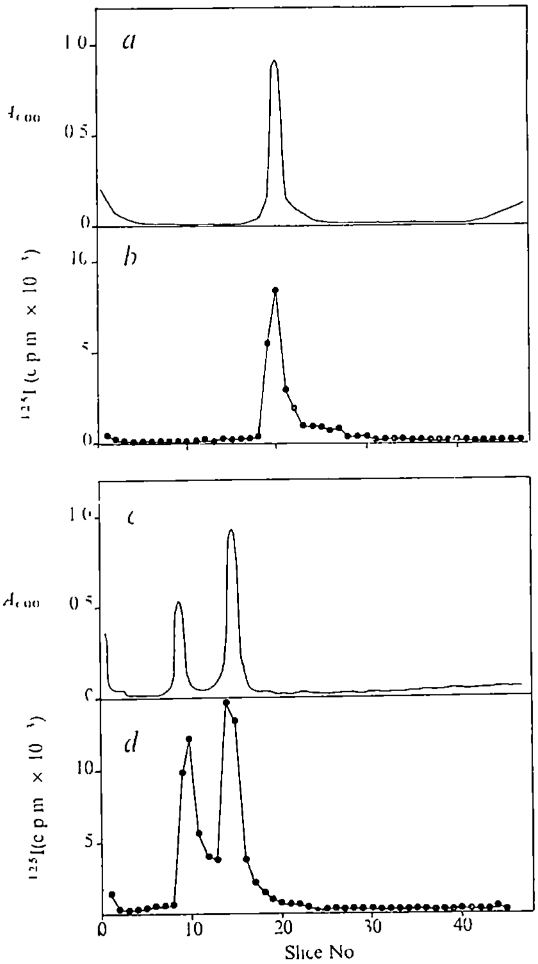

Fig 1 Polyacrylamide gel electrophoresis of RNAs before and after ^{125}I-labelling *a*, SV RNA, *b*, SV RNA labelled for 20 min, *c*, TRV RNA, *d*, TRV RNA labelled for 2 min Labelled and unlabelled RNAs were electrophoresed in parallel for 2 h in 8 cm, 2 4% acrylamide, 0 5% agarose gels containing 0 2% SDS and at 7 5 V cm^{-1} as described by Peacock and Dingman[9] Gels were stained for 1 h in 0 1% toluidene blue in 40% methoxyethanol and destained in 30% methoxyethanol The isotope in the gel slices was determined by scintillation counting

labelled with ^{125}I to high specific activities without significant degradation, that such molecules hybridise fully with complementary strand RNA and that these properties are unaffected by storage We have used this technique to search for nucleotide sequence homology between the RNAs of satellite virus (SV) and its helper, tobacco necrosis virus (TNV)[6]

Conditions for *in vitro* iodination of RNA were adapted from those described by Commerford as follows The reaction mixture in a total volume of 25 μl contained 5 μg RNA, 5 × 10^{-4} μmol KI, 1 2 × 10^{-4} μmol $TlCl_3$, 1 mCi Na ^{125}I (carrier free) and 2 5 μmol sodium acetate, *p*H 4 8 The iodination was at 60° C for 20 min or for shorter periods for very large RNA species which were more susceptible to degradation The reaction was stopped by making the mixture 0 01 M with respect to sodium sulphite, and 0 5 ml 0 05 M Tris, 0 1 M NaCl, 5 mM EDTA was immediately added Yeast RNA (100 μg) was added as carrier and the RNA precipitated by addition of 2 vol ethanol The precipitate was dissolved in 0 25 ml 0 1 M ammonium acetate, *p*H 8 9, and heated at 60° C for 10 min to remove unstable derivatives[1] After addition of 0 25 ml 0 05 M Tris, 0 1 M NaCl, 5 mM EDTA, *p*H 7 2, the RNA was precipitated with alcohol The RNA was further purified by adsorption in 0 01 M potassium phosphate, *p*H 6 8, to a 0 5 ml column of hydroxyapatite, followed by elution with 0 25 M potassium phosphate The overall recovery of RNA was approximately 50%

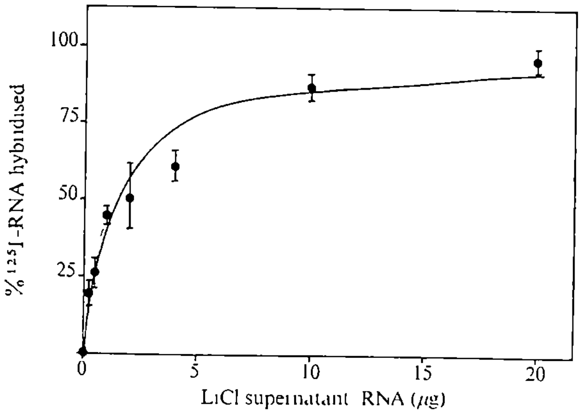

Fig. 2 Hybridisation of ^{125}I-labelled SV RNA with denatured double-stranded SV RNA RNA was extracted from leaves of tobacco plants 3 d after infection with TNV strain A and SV1 (ref 10) as described previously[11] High molecular weight single-stranded RNA was removed by LiCl precipitation[12] and the supernatant used as a source of double-stranded virus RNA[11] This RNA was mixed with 8,000 c p m ^{125}I-labelled SV RNA to a total volume of 0 2 ml in 2 × SSC, and denatured by heating at 115° C for 15 min Annealing was for 20 h at 70° C TCA-precipitable ^{125}I was measured after ribonuclease digestion[11] Each point is the mean of three determinations The solid line drawn is theoretical, and describes the relationship between the concentration of denatured double-stranded RNA and the fraction of single-stranded RNA hybridised under conditions where the reaction is complete[13]

Using this method iodination for 20 min yielded RNA with a specific activity in the range 3 × 10^7 to 8 × 10^7 d p m μg^{-1} Iodination for 2 min gave RNA with a specific activity between 5 × 10^6 and 3 × 10^7 d p m μg^{-1} Figure 1 shows the electrophoretic behaviour of these RNAs on polyacrylamide gels before and after iodination SV RNA (molecular weight 0 4 × 10^6)[7] is undergraded after iodination for 20 min The two RNAs of tobacco rattle virus (molecular weights 2 5 × 10^6, 0 7 × 10^6)(ref 8) were essentially intact after iodination for 2 min, but the larger of the two RNAs was considerably degraded during a 20 min labelling period The behaviour of the iodinated RNA on acrylamide gel electrophoresis was unaltered after storage for 3 months as an ethanol precipitate at −20° C

The ability of these labelled RNAs to hybridise with complementary strand RNA was examined by annealing them with denatured double-stranded virus RNA extracted from virus-infected plants Figure 2 shows the results of annealing ^{125}I-RNA of SV strain 1 with increasing concentrations of denatured double-stranded SV1 RNA At high concentrations of double-stranded RNA nearly all the ^{125}I is ribonuclease resistant The data fit well to the line drawn, which is theoretical and describes the relationship between the concentration of denatured double-stranded RNA and the fraction of single-stranded RNA hybridised under conditions where the reaction is complete[13] The results shown in Fig 2 were obtained with ^{125}I-RNA which had been stored for 3 months

These techniques have been used to look for common nucleotide sequences in TNV RNA and SV RNA The total dependence of satellite virus on TNV for replication[6] is thought to be due to a requirement by SV RNA for the RNA-dependent RNA polymerase specified by TNV and it has been suggested that TNV RNA and SV RNA may contain common nucleotide sequences which act as recognition sites for such a shared polymerase[14] The two RNAs are known to contain an identical trinucleotide at their 5′ termini[14-16], and Klein and Reichmann[17] reported that at least 10% of the SV RNA genome was homologous with that of TNV

In an experiment in which ^{125}I-labelled SV RNA was hybridised to denatured double-stranded SV RNA, in the absence of any competitor RNA, approximately 3,000 c p m of ^{125}I-labelled RNA was hybridised When unlabelled SV RNA (10^{-13} mol) was included as a competitor, hybridisation was reduced by about 90%, whereas the same molar concentration of TNV RNA had no detectable effect, indicating a lack of sequence homology between these RNAs A more sensitive approach is to attempt to anneal ^{125}I-labelled SV RNA with denatured double-stranded TNV RNA (Table 1) Less than 0 5% of the ^{125}I-labelled SV RNA hybridised to TNV complementary strand RNA in this experiment Since this concentration of TNV complementary strand was sufficient to anneal with 23% of the ^{125}I-labelled TNV RNA it follows that less than 2% of the SV RNA sequences are homologous with TNV RNA sequences Any sequence homology which may exist between these two RNAs is therefore limited to a total of less than 30 nucleotides, and this is difficult to reconcile with an earlier report of considerable sequence homology between these RNAs[17]

Table 1 Attempts to form hybrids between SV RNA and TNV RNA complementary strand

Source of double-stranded RNA	^{125}I-labelled RNA (c p m)	^{125}I-hybridised (c p m)
Uninfected plants	TNV (8,650)	151 ± 23 (3)
TNV infected plants	TNV (8,650)	2070 ± 120 (3)
Uninfected plants	SV (2,330)	43 ± 2 7 (6)
TNV infected plants	SV (2,330)	38 ± 1 6 (6)

Denatured LiCl supernatant RNA (100 μg) from either uninfected or TNV infected plants was annealed with ^{125}I-labelled SV or TNV RNAs, the iodinated RNAs being used at the same molar concentrations Experimental methods were as described in Fig 1 The mean values for the quantities of ^{125}I hybridised are given with their standard errors, and the figures in brackets in this column refer to the number of replicates in each case No detectable ^{125}I-labelled SV RNA was annealed by TNV complementary strand RNA (< 0 5% $P > 0 99$)

We have shown here that iodinated RNA has considerable potential in RNA–RNA hybridisation studies It should be particularly useful to plant virologists since pure virus RNAs are often readily available, but isotopically labelled RNA is particularly difficult to obtain by *in vivo* labelling methods

We thank Vicky Maxwell for technical assistance and Mr David Smith for assistance in propagating TNV We thank Drs D Barbara and B Kassanis for helpful discussion Purified satellite virus was a gift from Dr B Kassanis This work was supported by the Agricultural Research Council

Double helix formed by the dinucleoside phosphate thymidylyl-3′,5′-deoxyadenosine

IN our conformational studies of nucleic acid components we have obtained X-ray diffraction photographs from specimens of the dinucleoside phosphate thymidylyl-3′,5′-deoxyadenosine (TpdA) which are similar to those obtained from certain synthetic DNA copolymers The dinucleoside phosphate was obtained from International Enzymes Ltd as the triethylammonium salt Some of it was dissolved in a small quantity of water between a glass slide and a coverslip resting on two thin glass fibres Some of the material which dried out under the coverslip showed evidence of orientation when viewed between crossed polaroids X-ray diffraction photographs were taken on a microcamera using a Hilger and Watts semi-microfocus X-ray generator and one of these is shown in Fig 1

The diffraction patterns are similar to those obtained from fibre specimens of nucleic acids and they are characteristic of helical diffraction patterns, with an integral number of residues per turn of the helix The layer-line spacing at ~57% relative humidity is 26 3 Å There are discrete reflections only on the equator and these can be indexed on a hexagonal lattice with a=21 25 Å Both layer-line spacing and the equatorial pattern depend on water content and at ~92% relative humidity the layer-line spacing is 27 2 Å and a=22 7 Å The pattern is characterised by a very strong intensity on the seventh layer line close to the meridian, by a strong first layer line and a weaker second layer line These characteristics are similar to those observed in some of the fibre X-ray diffraction patterns of the synthetic double-helical copolymers poly d(A-T) poly d(A-T) (ref 1) and poly d(I-C) poly d(I-C) (ref 2)

The similarity in the diffraction patterns obtained with TpdA and the polymers can be explained if two TpdA molecules are related to each other by a twofold rotation axis so that they are linked to each other by Watson–Crick pairing of bases in a similar way to that observed in the single-crystal structure of the dinucleoside phosphates adenylyl-3′,5′-uridine (ref 3) and guanylyl-3′,5′-cytidine (ref 4) Pairs of TpdA molecules can then stack on top of each other to produce an extended helical structure The structure would thus be similar to a double helix in which alternate phosphate groups would be missing The fact that the backbone of such a helix is discontinuous suggests that stacking forces are important in stabilising the structure and in determining its integrity

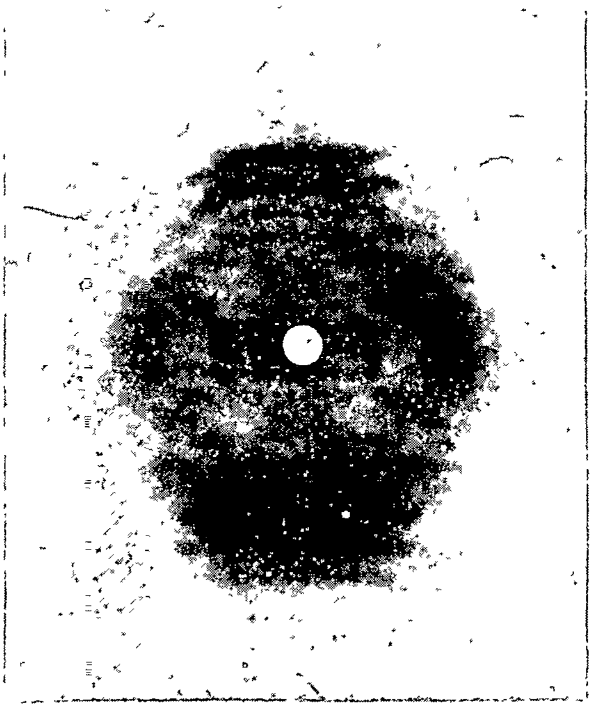

Fig 1 X-ray diffraction photograph of TpdA at 57% relative humidity

The intensity distribution on the fifth, sixth, seventh and eighth layer lines is similar in some ways to the distribution in the corresponding region of the diffraction pattern of the A-form of DNA[5], suggesting that the bases are tilted from perpendicular to the helix axis The tilt is 20° in A-DNA, where the rise per nucleotide along the helix is 2 56Å In TpdA, an estimate of the number of molecules in the 26 3 Å repeat gives a value of 12 or 10,—an odd number of molecules would mean a doubling of the repeat period which is not observed Twelve molecules would correspond to a stack of six pairs of molecules with a rise of 2 19 Å from one base to the next along the helix Ten molecules correspond to a stack of five pairs of molecules and a rise of 2 63Å, which seems a more reasonable value when compared with polynucleotide structures Further analysis of the diffraction patterns should clarify this point and should enable a detailed structure determination to be made It will be of interest to compare the TpdA structure with that recently proposed for poly d(A-T) poly d(A-T) (ref 6)

Specific binding of antitumour drug *cis*-Pt$(NH_3)_2Cl_2$ to DNA rich in guanine and cytosine

ONE of the more effective *cis*-platinum antitumour compounds currently being tested in cancer chemotherapy is *cis*-Pt$(NH_3)_2$ Cl_2 (ref 1) Evidence suggests that DNA is the effective site of action of the platinum drug[2,3] This study was initiated to determine the effective binding site on DNA Roberts and Pascoe have noted the similarity of action between *cis*-Pt $(NH_3)_2Cl_2$ and the classical antitumour bifunctional alkylating agents which crosslink DNA (ref 2) Low concentrations of several *cis*-platinum compounds suppress DNA synthesis *in vitro* while affecting protein and RNA synthesis to a much lesser extent[3] The studies by Horacek and Drobnik employing ultraviolet absorption spectroscopy indicate that the platinum moiety binds to the bases of DNA rather than to the phosphate backbone[4] Spectroscopic studies suggest that *cis*-Pt$(NH_3)_2$ Cl_2 preferentially binds to guanine–cytosine (G–C)-rich DNA[5,6] An increase in the buoyant density of T7 DNA and calf thymus DNA has been reported when one of several platinum compounds is present in solution[5,7] Here we report that the binding of *cis*-Pt$(NH_3)_2Cl_2$ to DNA results in large increases in buoyant density which are proportional to the G–C content of the DNA and to the molar ratio of platinum to DNA-P

Rat liver DNA (42% G–C), radiolabelled with ^{3}H-thymidine, and *M lysodeikticus* DNA (72% G–C), both prepared by standard methods[8], were mixed in 0 015 M sodium chloride Concentrations of the original DNA solutions were determined using the molar extinction coefficients at 260 nm of 6650 for rat liver DNA and 6700 for *M lysodeikticus* DNA (ref 9) Solutions containing 10^{-3} M *cis*-Pt$(NH_3)_2Cl_2$ in 0 015 M sodium chloride were added and the mixture incubated at room temperature in the dark Buffers were avoided because of their potential metal-binding properties[10] Periodic measurements during the course of the reaction indicated a *p*H of about 6 5 The ultraviolet absorption parameter $A_{250\,nm}/A_{270\,nm}$, an indication of platinum binding to DNA (ref 4), was used to monitor the reaction This ratio decreases until equilibrium is established In the conditions employed, this required about 1 d

Aliquots containing 10–30 μg of platinised DNA were then mixed with caesium sulphate solution and banded in an isopycnic gradient The refractive index and absorbance at 260 nm of sequential 0 3 ml fractions were determined and densities were derived using the formula of Vinograd[11] The radioactivity of each fraction was determined using Aquasol (New England Nuclear) and a Hewlett Packard liquid scintillation counter Some gradient fractions were dialysed to remove the caesium salt and the ultraviolet absorption spectrum of the recovered DNA was determined The ratio $A_{250\,nm}/A_{270\,nm}$ indicated that the molar ratio of DNA-bound platinum to DNA-P had remained unchanged during the isopycnic banding procedure

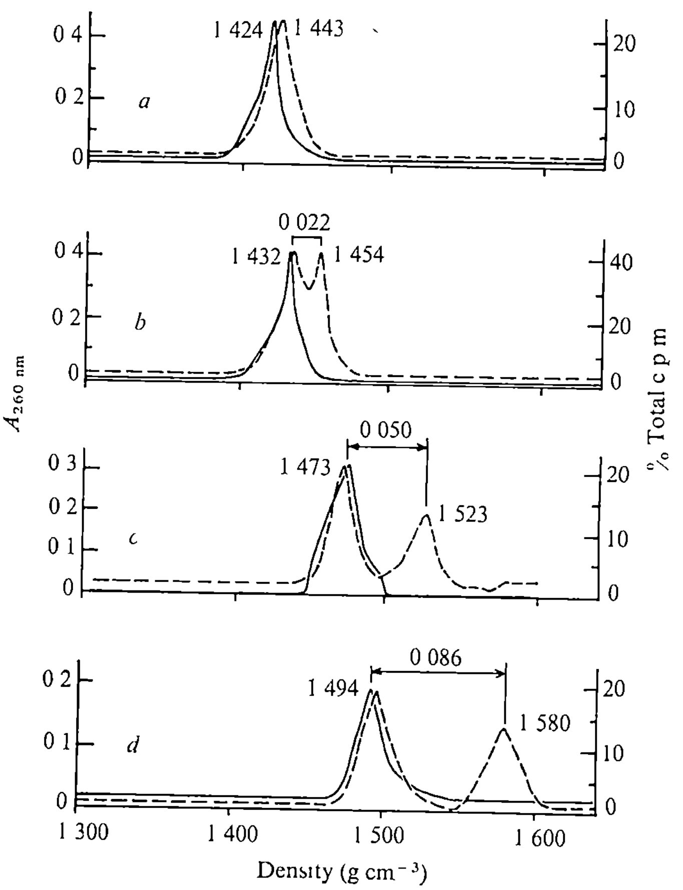

Fig 1 Rat liver DNA, radiolabelled with ^{3}H-thymidine, was mixed with *M lysodeikticus* DNA, reacted with various amounts of *cis*-Pt$(NH_3)_2Cl_2$ and analysed in a caesium sulphate isopycnic density gradient The gradients were fractionated and the refractive index, the absorbance at 260 nm (----) and the radioactivity (——) were determined as described in the text The buoyant densities of unreacted rat liver DNA and *M lysodeikticus* DNA were determined individually as 1 424 g cm^{-3} and 1 443 g cm^{-3} respectively The concentrations of rat liver DNA, *M lysodeikticus* DNA and *cis*-Pt$(NH_3)_2Cl_2$ used were *a*, 9 20 × 10^{-5} M (DNA-P), 1 17 × 10^{-4} M (DNA-P), 0, *b*, 8 40 × 10^{-5} M, 1 06 × 10^{-1} M, 9 90 × 10^{-6} M, *c*, 7 70 × 10^{-5} M, 9 72 × 10^{-5} M, 1 67 × 10^{-5} M, *d*, 6 93 × 10^{-5} M, 8 74 × 10^{-5} M, 2 57 × 10^{-5} M

Figure 1 illustrates the increasing separation of rat liver DNA and *M lysodeikticus* DNA at higher concentrations of *cis*-Pt$(NH_3)_2Cl_2$ *M lysodeikticus* DNA increases in density more than ^{3}H-thymidine-labelled rat liver DNA, which has a lower G–C content To rule out the possibility that *M lysodeikticus* DNA remained in the low density band, the experiment was repeated without rat liver DNA We obtained a single homogeneous peak for *M lysodeikticus* DNA and an increase in density similar to that obtained in the previous experiment When the experiment is performed without *M lysodeikticus* DNA a single homogeneous peak is also obtained for rat liver DNA

The effects of *cis*-Pt$(NH_3)_2Cl_2$ on other DNAs were determined in a similar manner The findings are presented in Fig 2 The buoyant density increase of each DNA is proportional to its G–C content and also depends on the molar ratio of platinum to DNA-P Similar results have been obtained using caesium chloride gradients

We wished to determine how firmly the platinum compound was bound to the DNA Exhaustive dialysis of platinised DNA against some of the usual chelating agents such as EDTA or penicillamine or in solutions containing high concentrations of such anions as sulphate or chloride failed to reverse the buoyant density and spectroscopic changes induced by treatment of DNA with the platinum compound Preliminary

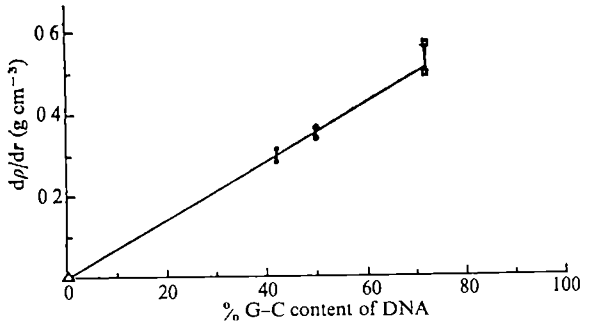

Fig. 2 The relationship between the increase in density of a DNA, treated with *cis*-Pt$(NH_3)_2Cl_2$, and the base composition of that DNA The increase in buoyant density, *d*ρ, of various DNAs as a function of the increase in the molar ratio of platinum to DNA-P, *dr*, is presented as *d*ρ/*dr* versus G–C content of the DNA *Cis*-Pt$(NH_3)_2Cl_2$ was reacted with individual DNAs in 0 015 M sodium chloride to completion The buoyant density was determined as described in the text and the value of *d*ρ/*dr*, the platinum dependent density change for the DNA, was obtained from a plot of buoyant density versus molar ratio of platinum to DNA-P To determine whether or not *d*ρ/*dr* was altered by the presence of another DNA, a second procedure was used which yielded similar values Equal amounts of a test DNA and a reference DNA, for which *d*ρ/*dr* was known, were reacted with *cis*-Pt$(NH_3)_2Cl_2$ in a 0 015 M sodium chloride solution These DNAs were banded in caesium sulphate as described in the text Then, $(d\rho/dr)$ test DNA $=(d\rho/dr)$ reference DNA $\times \dfrac{\Delta\rho \text{ test DNA}}{\Delta\rho \text{ reference DNA}}$ For example, from Fig 1, the increase in buoyant density for *M lysodeikticus* DNA is 1 8 times the increase in density for rat liver DNA from the same solution Therefore $(dp/dr)_{M\ lysodeikticus\ \mathrm{DNA}} = 0\ 30\mathrm{g\ cm}^{-3} \times 1\ 8 = 0\ 54\,\mathrm{g\,cm}^{-3}$ The value of 0 30 g cm^{-3} for rat liver DNA, in this case, was determined by the increments in density that occurred when this DNA alone was reacted with various concentrations of the platinum compound Values of *d*ρ/*dr* were obtained for (poly (dA) (poly (dT)) and poly (dA-T)[2] (Δ) calf thymus DNA (42% G–C) and rat liver DNA (42%G–C) (●) *E coli* DNA (50% G–C) (○), and *M lysodeikticus* DNA (72% G–C, (□)

indications, however, are that most, but not all, of the DNA-bound platinum can be removed by dialysis for several weeks with 10^{-3} M solutions of potassium cyanide and 0 015 M sodium chloride It is not presently known whether or not removal of the DNA-bound platinum results in nicking or other damage to the DNA

Understanding of the action of *cis*-Pt$(NH_3)_2Cl_2$ may result in the development of more useful analogues of these antitumour agents In addition, isolation of guanine rich regions of fragmented DNA might be facilitated using the larger increase in density which occurs with platinisation

RNase inhibition of reverse transcriptase activity in human milk

The aetiological role of RNA tumour viruses in mammary cancer of experimental animals coupled with observations of morphologically similar particles in human milk[1,2] has motivated considerable interest in the biological role of these virions in man The specificity and sensitivity of the simultaneous detection test[3] for reverse transcriptase (RT) which requires that the viral enzyme polymerise radioactive DNA using endogenous 70S and/or 35S viral DNA as template, suggested its usefulness for the detection of RNA tumour viruses in human milk[4] In two recent studies[2,5] comparing the detection of such virions in human milk by electron microscopy (negative staining) with the detection of RT activity, no correlation was observed As a part of our effort at relating the presence of such virions in human milk to a familial history of breast cancer, we employed reconstruction experiments to determine the reliability of the simultaneous detection test for the routine testing of human milk samples for the presence of RNA tumour viruses. Analysis of the products of the reaction was carried out by the use of gel electrophoresis instead of by velocity gradients[6] This method offers the advantage that, in addition to the 70S and/or 35S viral peak, it also detects a 4S peak which represents the DNA products of the reaction which are free from the large molecular weight viral RNA

Using this modification of the simultaneous detection test, we have repeatedly and reproducibly detected the presence of RNA tumour viruses from a variety of sources including some samples of human milk Experiments describing the high degree of proportionality and reproducibility readily attained with non-milk sources will be described elsewhere

In our reconstruction experiments, 3×10^4 focus forming units (FFU) of murine leukaemia virus (MuLV) (Rauscher) supplied by University Laboratories and assayed by them in FFU of helper virus) was added to each of 25 human milk samples obtained from healthy donors Under these conditions, any endogenous RT activity would be expected to contribute less than 10% of the total counts and thus not be a source of confusion Figure 1 shows the electrophoretic profiles of the products of the simultaneous detection test Profile *a* gives the products of the MuLV control diluted in 0 85% NaCl Four of the 25 samples gave profiles identical to this profile Profile *b* was seen in 17 of the 25 samples There is no 35S peak and little or no 4S peak Profiles *c* and *d* with reduced 35S and 4S peaks were seen in 4 out of 25 samples Similar results were obtained when avian myeloblastosis virus (AMV) was substituted for MuLV in this series of reactions It is clear, therefore, that the majority of the milk samples tested inhibited the detection of the reverse transcriptase reaction of at least two known RNA tumour viruses

We had previously observed profiles similar to these in Fig 1*b*, *c* and *d*, when, before beginning the enzymatic reaction, we had deliberately added RNase to the viral pellet to demonstrate the RNA dependency of the reaction Therefore, we made a direct examination for the presence of RNase in the viral pellet prepared from the milk samples described above Table 1 shows the relationship between RNase activity in the viral pellet from milk and the inhibition of RT activity of the same pellet The positive correlation between the presence of RNase in the viral pellet and the inhibition of the RT activity supports the suggestion that RNase in human milk is a significant inhibitor of the simultaneous detection test for RT It was not possible to examine these particular milk samples further since the limited amount of milk available was used in these assays

A similar interference with the RT activity of MMTV in milk from RIII mice by an inhibitor present in human milk was reported earlier[4] These workers also reported that on some occasions trypsin pretreatment could be shown to increase the RT activity detectable in human milk samples We tested trypsin pretreatment of human milk containing added MuLV and found that it rarely prevented inhibition of RT Similarly we found that it failed to lower the measured level of RNase present in such milk samples (J J McC, L J L, and M A R, unpublished)

Since the simultaneous detection test was inadequate for screening milk samples, we investigated whether another RT assay might offer a valid approach The use of exogenous synthetic templates, such as poly (A) oligo (dT) and poly (dA) oligo (dT) or poly (C) oligo (dG) (ref 7), to assay RT activity provided an extremely sensitive assay, but this reaction was also inhibited when reconstruction experiments with MuLV or AMV added to milk were carried out and the test run on the viral pellet

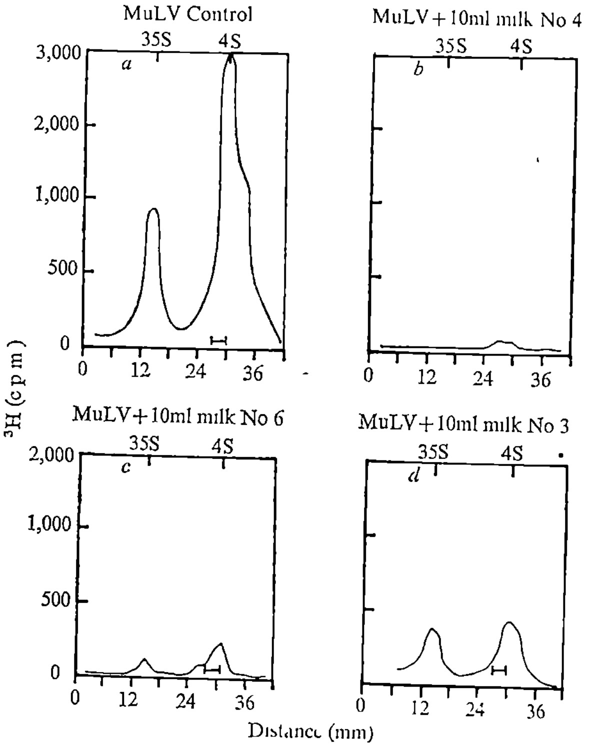

Fig 1 Twenty five human milk samples were 'seeded' with 3×10^4 FFU of MuLV assayed for RT activity according to the procedure of Schlom *et al* [4], (with the minor modifications described below) and the products analysed by polyacrylamide gel electrophoresis[6] The peak between fraction 12 and 14 represents the 35S viral RNA which is acting as template in the reaction The peak between fractions 24 and 36 represent the DNA products of the reaction which are no longer bound to the 35S RNA Four of the 25 samples gave profiles identical to that in *a* (MuLV assayed independently of milk), 17 of the 25 gave profiles like *b*, and 4 gave profiles like *c* and *d* 15 ml of milk containing added MuLV was diluted with 7 ml of 10 mM Tris-HCl, 150 mM NaCl, 2 mM mgCl, (*p*H 7 4) (TNM) and centrifuged at 4,000*g* for 10 min The clear 'milk-plasma' zone between the lipid and the pellet was removed and overlaid on a 8 ml glycerol pad and centrifuged at 4° C for 1 h at 98,000*g* in a Spinco SW 27 rotor to form the 'viral pellet' Centrifugation of the milk-TNM mixture at 4,000*g* for 10 min and of this supernatant at 16,300*g* for 10 min to clear the large molecular weight material before the centrifugation at 98,000*g* was not effective in enhancing the reverse-transcriptase activity of the viral pellet or of lowering the RNase activity of this pellet The use of EDTA instead of TNM did not aid in the precipitation of casein in human milk and inhibited the RT reaction of MuLV or AMV as has been noted[12] The RT assay was carried out with an incubation at 37° C for 1 h (identical curves showing about 25% as much incorporation were obtained with 15 min incubations)

Reverse transcriptase activity (% control) was determined as in Fig 1 The control was 3×10^4 FFU of MuLV seeded into 15 ml of 0 85% NaCl To determine the presence of RNase activity, 0 005 ml of the viral pellet immediately after resuspension in 0 050 ml of 10 mM Tris-HCl (*p*H 8 3) was added to tritiated mouse ribosomal RNA and incubated at 37° C for 1 h Glycerol was added to a concentration of 10% and the sample subjected to electrophoresis on a 1 8% acrylamide 0 5% agarose gel for 60 min at 2 mA per gel Gel sections were cut, hydrolysed in 30% peroxide at 60° C and counted in Aquasol in a Packard liquid scintillation spectrometer A sample was designated RNase negative if a sharp 28S RNA peak containing 75% or more of counts of the control was found The 28S peak was absent from all samples designated RNase positive

The other type of reverse transcriptase assay in common use is the endogenous template method[8] This is a less refined version of the simultaneous test in which all of the radioactive products of the reaction are precipitated together Such a method would also be unsatisfactory for the assay of MuLV or AMV seeded human milk samples since, as shown in Fig 1 in 84% of the samples tested the total amount of radioactive product is significantly lower than the control value

If RNase present in human milk is, indeed, inhibiting the reverse transcriptase activity of virus added to such a sample, it should be possible to demonstrate this by determining the amount of RNase present and then showing that adding this amount of RNase to a reverse transcriptase reaction in buffer causes the same amount of inhibition as adding the milk sample itself To determine the amount of RNase present in the reverse transcriptase reactions of a number of milk samples, we centrifuged them, as described for Fig 1, using the procedures we employed for preparing 'viral pellets'. We resuspended such pellets in 0.01 M Tris-HCl *p*H 8.3 in 1/100 the original volume and determined the amount of RNase present in aliquots of this solution using ribosomal RNA as described in Fig 2. We then determined how much inhibition of a virus RT reaction in buffer, using the template poly (C) oligo (dG), was caused by a particular volume of this resuspended milk pellet. To equate this inhibition with the concentration of RNase present, equivalent concentrations of pancreatic RNase were added to a parallel series of viral RT reactions and the percentage inhibition determined. Since mouse mammary tumour virus (MMTV) may be a better model for a human mammary virus than leukaemia virus, these assays were done with MMTV purified from RIII mouse milk[8] as well as with MuLV. The results are shown in Fig 2.

Milk samples 33 and 39 show the same degree of inhibition of the RT reaction with MMTV or MuLV as was obtained when the equivalent amount of pancreatic RNase was added to the MMTV RT reaction. Low levels of pancreatic RNase added to MuLV show a similar RT inhibition, but the RT appears to be more resistant to higher RNase concentrations. The viral pellet of sample 33 contains 2 ng RNase ml^{-1} of milk used to prepare the pellet and sample 39 contains 10 ng RNase ml^{-1} of milk used. From these data it is clear that the inhibition of RT activity by human milk samples can be accounted for by the RNase activity of the viral pellets.

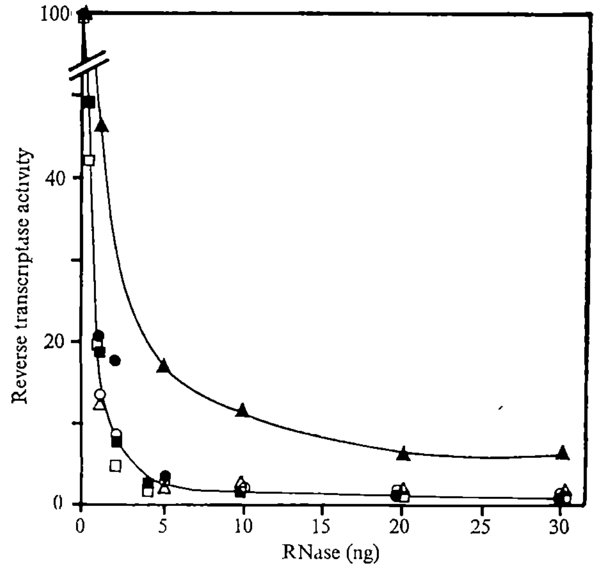

Fig 2 The inhibition of a synthetic template reverse transcriptase reaction by the addition of pancreatic RNase or milk 'viral pellet' which contains the same amount of RNase. The human milk was prepared as described in the legend of Fig 1, and the 'viral pellet' resuspended in 10 mM Tris-HCl (*p*H 8.3) in 1/100 the original volume. RNase was assayed quantitatively by measuring the TCA-precipitable counts after incubating tritiated mouse ribosomal RNA with the aliquots of the resuspended 'viral pellet'. Incubation was for 10 min at 0° C. 10% TCA was added to stop the reaction and 50 μg of yeast RNA was added as carrier. Samples were precipitated on cellulose nitrate filters, dried, and counted in a toluene–PPO–POPOP cocktail in a Packard liquid scintillation spectrometer. The units of RNase per test sample were determined by comparison with the TCA precipitable counts remaining after exposure of the RNA to a known amount of commercial bovine pancreatic RNase A (80 Kunitz units mg^{-1}) (Worthington Biochemical Corporation, Freehold, New Jersey). Aliquots of ▲, pancreatic RNase (dissolved in 10 mM Tris-HCl, *p*H 8.3), ●, the resuspended 'viral pellet' of human milk sample 2 33 (2 ng of RNase ml^{-1} of milk used) ■, human milk no 39 (10 ng of RNase ml^{-1} of milk used), each containing equal amounts of RNase activity, were added to RT assays containing 3 × 10^{3} FFU of MuLV and 5 μg ml^{-1} of the synthetic template (poly rC) (oligo dG) and the reaction carried out as described. An identical series of reactions was also carried out with MMTV in the RT assay (△, ○, □). The fact that a similar inhibition of the reaction is seen when identical levels of RNase are added demonstrates that the RNase present in the milk 'viral pellet' is sufficient to explain the inhibition of such reactions seen when MuLV, AMV or MMTV are added to human milk in reconstruction experiments.

It is not immediately clear how RNase, a small molecular weight protein, can reach the viral pellet since the centrifugation conditions (98,000*g* for 1 h over a 8 ml pad of 20 or 30% glycerol) are clearly not sufficient to pellet RNase. We have noted, however, that the milk samples centrifuged in these conditions form a large pellet. Since casein, a common milk protein, can form micelles of sufficient mass to pellet in these conditions, we examined the viral pellet for casein by the Ouchterlony double diffusion technique against rabbit anti-human casein. Human casein was readily detected in these pellets suggesting that RNase could indeed reach the viral pellet as part of a casein micelle.

We have found that the amount of RNase in the resuspended 'viral pellet' is proportional to the volume of human milk used and that the variation of RNase present in a group of milk samples tested was between 2 and 20 ng ml^{-1} (1 mg of RNase is equal to 80 Kunitz units (ref 9)). In the synthetic template RT assay shown in Fig 2, 3.0×10^{3} FFU of MuLV virus, which we have shown by laser light scattering contains about 0.5×10^{7} viral particles[10], is 95% inhibited by 2.5 ng of RNase. Assuming that the RT activity of the virus found in human milk using this template is as sensitive to RNase as MuLV or MMTV, a human milk sample would have to contain more than 0.5×10^{7} endogenous viral particles ml^{-1} if it contained 2 ng of RNase ml^{-1} and more than 1×10^{8} particles if it contained 20 ng of RNase ml^{-1} to exhibit positive RT activity with a synthetic template test. We have verified these figures by the addition of suitable amounts of MuLV to human milk and found that when virus is in excess, positive RT's are obtained as predicted.

The milk of various strains, especially RIII, is well known to contain large amounts of MMTV and such samples have routinely given positive RT assays. We have found that the RNase activity of the 'viral pellets' of RIII mouse milk falls in the same range as that from human milk samples, but that the viral content of such samples as determined by laser light scattering is 25–500 times higher than the amount of virus added to human milk in our reconstruction experiments. It is clear that the large difference in the number of viral particles can account for the high frequency of positive RT assays with RIII mouse milk as opposed to human milk.

The data presented here may well account for the lack of correlation between RT activity in human milk, and the detection of virus particles by electron microscopy, or the epidemiological risk to breast cancer[2,5,11]. Attempts to assess the RNase sensitivity of endogenous RT activity in human milk and to develop an inhibitor or RNase compatible with the detection of RT activity are in progress.

We thank Dr Jeffrey Schlom for setting up the simultaneous test in our laboratory, Ms Ruth Rich for help, Dr Sam Albert under whose direction the milk was acquired, and Dr Herbert Rose for carrying out immunological determinations.

This work was supported by the National Cancer Institute, United States Public Health Service. Additional support came from an institutional grant to the Michigan Cancer Foundation from the United Foundation of Greater Detroit. MuLV was supplied by university laboratories and assayed by them in FFU of helper virus. AMV was supplied by Drs Joseph Beard and Dorothy Beard, Duke University

MMTV was supplied by Dr Donald Fine of the Frederick Cancer Research Center

Capacity of complement C3 phenotypes to bind on to mononuclear cells in man

SINCE the discovery of the genetic polymorphism of C3, the third component of human serum complement[1-3], no demonstration of functional differences between the common phenotypes F and S has been published Total or specific C3 haemolytic activity has been found to be the same for C3 variants[1,4] as was also the case with immune adherence titres in sera with different C3 phenotypes[1]

Evidence has accumulated about the complement receptors in the membrane of leukocytes in various animal species including man[5,6] The complement component involved in the binding to the leukocytes seems to be C3 (ref 5) It seemed worthwhile investigating the possibility of genetically determined differences in C3 molecules showing in this potentially significant immunological function of C3 Here evidence is put forward that there are functional differences in man between the common phenotypes F and S in the capacity to bind with the complement receptor on mononuclear cells *in vitro*

Mononuclear cells from normal human individuals were obtained by Ficoll-Isopaque centrifugation of defibrinated peripheral blood and washed twice by centrifugation at 200*g* with Hanks's basal salt solution (HBSS) and resuspended in HBSS C3 phenotypes of healthy laboratory staff and blood donors were determined by starch gel electrophoresis as described previously[7] Complement was coupled on to erythrocytes by two methods First, the method of Jondal *et al* [8] was used Human blood group O red cells were coated with antibody by incubating with inactivated rabbit anti human O red cell serum diluted 1 1000 For the binding of complement, human sera at a dilution of 1 10 were incubated with the erythrocyte-antibody complex (HEAC-technique) Secondly, low ionic strength was used in order to coat red cells with complement[9] One millilitre of 5% human erythrocyte suspension in saline was spun down and the supernatant discarded One drop of fresh human serum was added to the packed cells followed by 1 ml 10% sucrose (w/v) The mixture was incubated at 37° C for 15 min Then the cells were washed three times with saline and finally suspended in 2 ml of HBSS (HEC-technique)

Table 1 The effect of C3 phenotype on the number of HEC rosette-forming mononuclear cells and the concentration of serum C3

	C3 phenotype S	C3 phenotype F
No of sera studied	9	10
HEC-rosettes (mean %)	3 7	6 4
Total no of HEC rosettes counted	294	521 (χ^2 – 63 64)
Total no of mononuclear cells counted	3,966	4,061 ($P < 0$ 001)
C3 concentration in serum (mg per 100 ml, mean ±s d)	73 3±12 2	68 1±25 1

For the preparation of rosettes, 0 5 × 10^6 mononuclear cells and 0 1 ml of 2 5% complement coated red cell suspension were mixed in a final volume of HBSS of 0 5 ml and centrifuged at 200*g* for 5 min A drop of 0 02% acridin orange was added in the tube and the mixture was resuspended for 2 min on a slowly rocking mixer The counting of the rosettes was performed in a Hawksley Cristalite haemocytometer under an ultraviolet light microscope where the nucleated cells could easily be distinguished by their yellow stain All the determinations were made in duplicate To minimise the possible effect of day to day variation, an approximately equal number of F and S sera were tested in each experiment The concentration of serum C3 was determined by radial immunodiffusion[10] (M-Partigen C3c Behringwerke, Marburg, Germany)

In the first phase of the study, sera were investigated which had been frozen for 3 yr With the HEAC-technique, 10 C3F and 11 C3S sera were tested and the mean percentages of rosette-forming cells were 9 6 and 7 5%, respectively

Because of the difference it seemed worthwhile to investigate the matter further and fresh serum samples from individuals typed previously for C3 phenotypes were requested The results from this material are shown in Table 1 and Fig 1 The HEC-technique was utilised because, with the antiserum used for sensitising red cells in the HEAC technique, the background rosettes (that is, rosettes obtained with antibody coated erythrocytes) were nearly as numerous as the complement rosettes By coupling the complement on to the erythrocytes with low ionic strength the interference caused possibly by the antibodies and the respective receptors on monocytes was avoided The amount of antibody coupled on to the erythrocytes with this technique was nil or negligible, this was indicated by the fact that no rosettes were obtained

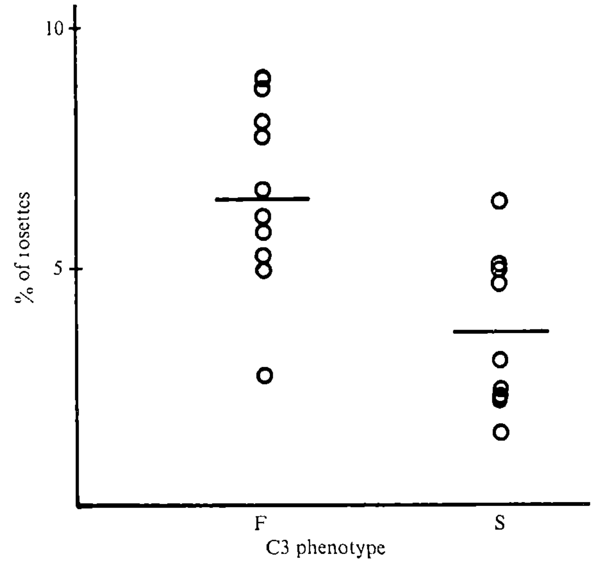

Fig 1 Influence of serum C3 phenotype on the number of HEC rosette-forming mononuclear cells Each point represents the mean of duplicate determinations The mononuclear cells used in this series of experiments originated from a single donor of C3S phenotype The difference is statistically significant ($P < 0$ 01) by Finney's first analogue of Fiellers theorem[17]

with red cells treated with fresh inactivated sera Furthermore, no immunoglobulins could be shown on the red cells with antiglobulin technique The result observed here could have arisen from differences in *in vitro* conversion between C3 F and S This is unlikely, however, as no such difference has been found previously[11,12] This possibility was further studied with fresh serum samples from two C3F and two C3S individuals The results of the experiment, completed within 5 h from the moment of venepuncture, were comparable to those in Table 1 The possibility of C3F and S being coupled on to the erythrocytes in different amounts is unlikely, too, because the red cells treated with doubling dilutions of C3F and S sera were agglutinated to similar titres with anti-complement serum It seems most probable that, compared to C3S, C3F has an enhanced capacity to bind with the respective receptor on mononuclear cells

Preliminary attempts were made to classify the cells which exhibited the receptor for complement with the present method The number of rosettes did not correlate with the number of polymorphonuclear cells in experiments with buffy coat leukocytes In two experiments where mononuclear cells were allowed to adhere on a plastic surface and were separated subsequently into adherent and nonadherent cells the HEC rosette forming cells were enriched into the former cells The mean figures were 8 4% in the initial cells suspension, 30 6% in the subpopulation of adherent cells and 1 2% in that of nonadherent cells Moreover, the majority of the cells able to form HEC-rosettes seem to possess the capacity of phagocytosing particles (unpublished results) These findings imply that the cell in question may be monocyte

In European populations the frequencies of homozygotes for $C3^S$ and $C3^F$ are roughly 60–70% and 3–5% respectively[7] My observation that C3F and C3S differ in the capacity to bind on to mononuclear cells is interesting from several points of view First, C3 seems to be one of the few genetically polymorphic human serum proteins where functional differences between the variants have been demonstrated Because a lot is known about the biological function of C3 in body defence mechanisms this-protein might deserve a closer look by geneticists, especially the supporters of the selectionist view[13]

Second, the nature of the receptor site on the membrane of the leukocytes is virtually unknown Studies with C3F and S molecules might shed more light on properties of the C3 receptor on mononuclear cells Also C3 phenotype may be another variable in studies where human complement-coated erthrocytes are used for detecting subpopulations of mononuclear cells

Thirdly, of particular interest in this connection are the findings of Bronnestam[14] and Farhud *et al*[15] They observed independently a significant surplus of $C3^F$ gene among patients with rheumatoid arthritis Furthermore, an association between $C3^S$ gene and high titres of anti-A or anti-B in newly delivered mothers[16] is another observation suggesting that C3 phenotype may have an influence on various immunological processes *in vivo* This present *in vitro* finding might offer a clue to explaining the mechanism of these phenomena

Factors influencing microculture of leukaemia cells

THE culture of normal haemopoietic cells was accomplished[1] by obtaining colonies of granulocytic and monocytic cells from mouse bone marrow grown in a semisolid agar system The method was modified for human bone marrow and subsequent studies showed that leukaemia cells from the peripheral blood and marrow of patients with acute myelogenous leukaemia (AML) produced small colonies or clusters[1,2] Using this technique, serial sampling and morphological or biochemical studies of the growing cells was difficult A liquid culture technique was then developed to study the growth of granulocytic or monocytic cells from normal bone marrow[3] This *in vitro* diffusion chamber technique had the advantage of easy sampling but involved the use of large culture vessels The method has subsequently been used to cultivate AML cells[4]

We describe here a new short term microculture technique for growing AML cells in suspension which overcomes the cumbersome nature of the above methods and facilitates the study of multiple factors influencing the growth of these cells The method is simple, reproducible and does not require the addition of a colony stimulating factor

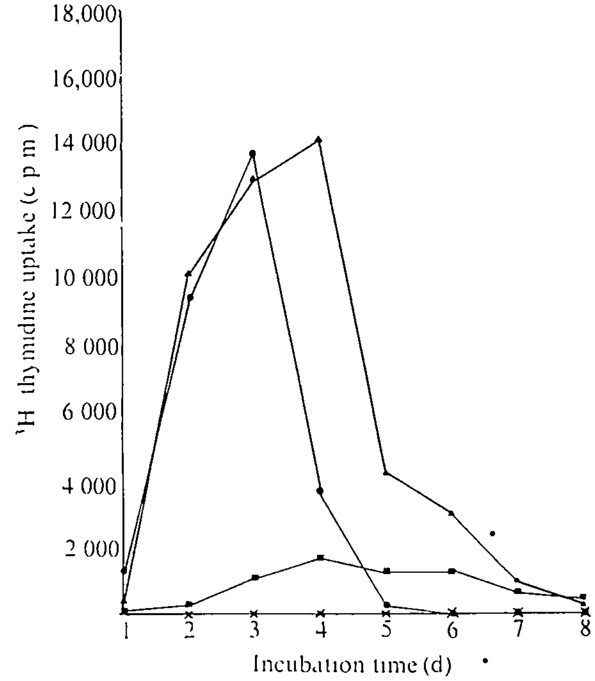

Fig 1 The optimum cell number and time of collection for the microculture of AML cells ×, 1 × 10³, ■, 1 × 10⁵, ▲, 1 × 10⁶ and ●, 1 × 10⁷ cells ml⁻¹

Both fresh and liquid nitrogen-stored leukaemia cells have been grown successfully in this system Red cells were removed from fresh heparinised blood by the addition of a 2% solution of methyl cellulose to accelerate their sedimention and the white cell layer washed once Leukaemia cells were collected from the peripheral blood of patients with AML using an NCI IBM cell separator and were stored with 10% dimethylsulphoxide in liquid nitrogen For culture, these cells were thawed rapidly, diluted slowly with RPMI 1640 medium (Biocult Limited) and then washed After washing, the cells were resuspended at a concentration of 1×10^6 ml^{-1} in medium 199 (Wellcome) containing 0 3 ml of L-asparagine, 6 6 mg ml^{-1}, and 10% foetal calf serum (Flow Laboratories) or 10% AB serum Aliquots of this suspension (0 2 ml) were added to microculture plates (Falcon 3040) Following 3 d incubation in a humid 5% CO_2 atmosphere the growth of these cells was measured by the addition of 0 1 mCi ^{3}H-thymidine (specific activity 5 Ci mmol^{-1}) to each well for 16 h The trichloracetic acid precipitable material was collected on filter paper and counted in a liquid scintillation counter

Some samples of leukaemia cells stored in liquid nitrogen showed low viability A method of slow dilution of 2 ml of original cell suspension to 20 ml over 10 min greatly improved the viability of the cells as measured by trypan blue exclusion, the incorporation of tritiated thymidine in liquid microculture and colony formation in semisolid agar. The results are shown in Table 1

A wide range of media were tested using both fresh and stored cells from several patients, and it was found that Medium 199 (Wellcome) supplemented with 10% serum and L-asparagine produced the best growth The results depicted in Fig 1 show that after an initial decline the cell concentration increased to a peak on day 4 or day 5 of culture and that DNA synthesis, as measured by the uptake of tritiated thymidine, reached a peak on day 3 or day 4 of culture This experiment also showed that the cell concentration for optimal growth in this system was 1×10^6 ml^{-1} Autoradiographs of cells obtained from these cultures showed that labelled cells had the morphological and cytochemical characteristics of AML cells This technique has therefore been shown to measure a true proliferation of AML cells in short-term culture, with an increase in cell number as well as thymidine incorporation

Table 1 Relationship between rate of dilution and viability of AML cells stored in liquid nitrogen

Rate of dilution	Initial viability	Plating efficiency (agar)	Uptake of ^{3}HTdr (liquid culture)		
Fast	64%	0 4%	6,052	6,118	
			6,165	6,656	(6,007)
			5,401	5,652	
Slow	80%	3 0%	9,913	11,728	
			10,936	12,731	(11,562)
			12,570	11,491	

More than 25 samples of acute myeloblastic and myelomonoblastic leukaemia cells have been grown from fresh blood with complete success The success rate for growing liquid nitrogen-stored cells was approximately 80% but this is now increasing as our storage techniques have improved The AML cells which multiplied in liquid culture did not mature in the normal manner After 4 d the cultures consisted almost entirely of myeloblasts and promyelocytes or primitive monocytoid cells Some small lymphocytes were also present The cultured cells from patients with acute myeloblastic leukaemia were nevertheless usually easily identified as being of the granulocytic series The typical granulation was often prominent and special stains (Sudan black and periodic acid–Schiff) were consistent with this diagnosis Cultures have also been obtained using peripheral blood cells from patients with chronic granulocytic leukaemia In these instances maturation to myelocytes and segmented forms was characteristic Leukaemia cells from the blood of ten patients with acute lymphoblastic leukaemia failed to grow using this system

This raises the possibility of using the method for diagnostic purposes in patients with acute leukaemia A relatively easy, objective test, distinguishing acute myelogenous and lymphoblastic leukaemia would be of great value Our results suggest that this method may be useful in this context A study of patients with undifferentiated leukaemia is now being made

Using the microculture technique, we have shown that sera from AML patients immunised during remission with allogenic irradiated leukaemia cells can cause growth inhibition and cell death in cultures of allogenic AML cells This property is complement dependent and is probably due to anti-HLA antibody which is known to be present in these sera using conventional assays One patient in remission with AML has been found to have complement-dependent growth inhibitory activity against autologous stored leukaemia cells In this experiment the autologous remission serum was not inhibitory in the absence of complement, but the addition of complement to the autologous serum resulted in a reduction of 80% in uptake of tritiated thymidine Complement alone did not significantly affect the uptake of thymidine Further studies to determine the frequency of this finding are under way

We feel that this new technique is of value in a number of contexts, first, as an objective, diagnostic test to distinguish acute myelogenous and lymphoblastic leukaemia, second, in studies of serum factors influencing the growth of AML cells and, third, in studies of *in vitro* sensitivity to chemotherapeutic agents

Membrane antigens of murine leukaemia cells

THE membranes of lymphoid cells from tumours induced by oncornaviruses are antigenically altered The new surface antigen(s) are readily recognised by isologous (histocompatible) hosts which mount both cellular and humoral immune responses[1,2] It is essential to know whether or not antigens induced by the various strains of murine leukaemia viruses (MuLV) are cross-reacting immunologically

The first thorough serological study, made in a completely isologous system, was done by Old et al[3] They compared the cell membrane antigens induced by Friend virus complex (MuLV-F), Rauscher virus complex (MuLV-R), Moloney leukaemia virus (MuLV-M) and Gross virus (MuLV-G) using cytotoxic antisera from inbred mice Similarity was noted between antigens induced by Friend, Rauscher and Moloney viruses and a single cross-reacting antigenic system designated FMR was described This antigen was not found on the cells of Gross leukaemia and, conversely, antiserum prepared against Gross leukaemia had no activity for FMR This classification was readily accepted by other investigators in the field[4]

Table 1 Cell membrane immunofluorescence test with various isologous antisera*

		1 2048			<10	

* For each dilution, 0 035 ml of serum was added to a pellet of washed leukaemic lymphocytes (10^6) from the above preparation After incubation at 37° C for 30 min, the cells were again washed twice with buffered salt solution (Dulbecco's BSS, GIBCO) and resuspended in fluorescein-conjugated goat anti-mouse globulin (Hyland) diluted 1 15 in BSS The tubes were then incubated again at 37° C for 30 min, washed twice with BSS and resuspended in 50% glycerol-BSS for storage Cells were then examined within one week using a Zeiss microscope with fluorescent optics and a BG 12 filter For controls tested with normal mouse serum, the number of cells positive with anti-globulin in the absence of specific anti-MA did not exceed 10–15%

† Two different pools of antisera to MuLV-F cells membrane antigen (anti-FMVA/1 and 2) and of antisera to MuLV-M cells membrane antigen (anti-MVMA/1 and 2) were tested Anti-FV/L is an isologous (BALB/c) antiserum cytotoxic for Friend leukaemia cells Normal serum was pooled from BALB/c mice

‡ YAC cell line

§ Lymph node cells from leukaemic mice

‖ Percentage of cells with traces of fluorescence was as low or lower than the background (10% or 15%) with normal serum

We were, therefore, surprised to find that a battery of various isologous antisera against MuLV-F leukaemic cells prepared in our laboratory in the course of two years gave relatively little cross-reaction with MuLV-M leukaemia cells and vice versa Subsequently we learned that another investigator had a similar experience (F Lilly, unpublished) Here we report our observations suggesting similarity between MuLV-F and MuLV-R cellular antigens and their distinction from MuLV-M antigen(s) and we present a careful look at the previous data concerning the 'FMR antigen' concept

MuLV-F originally purchased from the American Type Collection (Bethesda, Maryland) was obtained from Dr W Ceglowski of Penn State University, its previous passage history on BALB/c mice was reported[5] In our laboratory, this virus was also passaged in BALB/c (ref 6) It is equally infectious for BALB/c and Swiss/ICR mice MuLV-R also passaged on BALB/c, was obtained originally from pool No 46 AP-RLV MuLV-M, described in detail elsewhere[7] was supplied by Dr M R Proffitt (Massachusetts General Hospital, Boston)

Leukaemias were induced in young adult BALB/c mice (Charles River Laboratories, Wilmington, Mass) by intraperitoneal injections of the respective virus (0 05–0 2 ml of 1% w/v, cell-free, spleen homogenate) Leukaemia cells were obtained from spleens (for MuLV-F and MuLV-R leukaemias) or from lymph nodes (for MuLV-M leukaemia) In addition, MuLV-M leukaemia cells were obtained as an established YAC cell line derived from A/Hej mice[8] and grown in our laboratory in suspension with McCoy's 5a medium and 20% foetal bovine serum

Antisera to MuLV-F-induced cell membrane antigen, FVMA, were prepared by immunisation of BALB/c mice with formaldehyde virus vaccine[9] and with several intraperitoneal injections of isologous viable leukaemic spleen cells Another anti-FVMA serum, anti-FV/L (Tables 1 and 2) was prepared in BALB/c mice by injection of live N-tropic MuLV-F followed by boosts with increasing doses of live NB-tropic virus Antiserum to MuLV-M induced cell membrane antigen (MVMA) was prepared in A/Hej mice by immunisation with the YAC cell line (derived from A/Hej mice) The first injection of irradiated cells (10^6, 6,000 rad, cobalt 60, 320 rad s^{-1}) was followed by several additional intraperitoneal injections of 10^7 live YAC cells

The specific activity of antisera was tested by indirect membrane fluorescence[10] using fresh leukaemia target cells Anti-FVMA sera reacted strongly with the membrane of MuLV-F cells and (to a lesser degree) with MuLV-R cells, 85 to 100% cells expressed the antigen (Table 1) Anti-FV/L serum (prepared in the former manner showed a similar specificity for MuLV-F and MuLV-R cells In contrast, these sera reacted very weakly, and only at high concentrations, with MuLV-M cells The cross reactivity disappeared at dilutions of 1 8 or higher The stronger of the antisera, anti-FVMA/2, had a titre of 256 with MuLV-F cells and only a titre of 4 with MuLV-M cells (Table 1, experiment B) The isologous anti-MuLV-M serum seemed to be even more specific pool 2 had a titre of 1,024 against MuLV-M cells and a titre of 2 with MuLV-F and MuLV-R membrane antigens

Cross-absorbtion studies supported the seemingly close relationship between MuLV-F and MuLV-R membrane antigens and their distinction from MuLV-M antigen (Table 2) The reactivity of anti-FVMA sera with homologous Friend cells was completely abolished by absorption with either MuLV-F or MuLV-R cells but was not diminished (at the given concentration of the antiserum) by absorbtion with MuLV-M cells Conversely, the specific activity of anti-MuLV-M serum was absorbed with MuLV-M cells but not with MuLV-F or MuLV-R cells

Table 2 Cell membrane immunofluorescence with cross-absorbed antisera to murine leukaemias*

Serum	Absorbed (cells)	Leukaemia Target Cells (% stained) MuLV-F	MuLV-R	MuLV-M
a-FVMA/1	MuLV-F	<10	<10	<10
	MuLV-R	25	<10	<10
	MuLV-M	>90	>90	<10
	Normal (control)†	>90	>90	<10
a-FV/Lilly	MuLV-F	<10	<10	<10
	MuLV-R	<10	<10	<10
	MuLV-M	85	>90	<10
	Normal (control)†	85	>90	<10
a-MVMA	MuLV-F	<10	<10	>90
±	MuLV-R	20	<10	>90
	MuLV-M	<10	<10	<10
	Normal (control)†	<10	<10	>90

*Absorption was done in three steps using equal volume of packed cells (washed thoroughly in BSS and preincubated with normal BALB/c serum for 40 min at room temperature to minimise a nonspecific loss of antibody) and undiluted antisera, 20 min at 37° C bath, 45 min at room temperature and overnight at 4° C Cells from the same source were used for both absorption and immunofluorescence assay (MuLV- M cells were YAC)

† Sera were absorbed with pooled, normal (non-infected) BALB/c spleen cells

These results argue against the concept of FMR as the major cell surface antigen common for the three leukaemias A careful evaluation of previously published work, in which the relationship between the murine leukaemia cellular antigens was studied using either serological techniques or transplantation resistance, seems to support our criticism Glynn *et al*[11] and Bianco *et al*[12] reported that BALB/c mice were protected against transplantation of Moloney lymphomas by pre-treatment with syngeneic MuLV-M cells but not with MuLV-R leukaemia cells, suggesting a lack of cross-reactivity between the transplantation antigens of the two leukaemias Using similar techniques, Glynn *et al* later reported positive finding of cross-reactivity between the F, R and M leukaemias induced in C57 Bl/6 mice[13] We found, however, that the data in their experiments showed a close relationship between F and R, but some separate specificity for M Thus, mice pretreated with MuLV-F or MuLV-R leukaemia cells were completely resistant to Friend lymphoma, whereas immunisation with MuLV-M cells conferred only a partial protection which did not seem to be much different from the protection conferred by Gross leukaemia cells[13] (Table 5)

Although it can not be assumed that the antigens responsible for transplantation immunity are necessarily the same as those involved in serological tests, the latter appears to correlate with the transplantation studies discussed above As employed by Glynn *et al*[13], membrane fluorescence showed a degree of cross-reactivity between F, M and R antigens, but there was an indication for existence of FR and M sub-groups at higher serum dilutions

The cytotoxic assays of Old *et al*[3] showed clear distinction between G and FMR antigens but results were not as clear for equally strong cross-reactivity between F, R and M because titres of antisera (particularly following *in vivo* absorbtion) were as low as 2–4 In this respect it is interesting that Klein and Klein found high titred antisera to Moloney leukaemias which reacted rather well with Gross leukaemia cells in the membrane fluorescence test but not in cytotoxic assay[10]

It seems that the number of antigen types found on the surface of leukaemia cells may be much more complex then previously thought In addition to the virus induced antigens[14,15], these might include virus envelope antigens[16,17], virus core antigens[18], foetal antigens[18,19] and other specificities[20,21] Our observations, as well as these reports, suggest that the 'FMR' term is probably misleading and it should be interpreted with caution

We thank Dr G Klein, of the Karolinska Institute, Stockholm, and Dr F Lilly, of the Albert Einstein College of Medicine, New York, for encouragement MuLV-R was a gift from Dr M R Proffitt of the Massachusetts General Hospital, Boston, anti-FU/L antiserum was a gift from Dr F Lilly and MuLV-M leukaemia cells were a gift from Dr M Cikes of the Karolinska Institute We also thank Ms L Demler and A Slizki for technical assistance This work was supported by a grant from the American Cancer Society and a grant from the United States Public Health Service M E is a Scholar of Leukemia Society of America

Autologous human B and T lymphoblastoid cell lines

HUMAN lymphoblastoid cell lines (LCLs) have been derived from patients with acute and chronic leukaemias as well as from normal individuals[1–3] Most of these LCLs express characteristics of bone marrow-derived (B) lymphocytes[4,5] and contain the Epstein–Barr virus (EBV) genome[6] and the EBV-determined nuclear antigen (EBNA)[7] Cell lines derived from the blood of patients with myelogenous leukaemia also contain B lymphocyte markers[4,8], which may indicate that they are not of leukaemic origin In patients with lymphatic leukaemia, it has been less clear whether a derived LCL represents the neoplastic cell population Recently, LCLs derived from patients with acute lymphoblastic leukaemia were found to possess characteristics of thymus-derived (T) lymphocytes[3,5,9]

We have studied two LCLs, both derived from the same blood specimen of an 11-yr-old boy with lymphoblastic lymphoma which progressed to an acute leukaemic phase Their isolation has been previously described[10,11] We report here that these two lines displayed very different biological properties One line, CCRF-SB (here designated SB) expressed B-lymphocyte characteristics, had a human diploid karyotype, contained the EBV genome and EBNA, and activated normal allogeneic lymphocytes in the mixed lymphocyte reaction (MLR) to proliferate and develop cytotoxic capability In contrast, the other line, H-SB2, expressed T-lymphocyte characteristics, had an abnormal human karyotype, lacked detectable EBV genome and EBNA, and did not activate allogeneic lymphocytes These and other observations to be discussed suggest that the T-LCL is derived from the malignant lymphoblast population

SB and H-SB2 were examined for HL-A antigens and for the presence of five independent markers of B and T lymphocytes, as described previously[5,12] B-lymphocyte markers included surface immunoglobulin (SIg), complement C3 receptor (CR), and the human B lymphocyte-specific surface antigen (HBLA) T-lymphocyte markers included the sheep red blood cell (SRBC) receptor and the human T-lymphocyte-specific surface antigen (HTLA) EBV genome was detected by DNA–DNA reassociation kinetics analysis[13] and EBNA by anti-complement immunofluorescence[7] The capacity of the LCLs to stimulate normal peripheral lymphocytes in a one-way MLR was tested as previously reported[14] In addition, after culture for 6 d with either SB or H–SB2, these peripheral blood lymphocytes were tested for their ability to kill SB and H–SB2 in a 4 or 5 h ^{51}Cr–release assay previously described[15]

Both SB and H–SB2 grow in suspension culture and have the morphological appearance of lymphoblasts Originally, SB cells were diploid, whereas, H–SB2 cells displayed F-group trisomy in approximately 50% of the cells[16] In addition, both lines were found to share common HL–A antigens (A_1, A_2, A_{12}, W_{17}) Table 1 summarises our findings

Tests for T and B lymphocyte markers revealed that SB expressed B-cell characteristics while H–SB2 expressed T-cell characteristics Virtually all SB cells had SIg and HBLA, 15–75% formed rosettes with C3 coated SRBC, and all lacked T-cell markers In contrast, all H–SB2 cells had HTLA, 20–60% formed rosettes with unsensitized SRBC and all lacked B-cell markers

Tests for the presence of EBV (Table 2) demonstrated that all SB cells contained EBNA and that by DNA–DNA renaturation kinetics analysis the cell line contained eight genome equivalents of EBV DNA per cell H–SB2 lacked EBNA and was negative for EBV genome at the limit of the test sensitivity which was 0 2 genome equivalents per cell

The MLR tests (Table 3) revealed that SB activated the lymphocytes of three donors with stimulation indices ranging from 24 0 to 39 5, whereas, H–SB2 failed to activate lymphocytes from the same donors H–SB2 did not inhibit the response to SB when both cells were used together as stimulators, demonstrating that the absent MLR response to H–SB2 was due to a lack of stimulation capacity rather than active inhibition by H–SB2 Furthermore, SB but not H–SB2 was found to generate significant cytotoxic effector cells Lymphocytes activated by SB killed both SB and H–SB2 equally well, however, presumably on the basis of cross-reactive antigens

The heterotransplantability of SB and H–SB2 has been studied by Adams, *et al*[19] They discovered that H–SB2 could be successfully transplanted in normal neonatal Syrian hamsters, whereas SB could not be transplanted unless the recipient hamsters were first immunosuppressed with anti-lymphocyte serum In addition, H–SB2 tumours progressed to a leukaemic phase in 5% of the animals bearing tumours, whereas SB tumours never progressed to a leukaemic phase Perhaps the capacity of H–SB2 to proliferate in the untreated hamster is related to the failure of these cells to stimulate lymphocytes in the MLR

The proliferative and cytotoxic effector phases of the MLR can serve as models of immune recognition and cell-mediated immunity (CMI) *in vivo*[17] It has been suggested that the *in vitro* MLR represents the first stage of the immunological surveillance mechanism which ultimately removes abnormal lymphoid cells which arise *in vivo*[18] Therefore, the failure of H–SB2 to elicit CMI responses *in vitro* may have biological significance with respect to the *in vivo* surveillance of certain T cell malignancies

The results reported here extend previous observations[19,20] suggesting that SB and H–SB2 may be derived from different lymphoid cell populations SB had B-lymphocyte surface markers and a normal karyotype, whereas, H–SB2 had T-lymphocyte surface markers and an abnormal karyotype In addition,

Table 1 Characteristics of SB and H–SB2 cell lines

Cells	% of cells with B-lymphocyte markers*			% of cells with T-lymphocyte markers*		Presence of EBV		Stimulation of lymphocytes *in vitro*	
	SIg	CR	HBLA	SRBC	HTLA	Genome	EBNA	Proliferative response	Cytotoxic response
SB	90–100	15–75	100	0	0	+	+	+	+
H-SB2	0	0	0	20–60	100	—	—	—	—

SIg, Surface immunoglobulin, CR, complement receptor, HBLA, Human B lymphocyte antigen, SRBC, sheep red blood cell (receptor), HTLA, human T lymphocyte antigen
* Day-to-day variation occurs with some tests and is indicated by a range of values

Table 2 Presence of EBV genome and EBNA

Cells	No of EBV genome equivalents per cell*	% of cells showing EBNA†
SB	8	100
H–SB2	<0 2	0
Negative control (Calf thymus DNA)	<0 2	
Positive control (Raji cell line)	60	100

* DNA–DNA reassociation kinetics analyses were carried out as previously described[13] with 0 01 μg of ^{3}H–EBV DNA ($2\ 7\times10^6$ c p m μg^{-1}) and 2 mg of sonicated cell DNA extracted from the cultured lymphoblasts The portion of DNA reassociated was determined by hydroxyapatite column chromatography and the number of EBV genome equivalents calculated as described[13,26] EBV was purified from the extracellular fluid of the HR1K cell line

† The EBNA test was a modification of the anti-complement immunofluorescence technique described by Reedman and Klein[7] Acetone–methanol fixed cells were treated with a 1 1 mixture of human serum containing antibody against EBNA and fresh human complement obtained from an individual negative for EBV antibody (final dilution 1 10 for each) After incubation at 37° C for 45 min, the smears were washed and treated with a 1 10 diluted fluorescein isothiocyanate-conjugated anti-human β_1C/β_1A globulin at 37° C for 45 min EBNA positive cells did not react with control serum lacking antibody to EBNA

SB carried the EBV genome and EBNA, could not grow in normal neonatal hamsters, and could activate normal lymphocytes *in vitro* to proliferate and develop cytotoxic capability Similar properties have been found for other LCLs derived from normal people[6,7,19,21] In contrast, H–SB2 lacked detectable EBV genome, grew as tumours in normal newborn hamsters, and failed to activate lymphocytes to proliferate or to become sensitised killer cells Other T–LCLs, MOLT–4 (ref 3), CCRF–CEM (ref 1), and RPMI–8402 (ref 22), have displayed these same properties when examined[14,22-27] and have been derived only from patients with acute lymphoblastic leukaemia

Table 3 DNA synthesis and cytotoxic effect of lymphocytes activated by SB and H–SB2 in the mixed lymphocyte reaction

Activation mixture*	^{3}H–thymidine incorporation CPM	Stimulation index†	% ^{51}Cr release‡ ±s e from SB	H–SB2
A+SB$_m$	82,501	24 0	68 3±3 3	59 1±0 6
A+H–SB2$_m$	2,430	0 7	1 0±0 1	−17 7±0 9
B+SB$_m$	122,075	39 5	52 8±13 7	75 0±2 2
B+H–SB2$_m$	3,390	1 1	−11 8±0 4	−1 6±0 3
C+SB$_m$	108,932	31 0	91 3±3 3	84 0±6 4
C+H–SB2$_m$	2,222	0 4	0 5±0 3	13 1±0 6

DNA synthesis was measured on day 6 in a one-way MLR, as previously described[14] Each raction mixture contained $2\ 0\times10^5$ responding lymphocytes and $0\ 5\times10^5$ stimulating LCLs treated with mitomycin C The cytotoxic effect of the stimulated lymphocytes was measured on day 6 after setting up activation mixtures, as previously described[15] Cytotoxicity was measured by incubating $1\ 0\times10^6$ attacking lymphocytes with $1\ 0\times10^4$ ^{51}Cr–labelled target cells in RPMI 1640 medium containing 10% heat-inactivated foetal calf serum for 4 or 5 h at 37° C The cells were then centrifuged and the supernatant aliquots removed for counting of ^{51}Cr release Controls consisted of target cells incubated with cultured but non-sensitised lymphocytes from the appropriate donor Maximum ^{51}Cr release was obtained by freeze-thawing the labelled target cells in distilled water three times

*A, B, and C, peripheral blood lymphocytes from three donors, SB$_m$ and H–SB2$_m$, mitomycin C-treated LCLs of these lines

† Values are ratios of the mean c p m of ^{3}H–thymidine uptake in the stimulated lymphocytes and the mean c p m in the unstimulated lymphocytes (cultured alone)

‡ Values are corrected for ^{51}Cr release from control cultures

SB was probably derived, as are virtually all B–LCLs of normal people, from EBV containing normal B lymphocytes that spontaneously transform during *in vitro* culture H–SB2, on the other hand, was probably derived from the malignant T lymphoblasts of the leukaemic donor By analogy, the other known T–LCLs of leukaemic patients are probably also of neoplastic origin

We thank Dr G R Pearson (National Cancer Institute) for performing the EBNA test, Mr R B Pitts, Ms K S Hathcock, and Mrs C H Huang for technical assistance, and the NCI Human Histocompatability Typing Center (at Microbiological Associates, Inc) for the HL–A typing Part of this study was conducted within the Virus-Cancer Program of the NCI

Science needed Christianity

P. E. Hodgson

Science and Creation By S L Jaki Pp vii+367 (Scottish Academic Press Edinburgh and London, July 1974) £4 50

ONE of the most intriguing questions that can be asked about the development of science is why it took place in Europe between 1250 and 1650 and not in any of the great civilisations of antiquity Ancient Babylon, Egypt and China, to take but three examples, enjoyed long periods of relative stability and developed the technological arts to a very high degree, but of science as we know it there were hardly more than a few scattered beginnings The Greeks came nearest with the mathematics of Euclid, the physics of Archimedes, the astronomy of Aristarchus and the accurate biological observations of Aristotle, but in spite of all this the enterprise never really got off the ground and soon it was all forgotten, to be rediscovered later and developed in the Middle Ages

Dr Jaki's book is a detailed examination of this problem He surveys all these civilisations as well as those of the Hindus, the Incas, the Aztecs and the Mayas to see if it is possible to isolate the reason for the many stillbirths of science before its final birth in Europe He finds that, in one way or another, all the earlier civilisations had a cyclic conception of the universe In spite of its evident absurdity this idea, with every event repeating itself exactly at regular intervals an infinite number of times, has exerted a perennial fascination on man It has always brought with it deep pessimism and despair, a sense of the futility of all effort, sapping all confidence in steady progress Why try to discover anything if it is destined all to be forgotten and then discovered again, eternally? In addition, matter was often viewed as the battleground between capricious deities, and in such an atmosphere science could not develop at all

Although we seldom recognise it, scientific research requires certain basic beliefs about the order and rationality of matter, and its accessibility to the human mind, that are seldom found in ancient civilisations They came to us in their full force through the Judaeo-Christian belief in an omnipotent God, creator and sustainer of all things In such a world view it becomes sensible to try and understand the world, and this is the fundamental reason why science developed as it did in the Middle Ages in Christian Europe, culminating in the brilliant achievements of the seventeenth century This time there was no miscarriage, and science has flourished ever since as one of the most robust movements of thought the world has ever seen

The old ideas died hard, and the history of the first 15 centuries of our era is the history of a continuous struggle between the old and the new The early Christians were not directly concerned with paving the way for science yet this was one of the results of their labours St Basil was a relentless critic of astrology, and St Augustine established the intellectual framework of an intelligible creation that enabled science to emerge centuries later The early mediaevalists, notably Adelard of Bath, insisted that a rational explanation be sought for natural phenomena and More's *Utopia* articulated the ideas that later flowered in the science of Galileo, Kepler, Copernicus and Newton

Dr Jaki develops this thesis with impressive erudition, chronicling in great detail the false starts, fantastic speculations, and occasional brilliant insights of philosophers in a wide range of cultures It is very salutary to retrace these forgotten and stumbling steps, for thereby we can appreciate more clearly the magnitude of the achievements of those who at last succeeded in hammering out the basic concepts of science as we know it, and showed how to develop and refine them by a systematic programme of reflection and experimentation ☐

Three in one

D W. Yalden

Biomechanics By Carl Gans Pp x+261 (Lippincott Philadelphia, May, 1974) Cloth $12 50, paper $5 95

BIOMECHANICS seems to have become a popular subject, and the appearance of another book on the subject might be greeted with some suspicion Were this another textbook, such suspicion might be justified, but it is nothing of the sort It is, as the author says, a highly personal, individualistic discussion of a few of the biomechanical problems on which he has worked There are just five chapters, one is introductory, the others consider in turn egg-eating snakes, legless locomotion (by snakes, amphisbaenians, and caecilians), burrowing by amphisbaenians, and anuran respiratory/vocal systems Fish, birds, and mammals get scant attention, and invertebrates none at all, yet these omissions are scarcely noticed, so interesting is the book

Each chapter commences by posing the obvious questions that a functional anatomist would ask, proceeds to find answers to them, and continues with the further questions that these answers throw up, it includes discussion of the limitations both of the answers and of the methods used to obtain them Obviously, the treatment of the topics is thorough, yet the book is by no means couched in technical language or otherwise difficult to understand The wealth of illustrations (over 150) which include explanatory graphs and complex anatomical drawings, and superb photographs, clarifies and considerably enhances the book

This is indeed a most worthwhile book on at least three levels Though not stated explicitly, it is in fact a herpetology book, and useful because of, for example, its treatment of some of the more obscure reptile groups Second, it is indeed a book of biomechanics, and has useful points to make on the application of physical principles to some quite unexpected facets of animal life Third, it is a methodology book, and I feel that for this reason in particular it deserves to be read by every zoology undergraduate who has the slightest interest in whole animal zoology Perhaps too, it ought to be read by anyone retaining the conceited view that all can be explained at the molecular level Here is the mind of a modern zoologist at work, combining time-honoured methods of comparative anatomy and new-fangled instrumentation in an attempt to understand how animals live and work

Recent titles from Longman

Introduction to Molecular Biology Second Edition
G H Haggis
This book draws together the various approaches to cell structure and function The text has been completely revised and updated, much has been completely rewritten It is suitable for students in the first years of university courses in biology, biochemistry, botany, zoology, microbiology, preclinical medicine, veterinary and agricultural science
£2 95 net

Methodological Developments in Biochemistry Volume 4
Subcellular Studies
Edited by Eric Reid
This is a wide ranging assembly of working procedures, coupled with largely new experimental results and critical discussions The subject matter assumes a basic knowledge of subcellular chemistry and centrifugation
£5 00 net

Defence in Animals
A survey of anti-predator defences
M Edmunds
This book describes the fascinating and ingenious means whereby animals avoid being eaten by predators It is fully illustrated with more than 150 figures, as well as numerous colour photographs
£4 95 net

Coconuts Second Edition
R Child
Covers all aspects of coconut cultivation, including the history and botany of the crop, its cultural requirements, and the care and maintenance of plantations In this second edition chapters on Coconut Varieties, Seed Selection, and Breeding have been entirely rewritten In all, this book presents a concise but readable review of the palm and it products

Bony philosophy

Concepts and Approaches in Animal Morphology By P Dullemeijer Pp xii+264 (Van Gorcum Assen, Netherlands, 1974) n p

BIOLOGISTS who think about the philosophical basis of their work usually stop doing so rather quickly and scurry back to the laboratory Their unease is caused mainly by the historical and purposive aspects of biology—organisms and parts of organisms have become adapted in the past so that they perform particular functions now How can one make such systems philosophically respectable?

The main purpose of this book is to discuss the methods available to the morphologists in their attempts to determine the function of structures Dullemeijer spends much time discussing the problem of how one can make useful statements about the functions of structures, while acknowledging the truism that the functions can in no way cause the existence of the structures, as they have evolved *pari passu* The author suggests there are only three methods of much use the experimental method, the paradigm method, when crudely we think how we would do something and then see whether nature makes as good a job of it, and the comparative method, when we examine structures performing, possibly, the same function

This is a difficult book The level of abstraction is high at the beginning and end, in the middle the text becomes a detailed and somewhat controversial review of bone and bony skeletons In general this middle section would be quite interesting to someone interested in skeletons, though there are a great number of statements with which one might disagree But, if one is illustrating a principle, surely it would be better to keep to less controversial material It is too technical to be accessible to the average morphologist What is he or she to make of this, for instance "On the whole, the resistance to mechanical influence varies in the spongiosa from maximal (the trabeculae) to zero (the interspace) This at first sight self-evident, heterogeneity has an interesting consequence, because in calculations of bony structure there are specific marginal effects that have to be taken into account Such effects play a very minor effect in homogenous material Some hold the view that the elasticity modulus for spongiosa should be smaller than for compacta Considering the above-mentioned marginal effects, which will affect measurements, this seems at least doubtful"

That passage, apart from airing but not resolving a rather technical point, shows two other characteristics of this section First, most workers on bone would disagree with it the modulus of elasticity of the spongiosa is much lower than that of the compacta, that is a well attested fact Second, the quality of the English is such that one is never quite sure one has grasped the author's meaning Unfortunately, this fault is found throughout the book The phrase "specific marginal effect" for instance, is crucial to the sense of the quoted paragraph, but its meaning is quite obscure In such a philosophical book this persistent lack of clarity in exposition is most damaging to sense and, after a while, to the reader's interest

If morphologists are worried about the philosophical foundations of their work and if, unless experts, they are prepared to take the middle section on trust (which they should not), then this book may perhaps make them feel more or less comfortable It is unlikely, though, that it will have much effect on how they do their science

J D. Currey

Nucleic acids

Basic Principles in Nucleic Acid Chemistry Edited by Paul O P Ts'o Vol 1 pp xii+636, vol 2 pp xi+519 (Academic New York and London, April and June 1974) Vol 1 £18 00, $37 50, vol 2 £16 55, $34 50

AMONG multi-author books, these two volumes are unusual in that the editor has also written three long chapters which together form 37% of the text His first chapter ("In the Beginning") ranges far beyond the title of the series, from a historical review of nucleic acid research to prebiotic evolution, to contemporary biochemistry and, finally, to the destiny of man The range is so wide that it is not surprising to find occasional errors, such as the statement that cyclic AMP transmits the effects of estrogen There are also a number of spelling mistakes, and some of them also appear in the index So many facts are mentioned that a bewildered reader might be forgiven for his relief at reaching the "Concluding remarks on Evolution" (page 69) The few paragraphs in this section are, however, very confused indeed and they do not conclude the discussion of evolution "How", "why" and "fathomless" are used imprecisely, the artificial creation of living forms is irrelevantly introduced, and the difficulty of knowing the exact route of prebiotic evolution is wrongly equated with the problem of understanding gravity

In the final section of the chapter (The Beginning of the Influence of Nucleic Acid Research on the Future of Man — "Intelligent" Evolution), Ts'o argues that human nature should be altered by genetic development He states dramatically "our present genome carries the cause of our impendg destruction and has become in- lequate for the continuing evolution ' man We must develop a new species succeed *Homo sapiens sapiens*" inner's stratagem to apply behavi- ural science to avert the end of man considered to be futile ("How can controlled society be designed by be- viourists in which unknown change man is permitted and encouraged?") spice the mixture of arguments, ere are genuflexions to Teilhard de ardin and overtures to ESP Yet 'o never asks how we can hope to termine exactly which genetic anges are needed in order to alter man behaviour predictably

The other chapters are invaluable vanced reviews by authors who have ch made leading contributions to ir topics Some, such as Eisenberg d Bauer and Vinograd, have suc- eded in being critical and selective, t the general tone is encyclopaedic us, the volumes are more likely to used as a treasure house of reference than as teaching material, except very specialised postgraduate work this respect the title of the series misleading Volume 1 has a compre- sive chapter on chemical synthesis transformations of nucleosides (L odman), followed by clear, stimulat- accounts of mass spectrometry Closkey) and excited states (Gue- Eisinger and Lamola) Tsuboi's ter on infrared and Raman troscopy assumes a prior know- e of Raman spectroscopy and the volume ends with a long chapter by the editor on the structure of bases, nucleosides and nucleotides and their interactions with each other and with polymers

Volume 2 is of more general interest to biochemists It has excellent chapters on the chemical reactions of polynucleotides and nucleic acids (D M Brown), ultraviolet spectroscopy, circular dichroism and optical rotatory dispersion (Bush), hydrodynamic and thermodynamic studies (Eisenberg) and on circular DNA (Bauer and Vinograd) A final chapter by Ts'o is on the conformations and interactions of dinucleotides and oligonucleotides The two chapters by Ts'o at the end of each volume are long and very detailed indeed, but they are in a field in which he has made important and extensive contributions Naturally, there is some overlap with other chapters but it is often useful to discuss the material in a different context

Although the preface remarks on the one hundred years since Miescher, it is more to the point that nineteen years have passed since the publication of the first two volumes of *The Nucleic Acids* edited by Chargaff and Davidson Despite the presence of irrelevant material, the present volumes are particularly welcome, since the physicochemical aspects of nucleic acids have been reviewed far less than their biology and enzymology We can look forward to the later volumes of the series

K. Burton

ll about the gibbon and the siamang

bon and Siamang Vol 3 Natural 'ory, Social Behaviour, Reproduc- , Vocalization, Prehension Edit by ine M Rumbaugh Pp vii+208 rger Basel and London, 1974) 130, £18 85, $40 30, DM124

s volume contains one long paper Ellefson, reporting a field study on white-handed gibbon *Hylobates lar,* three much shorter papers These respectively, an account by kelman, Ross and Pantuwatana of ocial behaviour of a small experi- al colony of *H lar* on an island in ulf of Thailand, a description in s of functional morphology of the batid hand by R Lorenz and an ysis of vocalisations from captive ons and siamangs by Tembrock

ifortunately, much of the value ig from the fact that the papers ublished together in the one book, r than appearing separately in ials, is lost by the fact that there liaison between them For ex- le, when Brockelman *et al* and nz refer to Ellefson's work they to his unpublished doctoral dis- ion rather than to his paper in this and Tembrock's paper contains no reference to Ellefson's work at all This lack of liaison may have been no fault of the authors, but it does point to poor planning in the production of the book

The three short papers are each useful additions to the primate literature Ellefson's paper is more of a problem The blurb on the dust jacket says "Observational data have been reduced when appropriate to quantitative summaries, but their interpretation and/or possible meaning is never lost" This policy seems little short of disastrous It ensures that no reader can check the validity of Ellefson's conclusions against his data, nor does it allow detailed quantitative comparisons with published data from other primate field studies In addition to the cavalier treatment of data, the treatment of theoretical issues, such as the aetiology of vocalisations and the concept of dominance, are naive in comparison with the relatively sophisticated literature that has been published on these topics in recent years It is disappointing that what was clearly such a diligent study should have been so poorly reported

N. R. Chalmers

Spectrophysics
LADY ANNE THORNE
Hardback September 1974
416 pages 163 line illustrations 412 12510 2 £6 50
Science Paperback 412 12530 X £3 90

Spectrophysics describes the main methods of experimental spectroscopy and their application to the study of physical phenomena with particular reference to the determination of transition probabilities and to problems in laboratory and astrophysical plasmas

SEVENTH EDITION
Insect Physiology
SIR V B WIGGLESWORTH, F R S
Hardback October 1974 176 pages 20 line illustrations 412 11150 0 £2 95
Science Paperback 412 20980 2 £1 65

The seventh edition of this readable introductory account of the physiology of insects has been completely updated and includes a new chapter on insect hormones This book will be intelligible to any reader with no more than an elementary knowledge of biology but at the same time it gives a very complete survey of the subject References are given to more complete treatment where necessary

MATHEMATICS SERIES
Introduction to Optimization Methods
P R ADBY and
M A H DEMPSTER
Limp Binding October 1974
214 pages 412 11040 7 £2 50

This book is an introduction to non-linear methods of optimization The basic methods of single and multi-parameter optimization presented here in a simple uniform terminology, are an essential prerequisite to a study of the current advanced methods reviewed under a few generic headings in the final two chapters

Further information on these titles and a list of stockists is available from the publishers on request

announcements

Appointment

Desmond Gareth Julian has been appointed to the British Heart Foundation Chair of Cardiology at the **University of Newcastle-upon-Tyne**

International meetings

December 3–5, **European Conference on Irradiation Behaviour of Fuel Cladding and Core Component Materials,** Germany, (Dr D R Harries, Metallurgy Division, AERE, Harwell, Didcot, Berkshire, UK)

December 5, **The Analysis of Gaseous Effluents,** Teesside (The Society for Analytical Chemistry, Analytical Division, Chemical Society, 9/10 Savile Row, London W1X 1AF)

December 5–6, **Discussion Meeting on the Theory of Electric and Magnetic Waves in the Ionosphere and Magnetosphere,** London (The Royal Society, 6 Carlton House Terrace, London SW1Y 5AG)

December 9–13, **Symposium of the International Atomic Energy Agency on Ionizing Radiation for the Sterilisation of Biomedical Products and Biological Tissue,** Bombay (International Atomic Energy Agency, PO Box 500, A-1011, Vienna, Austria)

December 9–14, **65th Exposition de Physique,** Paris (Societe Francaise de Physique, Comite d'exposition, 33 rue D'Exposition, 75013 Paris)

December 12, **Membrane Components Involved in Transport and Diffusion,** Oxford (Dept of Biochemistry, University of Oxford, Oxford OX1 3QU)

December 15–20, **1st Asian Regional Congress on Radiation Protection,** Bombay (Mr S D Soman, Chairman, Organising Committee RCRP, Modular Laboratories, Room 1-216H, Bhabha Atomic Research Centre, Bombay 400-085, India)

December 29, **2nd International Congress of Biorheology,** Israel (Dr F A Meyer, Weizmann Institute of Science, Rehovot, Israel)

Corrigenda

In the article "Expansion pattern of flare-associated disturbances near the Earth's orbit during October 23 to November 4, 1968" by K Sakurai (*Nature phys Sci*, **246,** 70, 1973) there were two errors in Table 1 The first number in column 1 should read 24 not 23, and the second number in the last column should read 79 5 not 69 5

In the article "Effect of foetal calf serum and epidermal growth factor on DNA synthesis in explants of chick embyro epidermis" by S Bertsch and F Marks (*Nature,* **251,** 517, 1974) the first sentence of the legend to Fig 1 should be replaced by, "Effect of epidermal growth factor (EGF) on the pulse-labelling of DNA in chick embryo epidermal explants precultivated for 24 h in the absence (*a*) or presence (*b*) of serum After precultivation, the medium was replaced by serum-free medium containing EGF and the incubation was continued for the time indicated" In the last part of the legend omit the sentence, "The explants were preincubated in MEM (without serum) for 24 h before the addition of EGF"

Erratum

In the article "Grassland species can influence the abundance of microbes on each others roots" by P Christie, E I Newman and R Campbell (*Nature,* **250,** 570, 1974) the legend to Table 2 should read, *In part *a* letters (a and b) are for comparisons among the four weights, in part *b* for comparisons within each row
